Many times a salesman would like to take a prospective customer to a plant to show one of his firm's machines in action. This is sometimes difficult to accomplish; days when the machine would be working at its best are comparatively few. Even should a time be arranged for showing the prospect the machine at work, the surrounding conditions might detract from the effectiveness of the demonstration, and if the shop were far away from the prospective customer's location, he might be unwilling to go there. With a good film of his machine to show, however, a salesman could take his prospect, or several of them, to the nearest moving picture theater, and for a small sum the proprietor would be glad to run the film for him during the morning hours. There is scarcely a town of 500 inhabitants or more but what has its moving picture theater, and there is hardly one of the managers who would not gladly run special films during hours when the theater would otherwise be idle. Similarly, the morning hours of a theater could be utilized for instructing the apprentices of nearby factories.

The Motionscope Co., of Indianapolis, Ind., makes a port-

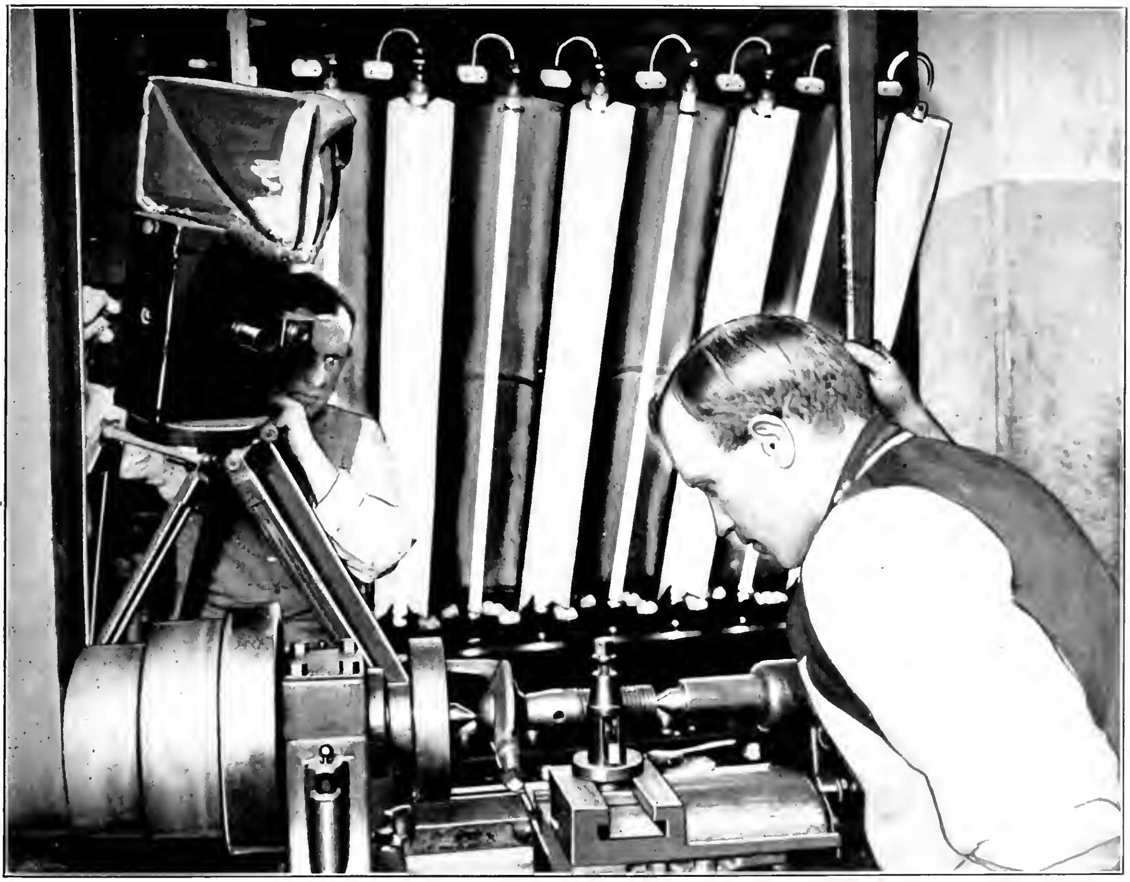

Fig. 4. The Way the Camera and Lamps are arranged to make a Detail Film

able outfit by means of which a salesman can show his prospect the film in his own factory or even in the salesman's room at the hotel. This machine is illustrated in Fig. 5, and is adjustable for any electric light current whether alternating or direct, 110 or 220 volts. Less than five minutes is required to put it in operation and it will show a picture as large as six feet wide. This machine may also be used for showing slides or stereoptican views. Equipped with a 24-inch screen, the outfit is contained in a case measuring 24 by 14 by 9 inches, and weighs approximately 35 pounds. Fig. 6 shows the way in which the machine is used in an office. The operation of any machine tool can be demonstrated with such an outfit. The salesman can stop at any point and dwell upon particular features that the view shows and he is not at the disadvantage of putting forth his argument in the midst of a noisy shop where much of his selling powers would be wasted. The film, of course, would show the machine working at its best, for moving pictures are not made on the "off days" of the machine.

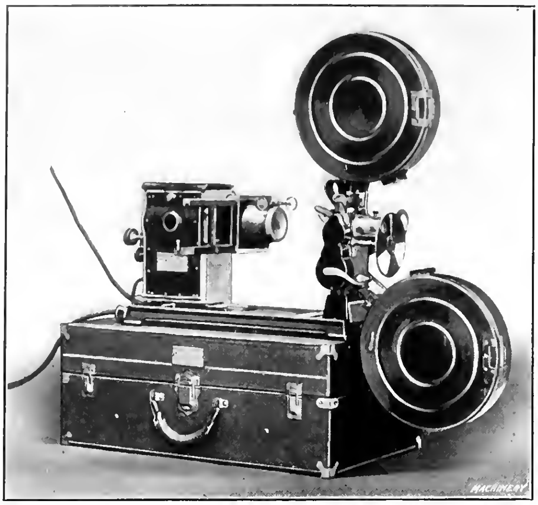

Fig. 5. Salesman's Portable Projecting Machine

In instances where it would be impracticable to send a salesman because of the distance, a film could be sent by registered mail to a prospective customer a thousand miles away. Arrangements could be made with a local moving picture house to show the film, this perhaps making the closing argument in a chain of selling correspondence.

The cost of making a mechanical moving picture film of one thousand feet or more in length is about one dollar per foot. This includes the services of the men who go to the plant, arrange the lighting and apparatus and make the film. When this film is once made, however, copies can be made at the cost of fifteen cents a foot. Should a sales manager decide to equip six of his salesmen with projecting machines and films to show a machine tool, it could be done at the rate of about thirty cents per foot, figuring the cost of the first film at one dollar per foot and the additional five at fifteen cents per foot.

Making a Mechanical Moving Picture Film

The requirements for making a moving picture film of a machine tool operation are comparatively simple. The film manufacturer understands how to get proper exhibition effects of any class of mechanism, and the lighting requirements are easily taken care of. It is seldom that a machine tool operation can be photographed without the aid of artificial light. Cooper-Hewitt electric lights are used to a large extent by the moving picture film men, and by using enough of these lights in conjunction with arc lamps it is possible to take views.

In order to show the exact method in which a mechanical moving picture of a machine tool operation is made, the views in Figs. 3 and 4 are reproduced. This shows the method of procedure in making a picture to demonstrate the operation of cutting a thread upon a jack screw. The lathe used was not equipped with a thread-cutting attachment as it was desired to have the operation explained on the ordinary type of lathe.

The lathe is shown set up for a thread-cutting operation, and as the object of the part of the film being made in Fig. 3 is to secure a general effect, showing the position of the operator and the manipulation of the lathe, the moving picture camera is situated at the back of the lathe. Cooper-Hewitt lamps are used, there being in this case three banks, each of which has eight tubes having 800 candlepower each; thus in each bank there is 6400 candlepower or a total of 19,200 candlepower in all. The positions of the banks of light upon the standards may be changed at will by raising, lowering or tilting. All being in readiness, the machine tool is operated in a natural manner, and the camera man turns his film at the rate of sixty turns per minute, making exposures at the rate of sixteen per second. Those exposures, of course, show the operator and machine in ever-changing positions, each of which represents conditions at intervals of 1/16 second; thus the fifteen views shown in the strip of film in Fig. 1 represent the 15/16 second time required for the lathe man to drop his hand from the shipper rod down to the cross-feed screw on the carriage.

To make the thread-cutting film complete, a section would necessarily show the selection of the change gears and method of setting up the work. The setting in of the cross-slide after the successive cuts could also be graphically shown. In fact, a film for teaching such an operation should show enlarged views of all of the important phases of the work. In making such detail sections of a moving picture, the camera is set up as illustrated in Fig. 4. In this view, but one bank of lights is required, raising and inclining it so the rays will fall directly upon the work. The camera has also been raised and is pointed down upon the top of the screw thread and tool so as to show the actual cutting operation, the form of chip turned off, and the comparative speed of the work. The object of this feature of the film is to show the reversing operation necessary at the end of the thread. The thread tool is nearing the end of the cut and the operator, with his hand upon the shipper, is about to reverse the traverse of the carriage. This section of the film would be particularly valuable in instructing the novice in properly withdrawing the tool and reversing the lathe at the end of a thread cut.

October 13 was celebrated in New York City by flights from Staten Island around Manhattan Island. The celebration commemorated the first flight with a motor-driven aeroplane by Wilbur Wright at Kittyhawk, N. C., October 13, 1903.

MACHINING CONVEX AND CONCAVE SURFACES

DESIGN OF CONVEX AND CONCAVE TURNING ATTACHMENTS FOR USE IN THE LATHE AND VERTICAL BORING MILL

BY ALBERT A DOWD*

The machining of convex and concave surfaces is a problem which frequently confronts the manufacturer, and its solution may be required under a great variety of conditions. Even the size of the work to be machined is a controlling factor, as it determines to a certain extent, the type of machine to be used. For example, the small steel cup washer shown in the upper part of Fig. 1 would naturally be machined on an engine lathe or turret lathe of the horizontal type, while the huge ball pipe joint in the lower part of the illustration would preferably be handled on some type of vertical boring machine. A manufacturing proposition may be necessary where one thousand or more pieces are to be handled, or it may be that only one piece is required. The work may be concave, or convex, in a plane perpendicular to the center of rotation, or it may be parallel with it and either internal or external. As the conditions governing the handling of work of this nature are so varied, and as the pieces themselves are of such widely different forms, it is very evident that we must consider several types of machines to which the forming devices may be attached. The construction of these devices must be adapted to the class of machine on which they are to be used, and this naturally influences the design of the attachments. The reader's attention is called to a few important points along these lines.

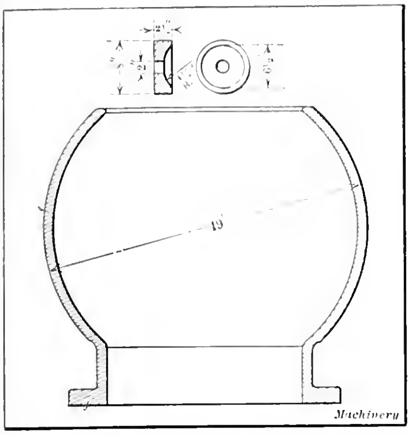

Fig. 1. Cup Washer and Ball Pipe Joint—Examples of Concave and Convex Turning

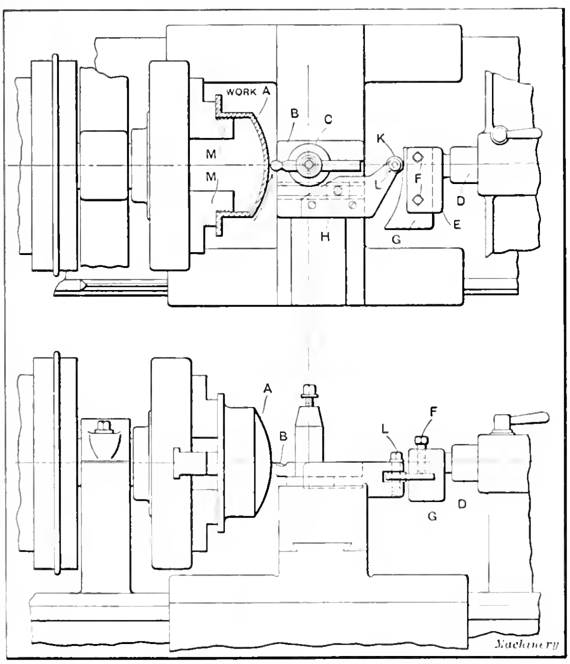

Fig. 2. Simple Attachment for Convex Turning in Engine Lathe

Important Points in Design

1. Whenever possible the attachment should be so designed that the form will be generated radially, so that the same portion of the tool will do the cutting at all times.

2. Try to use stock sizes of steel for the cutting tools so that replacements can be made easily.

3. See that the tool does not overhang too much, and that it is well supported and rigidly held. Care should also be taken that moving portions of the tool-holder or slide are of generous proportions and possess means of adjustment for wear.

4. Generate the curve by means of the machine alone, whenever possible, so that errors in the contour may not be occasioned by the failure of the operator to keep a certain roll or stud in contact with the forming plate.

5. When the attachment is of the type requiring the use of a roll and forming plate, it is essential to so arrange the plate that it will act as a guard against the tool being forced away from the work. That is, the action of the roll against the plate should be in the direction tending to carry the tool into the work, so that the thrust of the cut will always assist in keeping a positive contact between the roll and the plate. Counterweights or springs should also be used to obviate any tendency to draw in.

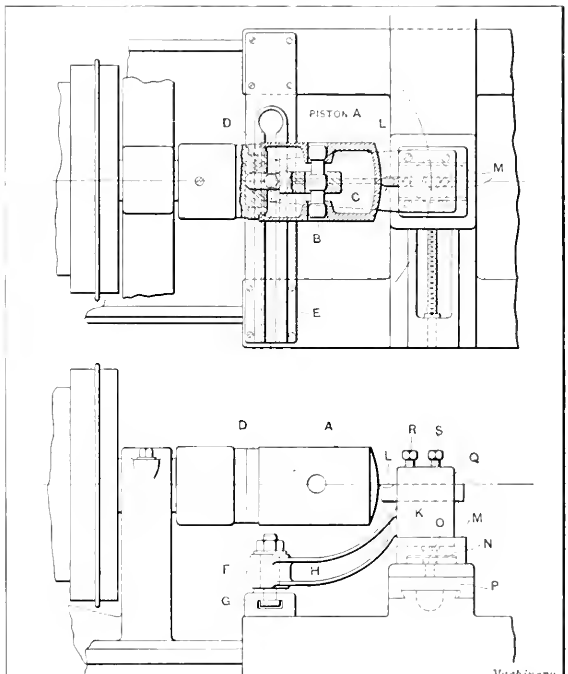

Fig. 3. Piston Crowning Attachment for the Lathe

6. Economy in operating expense and the first cost of the attachment should also be considered, while the difference in workmen's rating is also a factor which should not be overlooked.

Radius Turning on the Engine Lathe

When concave or convex turning or boring is required or only one or two pieces, or, in cases where it is not practicable to combine the radial work with other operations, the engine lathe may be adapted to a great variety of conditions. In manufacturing, it may occasionally be used to advantage, especially in cases when the length of time required to do work is sufficient to permit one man to run two machines.

Fig. 2 shows the simplest kind of a forming attachment for convex work, which is adapted to the engine lathe. The work .t is held by the inside in the chuck jaws *M*. The bracket *H*

* Address: 84 Washington Terrace, Bridgeport, Conn.

is screwed to the top of the cross-slide and carries at its outer end, the tool steel hardened and ground roller K, held in place by the screw L. The tailstock spindle D receives the holder E in which the plate G is inserted and secured by the two screws F. This plate is formed to the proper radius and is of tool steel unhardened. The cutting tool B is held in place in the regular toolpost C. The form of the cutting end of this tool is important as it must be formed to a perfect radius, in order that the cutting action may be uniform. In operating this attachment, the cross feed-screw is thrown into engagement, and the operator is required to force the roll K against the forming plate by means of the handwheel controlling the longitudinal feed of the carriage. An attachment of this sort requires the entire attention of the operator and, therefore, variations are liable to occur in the contour of the work, due to imperfect contact between the roll and plate; hence it is a very poor attachment to use if there are many pieces to be machined.

Piston Crowning Attachment for the Lathe

The arrangement shown in Fig. 3 was used for manufacturing in large quantities, and four lathes were equipped in this manner and required the services of two men to operate them. The piston A was located on a special draw-back chuck, on the steel locating ring D, and was drawn back firmly by the rod C acting on the pin B through the wrist-pin holes. A cast-iron bracket E is bolted onto the carriage of the lathe and is slotted at G. A cast-steel bracket H terminates at its upper end in the tool-block K which is dovetailed at M as shown in the plan view. The stud F is tee-shaped at its lower end to fit the slot in the bracket E. A steel block is screwed to the top of the cross-slide P, and is shouldered at N to fit the upper block in which the dovetailed tool-block K slides. The screw O simply holds the units together. A steel plate Q contains the two screws R and S which securely hold the tool L. In operating this device, the cross feed-screw is simply thrown into engagement and its forward action causes the tool to swing radially at the desired distance from the center F, thus developing a spherical surface. This device was comparatively inexpensive and the results obtained by its use were very satisfactory.

Concave Turning with a Compound Rest

A very simple device which may be used when one or two pieces only are required is shown in Fig. 4, but the radius which can be generated by this method is limited by the size of the compound rest. The work A is held by the outside in chuck jaws, and the tool C generates a radius equal to the distance from the end of the tool to the center of the swivel. The socket G is placed in the tailstock spindle and the overhanging end contains the round head pin H. The bar D is cup-shaped at E and F and bears against the end of the compound rest screw at E, while the other end engages the button at F. In using this arrangement, the holding-down gibs or straps of the compound rest swivel, are set up to produce considerable friction, and the tailstock spindle is fed forward by hand, thus causing the compound rest to swing on its own center, thereby generating the desired radius. It is obvious that the carriage gibs must be tightened to prevent any longitudinal movement.

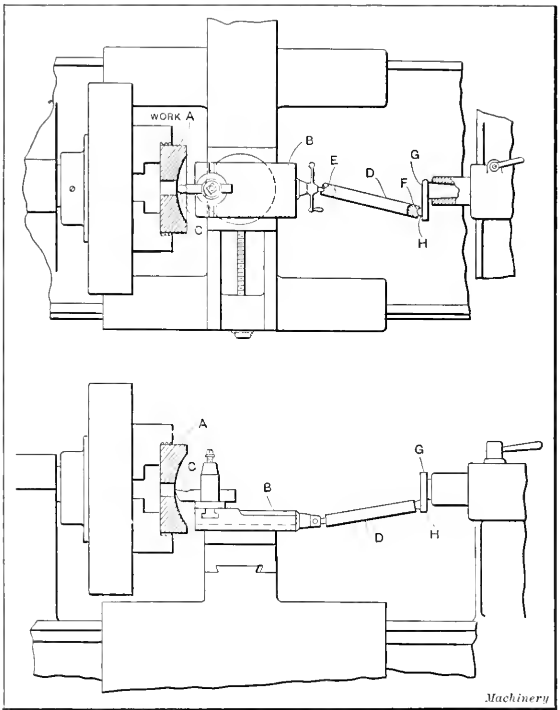

Fig. 4. Concave Turning with Compound Rest

Radius-bar for Concave Turning

A very simple arrangement for the engine lathe is shown in Fig. 5. The work A is held by the outside in chuck jaws and the round nose tool B is used to generate the concave surface. The tool is held in the ordinary manner in the toolpost C on the cross-slide of the lathe. A slotted holder K is tapered on its rear end to fit the tailstock spindle L and is slotted to receive the flat steel radius-bar G which is held in position by means of the shoulder screw H. The stud F enters the tool slot of the cross-slide and serves as a pivot for the forward end of the radius-bar. This bar is made of the correct length to generate the desired radius. As in a previous instance, the cutting end of the tool B must be ground to a perfect radius. The arrangement shown here is a very simple one and may be used for various pieces of work by the substitution of a bar of the proper radius.

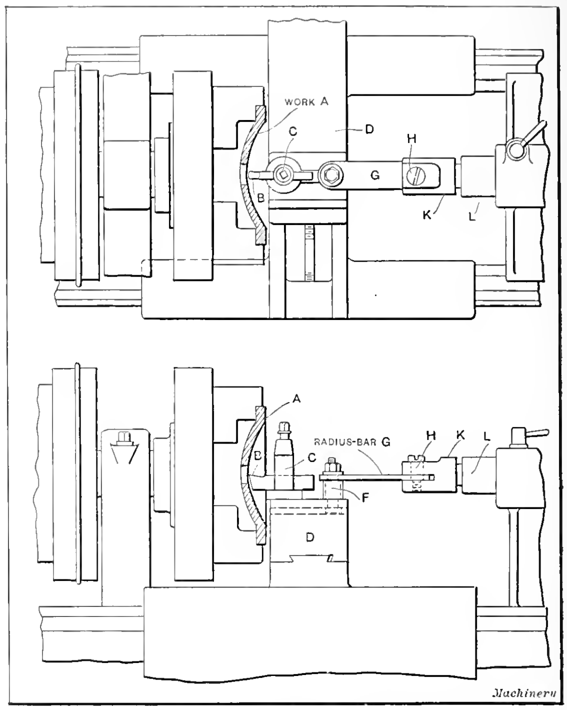

Fig. 5. Radius-bar Type of Concave Turning Attachment

Pulley Crowning Attachment for the Engine Lathe

Fig. 6 illustrates an arrangement that was applied to an old-style Pratt & Whitney lathe which had, at one time, been equipped with a taper attachment. The arrangement shown was specially designed for crowning pulleys which previously had been "chucked," faced and rough-turned straight on the periphery. A keyway had also been cut through the hub. A special arbor D was held on centers in a lathe, the dog E acting as a driver in the special faceplate F. The pulleys were put on the arbor until the face of the hub came up against the shoulder H, the spacer J being interposed between the two hubs. The cast-iron driving plate K was then put on,

followed by the washer M. The nut L was then used to tighten the pieces in position. The driving bar G was used in order to prevent vibration which would otherwise be troublesome due to the thin flange of the pulleys. The two round-nosed tools B were mounted on the tool-slide C and held in the ordinary manner. A steel plate Y was bolted to the end of the slide and overhung sufficiently to permit the bar X to pass through it. This bar passed completely through the carriage and was a sliding fit in it. The stud Q passed through the bar and formed a bearing for the roller R. The cast-iron bracket N was fastened to the rear of the carriage and was tapped at its outer end to receive the screw O, which was used for adjusting the compression of the spring P. This spring was of square section 1/4 inch in size and served to keep the roll in contact with the cam-plate S. Two brackets V and the plate U were a part of the taper attachment with which the lathe was originally equipped. The dovetail plate T served as an adjustable support for the cam-plate S and it was held in its proper location by the screws W. The upper view in the illustration is partially broken away to show the roll R in position

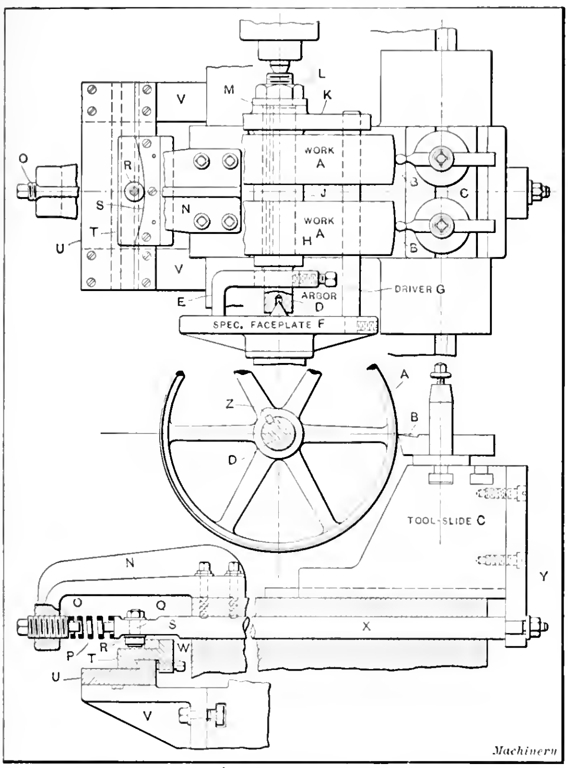

Fig. 6. Pulley Crowning Attachment for Engine Lathe

against the cam-plate. The operation of this attachment is obvious and it is only necessary to state that its action was very satisfactory.

Convex Turning Attachment using a Radius-bar

Fig. 7 shows a rather peculiar attachment for turning the convex surface on the cast-iron head-piece shown at A. The device is applied to the engine lathe, and its construction is such, that by the substitution of various lengths of radius-rods, it may be used for an infinite number of radii. The cutting tool B is held in the toolpost C in the ordinary manner and the longitudinal feed-screw is left free so that the carriage R may be perfectly independent. The bracket F is secured to the inner ways of the lathe so that it is absolutely prevented from moving. This bracket is dovetailed along its upper face and the slide G is mounted upon it. A tool-steel stud E is screwed into the side of the cross-slide and enters the bushing H which is contained in the bracket slide G. This bushing is eccentric and is split along one side thus permitting a slight adjustment to compensate for wear. The binding screw J holds it rigidly after setting. The tie-rod L connects the carriage R with a special bracket Q at the rear end of the lathe, this bracket taking the place of the regular tailstock, and being gibbed to the ways in such a manner that it is free to slide longitudinally. The tie-rod is held in place by the

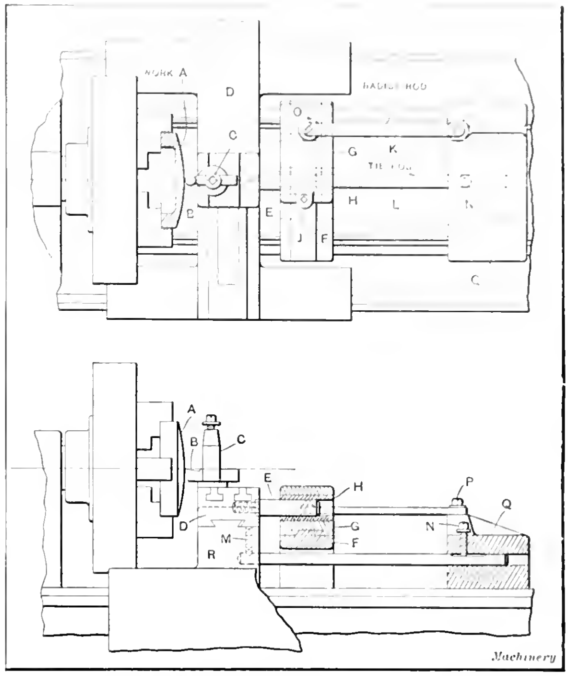

Fig. 7. Convex Turning Attachment of Radius-bar Type

screws N and M. The radius-rod K is made from a piece of flat steel and swings on the two screws O and P, located in the bracket slide and the tailstock substitute respectively. In the operation of this mechanism, the cross feed-screw is thrown

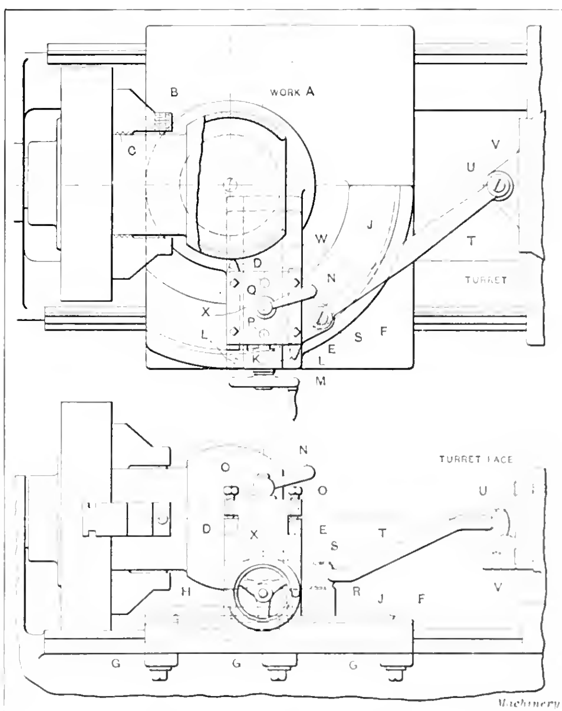

Fig. 8. Spherical Turning Device for Horizontal Turret Lathe

into mesh and the slide D moves forward carrying with it the bracket slide G to which the radius-rod is attached. As the bracket F cannot move longitudinally, it is evident that the tail-

stock substitute Q will be forced backward by the radius-rod and will carry with it the entire carriage and cross-slide, thereby generating the desired radius.

Ball Turning Device for the Horizontal Turret Lathe

We now come to a somewhat more pretentious device designed for the horizontal turret lathe for the purpose of generating the spherical portion of the steel pipe joint shown at A in Fig. 8. This work is held in chuck jaws at C, the supplementary screws B being used in the outer ends of the jaws to assist in supporting the work. The regular turret lathe cross-slide and carriage are removed and the special slide F is substituted. It is gibbed firmly to the ways in the desired position by the gibs G. Directly under the center line of the spindle, a large circular recess is bored to receive the swivel H, and circular rim J is dovetailed so that the outer end of the swivel may be gibbed at K to insure rigidity. The two screws L hold the gib. The slide W is dovetailed and has an adjustment for diameters, controlled by the handwheel M. The roughing and finishing tools D and E are held in the indexing toolpost X, the tools being secured by the screws O. The index location is insured by means of the pin P entering a hole directly underneath it in the slide, and the other index position is determined by the hole Q. The binder N locks it rigidly. At the right of the swivel the lug R is built out to receive the pivot screw S, on which the forward end of the radius-arm T is fastened. A bracket V is bolted to the face of the turret and carries the screw U which supports the other end of the radius-arm.

In the operation of this device, the turret longitudinal feed is used while the roughing tool D removes the scale from the casting. The toolpost is then indexed and the finishing tool E completes the work. This attachment gave very good results

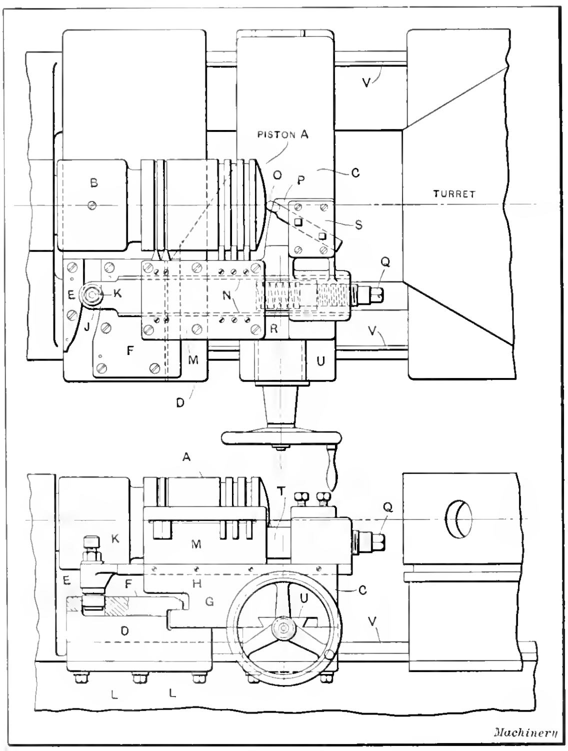

Fig. 9. Turret Lathe Piston Crowning Attachment

and was satisfactory in every respect. There are several points in the construction of this device to which attention should be directed. One of the points is the turret toolpost by means of which the tools always remain set, so that the diameters are easily held to size. Another point is the dovetail gibbing of the outer portion of the swivel. This method does away with all possibility of chatter, providing the gib is kept tight. Another advantage is the adjustment for various diameters by means of the slide W which is mounted on the swivel.

Turret Lathe Attachment for Crowning a Piston Head

The attachment in Fig. 9 is part of an equipment of tools for finishing the piston A, the work being held by the inside on a special chuck B, which is screwed onto the end of the spindle. There are turning tools fastened to the turret which are in action simultaneously with the attachment shown. These are not shown in the illustration, as they have nothing to do with the radius attachment. A special steel cross-slide C is mounted on the carriage in place of the regular slide, and

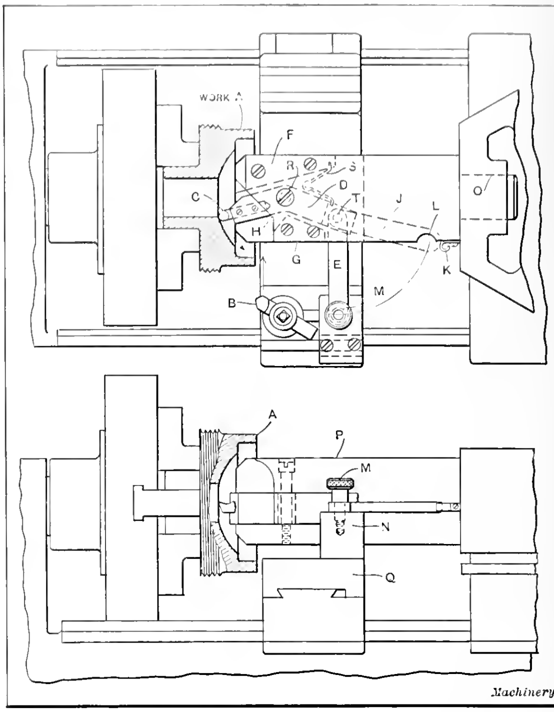

Fig. 10. Turret Lathe Attachment for turning Concave Seat

the overhanging portion G carries a tool-block M in which the grooving tools for the piston are mounted. A special bracket D is firmly gibbed to the ways and secured by the screws L. The tool-steel forming plates E and F are screwed to this bracket and doweled in position. The plate F also acts as a strap for the overhanging portion of the cross-slide at H. A hardened and ground tool-steel roller J is pivoted on the stud K, and controls the form of the crown by its contact with the plate F. The other plate E only acts as a guard. The radius forming slide is dovetailed at N and passes through under the tool-block. It carries a tool O mounted in the tool-holder S. A supporting pad P is provided on the cross-slide directly under the tool-holder and serves to prevent vibration. A heavy coil spring R is used to insure proper contact of the roll with the cam-plate. The necessary adjustment is obtained by means of the screw Q. A brass tube T protects the spring from chips and dirt which might otherwise impair its action.

This attachment was built for a large manufacturing plant in the East, and proved very satisfactory. It is designed so that all the tools can work at the same time. In building the attachment, it was found necessary to fit the dovetail slides and other moving portions, after the tool-blocks were put in place, and the tools clamped in position. This was unavoidable because of the clamping strains, as these caused a certain amount of distortion, making it necessary to do the fitting after the tool-blocks were in position.

Radius Boring Attachment for a Horizontal Turret Lathe

The device for generating the internal radial seat in the brass casting A, shown in Fig. 10, is somewhat out of the ordinary, and in addition to this, it is comparatively inexpensive. Furthermore, it is practically a self-contained unit, and requires no special fitting or attachments to the machine.

The steel bar P is held in the turret by the shank O and is

secured in place by the turret binder. The bar is slotted completely through to receive the swivel arm D which is a machinery steel forging ground on two sides to fit the slot. The forward end of this swivel arm carries the tool C which is set at the proper distance from the screw R to produce the desired radius. At the end of the bar, a mill cut is made at H in order to permit access to the screws which hold the tool in position. The steel filler blocks F and G are put in to give additional rigidity to the end of the bar. The flat spring S is simply used to prevent back-lash in the swivel arm. The operating link E enters a slot in the end of the swivel arm and is held by the pin T. A special steel block N is fastened to the cross-slide and the knurled screw-pin M couples the end

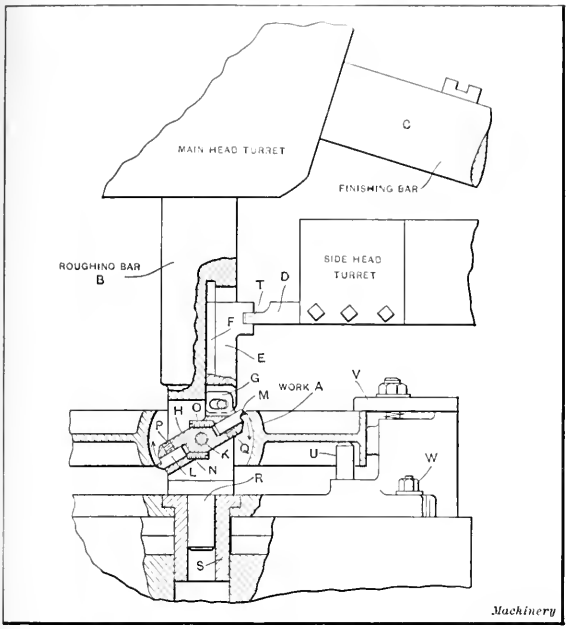

Fig. 11. Radius Boring-bar for Vertical Turret Lathe

of the link to the slide. The tool B is used in connection with the attachment for facing the end of the work.

In operation, the cross-slide feed-screw is engaged and the radius nicely generated by the radial action of the arm. As

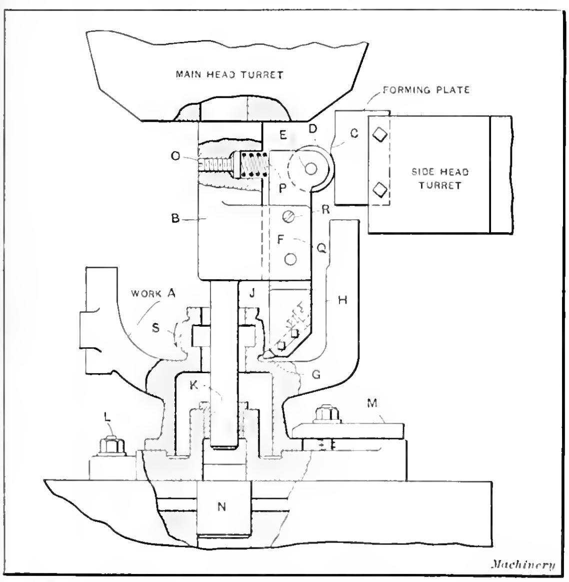

Fig. 12. Attachment for Convex Turning in Vertical Turret Lathe

soon as this operation has been completed, the knurled screw M is rapidly removed and the link E, swung over into the slot J where it is held by the flat spring K. The cut L allows the fingers to grasp the link when the radial attachment is again put into use. This attachment has many good points, the only serious draw-back being that there is a slight tendency to chatter when the cut is excessive.

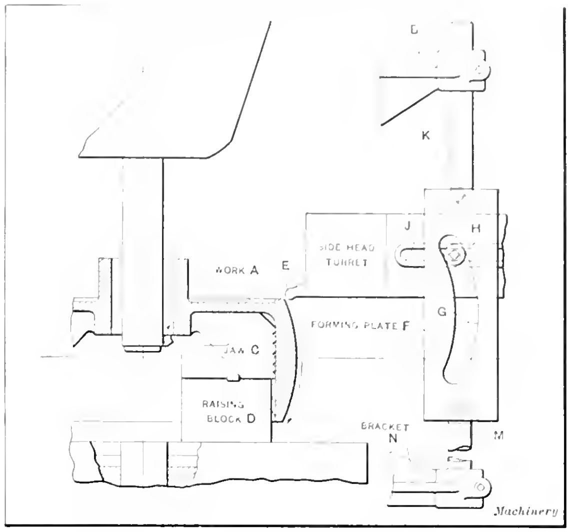

Fig. 13. Device for crowning Pulleys in Vertical Turret Lathe

Radius Boring-bar for the Vertical Turret Lathe

The device shown in Fig. 11 was designed for use on the vertical turret lathe, and was used in connection with other tools in the main and side heads for the purpose of boring the radial portions of the automobile crank-case cover bracket shown at A in the illustration. The work is held on a locating fixture upon three pins U and is clamped by means of the straps V. Only a part of the work is shown, as the piece is a

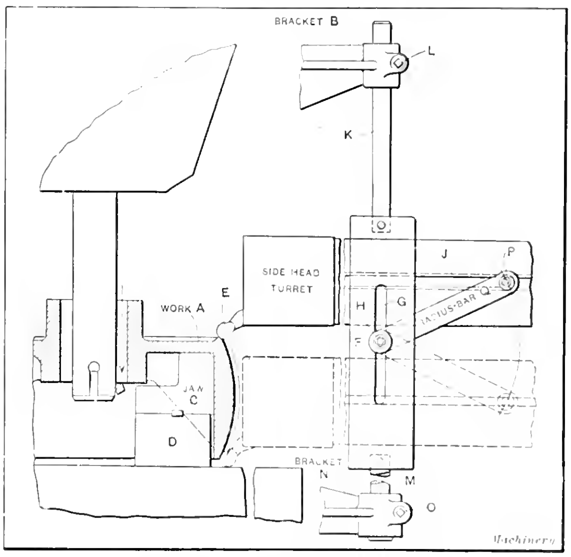

Fig. 14. Another Pulley Crowning Attachment

somewhat crooked one and the other portions have nothing to do with the radial boring. The fixture is held to the table by three tee-bolts W and it is centered by the steel bushing S, which also acts as a guide for the stem of the boring-bar R. This bar is slotted out at its lower end to receive the swivel block H, which carries the tools L and M for rough-boring the radius. The block swings on the pin K, when forced to do so by the downward action of the operating arm E. The two cutting tools are backed up and adjusted by means of the screws N and O, and they are held firmly in position by the set-screws P and Q. The bar B is slotted out to receive the tongue F on the operating arm, and the lower end of this arm contains a pin which works in a slot at G in the upper

portion of the swivel tool-block. The steel piece *D* is held in the side head turret and engages a groove in the upper part of the operating arm.

The finishing bar *C* is of the same general construction as the roughing bar except that only one tool is used for finishing, instead of the two shown in the roughing bar. It is well to note that the use of two tools in roughing practically reduces the roughing time one-half, it being only necessary to cut half way with each tool, as one comes up from the bottom while the other is coming down, so that the two cuts meet at the center. In operation, the down feed of the side-head turret is started, thus providing the necessary power for operating the device. This scheme gave very satisfactory results as far as accuracy is concerned, but as the mechanism was confined in a small space, the size of the tools could not be made large enough to properly conduct away the heat generated in boring.

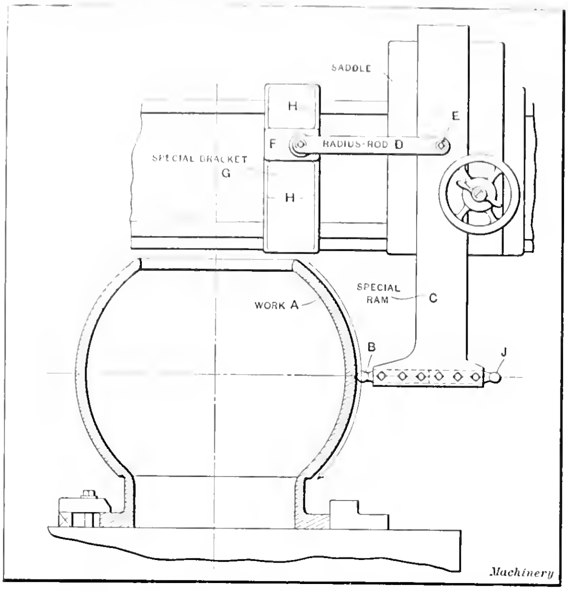

Fig. 15. Spherical Turning Attachment for Vertical Boring Mill

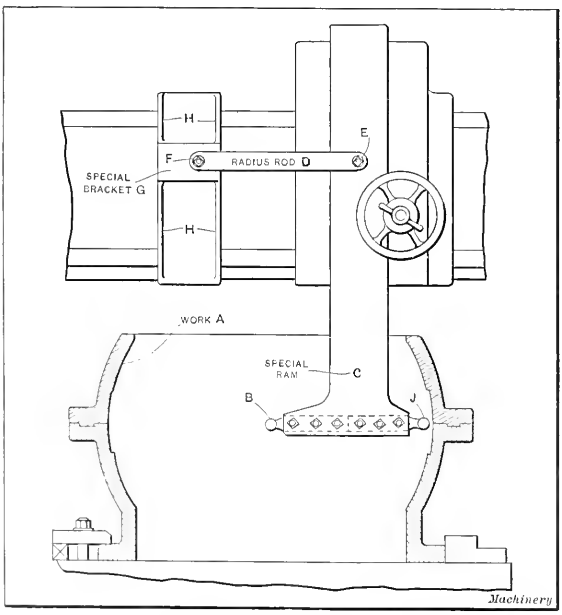

Fig. 16. Attachment shown in Fig. 15, used for Internal Work

Convex Turning Device for a Difficult Piece of Work

Fig. 12 shows a device for convex turning. The jack-shaft tube bracket *A* has been previously machined at its lower end and is located for this setting by the finished surfaces. A special fixture is bolted to the table of the vertical turret lathe, by the three tee-bolts *L*, and it is firmly secured by the straps *M*. The stud *N* serves to center the fixture on the table, while the bushing *K* acts as a guide for the end of the bar. The radial surface *S* is to be machined at this setting, and it will be noted that it is somewhat confined. The generating bar *B* is a 0.40 carbon steel forging, and the piloted end is carbonized, hardened and ground to a running fit in the bushing *K*. The projecting portion *Q* of the bar is of rectangular section and is slotted to receive the swinging arm *J*, which is pivoted on the pin *F*. This pin is equi-distant from the end of the cutting tool *G* and the center of the pin *E*. A hardened and ground tool-steel roller *D* revolves upon the latter, and is kept in contact with the forming plate *C* by means of the spring *P*, which is very stiff. Adjustment is provided through the screw *O*.

In operating this device, the turret down feed is used and the side-head turret is locked in the proper relation to the cutting tool, to produce the radius at the correct height on the casting. For the finishing cut, the roughing tool *G* is removed and a finishing tool substituted. A special screw *H*, having a large head against which the ends of the tools bear, makes this comparatively easy. The work can be turned closer to size if two roughing tools and a finisher are used, leaving only about 0.010 inch for the final cut. A defect in this fixture is that the thrust of the cut has a tendency to force the roll away from the cam-plate, and the action of the spring is sometimes insufficient to entirely overcome this. Had it been possible to design this attachment in such a way that the thrust of the cut would simply hold the roll more firmly against the forming plate, its action would have been more positive. The results obtained were sufficiently close, however, to conform to the required limits of accuracy, and it may therefore be stated that its work was satisfactory.

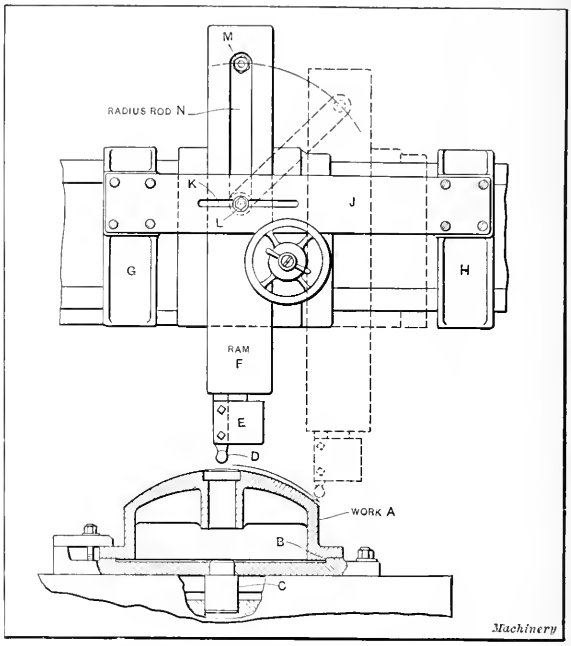

Fig. 17. Convex Turning in a Horizontal Plane

Convex Forming Attachment for the Vertical Turret Lathe

A simple arrangement for the vertical turret lathe which permits the simultaneous use of both the main head and side heads, is shown in Fig. 13. The work *A* is a tractor pulley of large size. This is held by the inside, in the jaws *C* which are mounted on the raising blocks *D*. The boring-bar shown may be used if desired, while the radius turning is taking place, as the radius attachment does not interfere in any way with the movements of the main head. The construction of this device is extremely simple and the results obtained by its use are very satisfactory. The upper and lower brackets

B and *N* are attached to the bed of the machine and carry the rods *K* and *M*, which support the forming plate *F*. This plate is cut at *G* to the desired radius, and the tool-steel roller *H* travels along the slot and forces the tool *E*, which is held in the side-head turret, to take a similar path, thereby producing the convex surface on the rim of the pulley. A tee-slot *J* is cut along the entire length of the side-head slide, and the roll *H* is fastened to a special bolt which can be adjusted to any position in the slot. The forming plate is also adjustable vertically, by sliding the rods up or down in the brackets.

Side-head Attachment using a Radius-bar

Another method for crowning the outside of a tractor pulley is shown in Fig. 14, a radius-bar being used in this case to

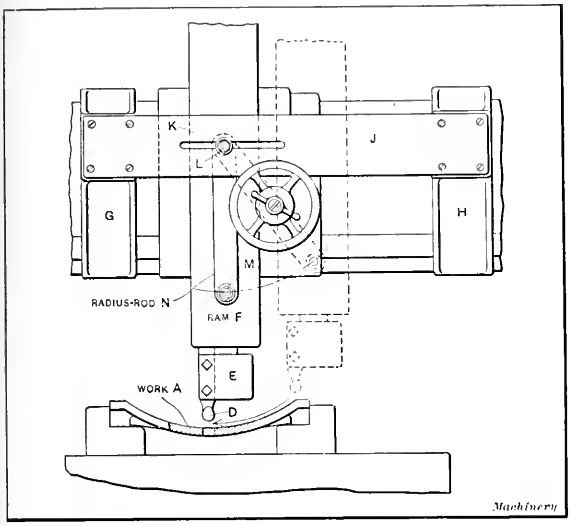

Fig. 18. Concave Turning in a Horizontal Plane

generate the desired curve. The work *A* is held, as in the previous instance, by the jaws *C* on the raising blocks *D*. The same brackets are also employed, but the plate *F* is not used for forming. It is slotted at *G* for adjustment only and a special screw or stud *H* is used in the slot as a pivot for the radius-bar *Q*. A tee-slot *J* is cut along the entire length of the side-head slide and receives a special stud *P*, to which the other end of the radius-bar is fastened. The down feed of the side-head is thrown into engagement when operating the device, and the tool *E* naturally follows the radial path controlled by the length of the radius-bar. This device is simple and good and only requires extra radius-bars in order to handle a great variety of work.

Vertical Boring Mill Attachment for Spherical Turning

The male member of a very large ball-and-socket pipe joint is shown at *A* in Fig. 15. The spherical portion, which is to be machined, has an outside diameter of forty-nine inches. This member fits the female portion shown in Fig. 16, and the attachments used for boring and turning are the same, although the locations and the tools are different. A special bracket *G* is mounted on the rail and is gibbed at the rear so that it can be adjusted easily. It is well gibbed at *H* to insure rigidity. The special ram *C* was made in the form shown, its lower end acting as a tool-holder for the tools *B* and *J;* the former is used for the outside turning and the latter for the inside boring. The ram itself is a steel casting of extra-heavy section on account of the excessive overhang required. The radius-rod *D* was fastened at the two ends by the screws *F* and *E*, and was made of the proper length to give the correct radius. A special arrangement, not shown in the illustration, permitted a side floating action to the saddle along the rail, when the down feed was engaged.

For handling the socket portion of the joint shown (Fig. 16), the entire mechanism was moved over on the rail far enough to bring the tools in the desired position for boring, the tool *J* being used for this purpose.

Attachment for Convex Turning in a Horizontal Plane

The work *A* shown in Fig 17 is a steel casting which has been previously machined at *B*. It is held on a fixture (located centrally on the table by the plug *C*) and clamped down by the three clamps around the flange. Two brackets *G* and *H* are mounted on the rail and serve to carry the supporting plate *J*. As these brackets necessarily extend some distance in front of the rail they are strongly ribbed, as shown in the illustration. The supporting plate *J* has a slot cut in it at *K* for adjusting the pivot stud *L* in a longitudinal direction. This stud supports one end of the radius-rod *N*, and the other end is attached to the upper portion of the ram *F* by pivot stud *M*. A regular tool-holder at the lower end of the ram holds the tool *D*. No special arrangement is necessary to allow the saddle to "float" in a transverse direction, as the horizontal feed-screw is used in this case, the vertical feed being simply thrown out of mesh. This permits the ram to float vertically, as controlled by the radius-rod *N*.

Attachment for Concave Turning in a Horizontal Plane

The steel casting shown at *A* in Fig. 18 is turned concave by the same device as that illustrated in Fig. 17, the only difference being that the radius-rod *N* is pivoted to the ram below the supporting plate instead of above. The operation of the mechanism is exactly the same as that for the convex surface.

Many variations of the devices described in this article have been used for generating radial surfaces, but enough have been described to enable the reader to select a method most suited to the particular problem that may require a solution. Adaptations may be readily made to fit almost any condition likely to be encountered in general manufacturing.

A LIGHTNING CALCULATION

BY UNCLE JOSH

Considerable amusement may be derived by this mysterious trick of "lightning calculators." The "professor" announces that five numbers will be written, three by the audience, and two by himself, and that after the audience selects the first number, he will immediately give the sum of the five *before the rest have been selected.*

Thereupon, one of the audience writes, for the first number, for instance, 4,962,783 and the professor immediately announces that the sum will be, 24,962,781. To illustrate:

The audience selects for the first figure............	4,962,783
The audience selects for the second figure..........	8,652,794
The professor writes for the third figure..........	1,347,205
The audience selects for the fourth figure..........	2,339,964
The professor writes the fifth number.............	7,660,035
The sum is found to be, as announced	24,962,781

This seems very mysterious, but is easily accomplished, as follows: For the sum, subtract 2 from the first number selected, and place the figure 2 to the left of it. Thus, subtracting 2 from 4,962,783=4,962,781, and placing a figure 2 before it makes it read 24,962,781.

The professor selects the third figure, by selecting such numbers that the figure in each column, added to the figure above it, will make nine.

Thus, the second figure being......................	8,652,794
He will write the third figure......................	1,347,205
The sum of each column = 9......................	9,999,999
The audience then writes the fourth figure..........	2,339,964
The professor proceeds as before, writing...........	7,660,035
The sum in each column being 9..................	9,999,999

[If the number of horizontal rows of figures is increased from five to seven, the sum can be obtained by subtracting 3 from the first number and placing the figure 3 to the left, whereas for nine horizontal rows, subtract 4 from the first number and place 4 to the left, etc.—EDITOR]

The life of shop brooms can be greatly lengthened by dipping the brush in hot water before using. The glue water is made by using one teaspoonful of good liquid fish glue for each quart of hot water.

ONE-PIECE ARMATURE DISK TOOLS*

UNUSUAL TOOLMAKING METHODS EMPLOYED BY THE ROBBINS & MYERS CO.

BY DOUGLAS T. HAMILTON†

Fig. 1. Armature Disk

Armature disks are made from a grade of sheet iron 0.025 inch thick called "electric" iron. This material is used because of its permeability—low resistance to an electric current—and though very soft, it is difficult to cut out, the wear on the dies being enormous. The shape of these armature disks, as Fig. 1 shows, is such that it has been considered inadvisable by many manufacturers, to make the dies or punches solid because the thin strips of metal remaining are likely to warp in hardening and break, and if made solid, the repairing of them would be difficult if not impossible. The Robbins & Myers Co., Springfield, Ohio, well-known manufacturers of the "Standard" line of fans, motor and generators, make all types of armature and field punches and dies up to 10 inches in diameter from one solid piece of steel, and machine them to the shape required. This not only calls for good tool work, but it also demands particular care in hardening and subsequent operations.

Construction of Solid Armature Disk Tools

The punch and die shown in Fig. 2 is not of the sub-press pattern, as is the usual practice followed in making sectional armature disk dies, but is of the plain blanking type of construction. The blanking die *G* is made from one solid piece of steel in which the required number of elongated slots are machined, as will be described later. The die fits in a counterbored seat in the die shoe *H* and is held in place by screws as shown.

The slitting punch *I* is made from a solid block of steel, which in this case is provided with a projection fitting in a recessed seat in the punch-holder *J*, to which it is held by screws. The punch *I* is also recessed to fit an additional plain blanking punch *K*, the latter cutting out a blank which is subsequently slit and made into a smaller sized armature disk *A*, Fig. 11. This method is used to economize in stock, and cut the scrap down to a minimum. The individual piercing punches *L* for the large armature disk *B*, Fig. 11, are driven into the punch-holder *J*, as illustrated. The prongs of the slitting punch *I* are formed by cutting a series of slots around the periphery of the blank and then shaping the individual prongs to the desired shape, as will be described later. The punch and die illustrated in Fig. 2 is the largest solid armature disk tool ever produced by the Robbins & Myers Co., and both the die and punch are made from solid pieces of "Ketos" non-shrinkable oil hardening steel.

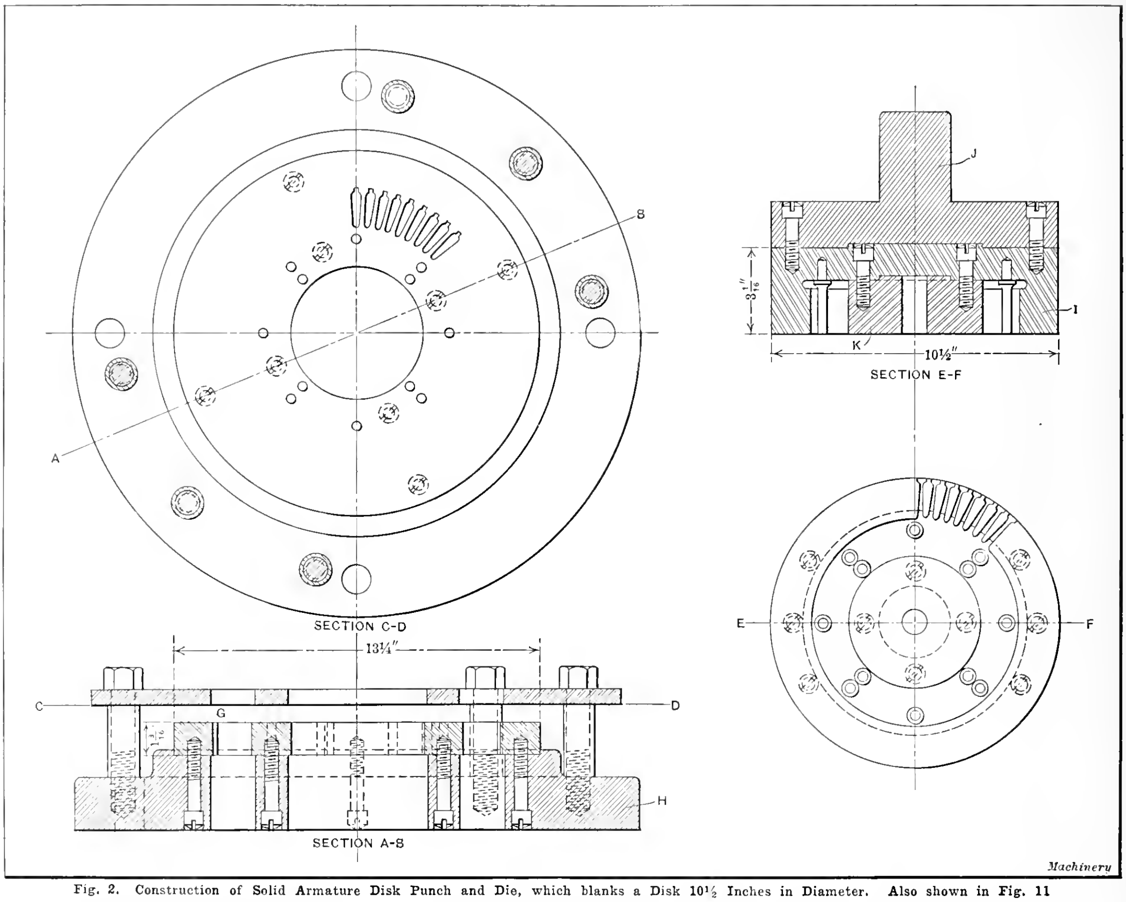

Fig. 2. Construction of Solid Armature Disk Punch and Die, which blanks a Disk 10½ Inches in Diameter. Also shown in Fig. 11

Making Solid Armature Disk Dies

Armature disk dies, as previously mentioned, are made solid up to 10 inches in diameter, and are cut from round bars of special non-shrinkable oil hardening steel. The blank, after the center hole has been drilled, is placed on an arbor and turned on the external diameter in the lathe; it is then ready for working out the elongated slots which form the projections on the armature disks. The first step in this operation is to drill a series of equidistantly spaced holes entirely through the blank as illustrated in Fig. 3. The die block *A* in this case is driven onto a taper arbor which is held in the dividing

* For information on punch and die work previously published in MACHINERY, see "Drawing and Forming an Automobile Clutch Cone" in the November, 1913, number, and articles there referred to.
† Associate Editor of MACHINERY.

head on the milling machine. A bushing type of drill chuck is then inserted in the spindle of the milling machine, carrying a drill of the required diameter. The internal ring of holes is usually drilled first, then the size of the drill is changed and an exterior ring of holes is drilled, these two rows of holes forming the approximate length of the slots. Following this, a series of holes is drilled so that they just break into each other, and thus remove the intervening webs.

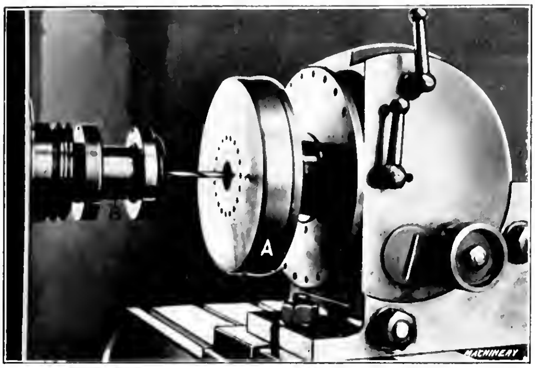

Fig. 3. Drilling Solid Armature Disk Dies in a Milling Machine

The next step is to finish-form the elongated slots, this operation being accomplished in the manner shown in Fig. 4. The die *A*, as before, is mounted on a tapered arbor, which is held in the dividing head on the milling machine, while slotting tools of the proper shape are held in the slotting attachment. The dividing head is held perpendicular and the slotting attachment is also set square, so as to produce a straight hole. The clearance angle is produced in a filing

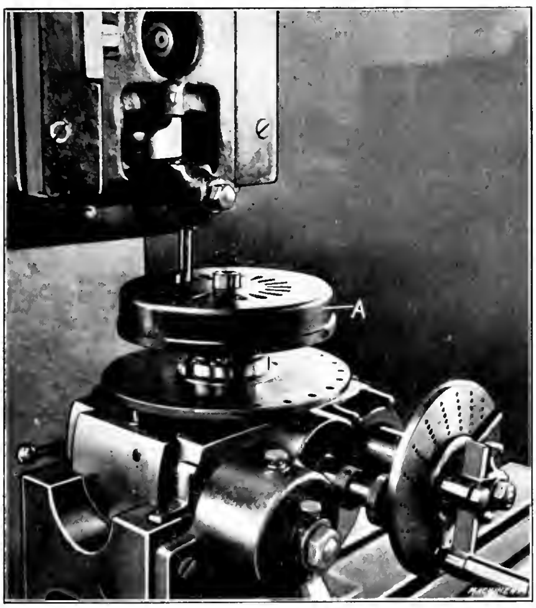

Fig. 4. Shaping Elongated Slots in a Solid Armature Disk Die, using a Slotting Attachment and Indexing and Dividing Head on a Milling Machine

machine as will be described later. The sides of the slots are machined first, after which the two arcs at each end of the oblong slots are machined. The outer arc has a slot cut in it. A tool of suitable shape is used to produce this slot after the arc has been finished and the slot cut to the desired length. The indexing attachment of the dividing head, of course, is used for spacing the holes correctly.

Finishing Operations on the Die Blank

After the elongated slots in the die have been machined to their approximate size, the final operation consists in filing them to the exact size. This is accomplished in the small bench filing machine as illustrated in Fig. 5. It consists of a table that can be set to the desired angle, which carries a file of such shape as to conform with the slots in the die. This machine is driven by an individual motor as illustrated, and in addition to bringing the slots to the proper shape it also produces the correct clearance angle. The clearance angle on armature disk dies is 0.003 inch on a side, the die blank being 1⅛ inch thick. It is necessary, therefore, to tilt the table over from the vertical line to an angle of about 7½ minutes.

The die blank is hardened and drawn before the punch is made and fitted to it. For hardening, a regular gas burning muffle furnace is used. The blank is placed in this furnace and brought to a temperature varying from 1375 to 1400 degrees F. The heating is done gradually and uniformly until the tools show a dark red throughout, indicating a temperature of about 1100 degrees F., before the heat is raised to the hardening point—1375 to 1400 degrees F. The tools are then dipped into linseed oil and left to cool, after which the temper is drawn very slowly to 250 degrees F. to relieve the strain. The hardening of solid armature dies calls for considerable ingenuity on the part of the toolmaker, as the least amount of shrinkage or warpage in the die would unfit it for use, and as it is of the solid type it would be practically impossible to do anything with it if distorted in hardening. It is therefore evident that not only must a good brand of steel be used,

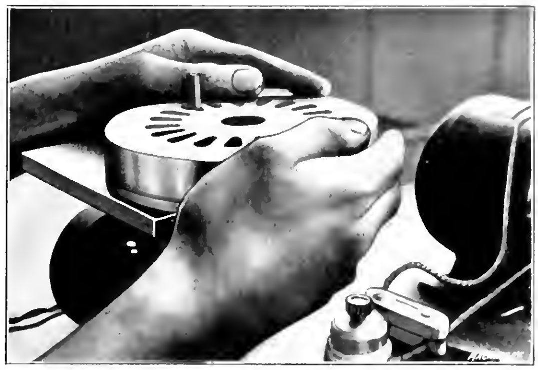

Fig. 5. The Final Machining Operations on a Solid Die—filing the Elongated Slots to the Proper Size and Shape

but considerable care has to be exercised in order to obtain satisfactory results. However, it may be stated that the Robbins & Myers Co. have been using this type of die for a considerable period, and they have not lost one tool during the past two years in the hardening operation.

Slotting Armature Disk Punches

The punch is made in a similar manner to the die in that it is cut off from a round bar of stock, drilled, turned and recessed in the lathe and is then slotted as illustrated in Fig. 6. The punch *A* in this case is driven onto a tapered arbor which

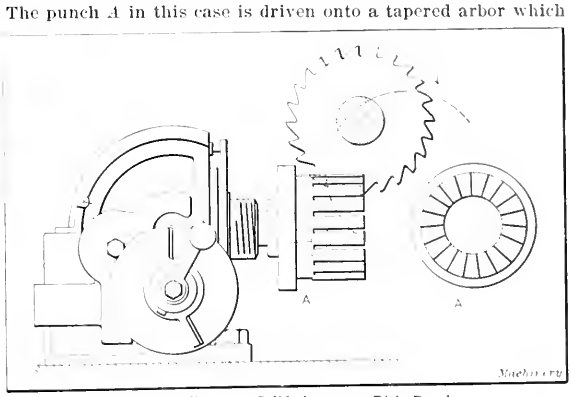

Fig. 6. Slitting a Solid Armature Disk Punch

is held in the dividing head of the milling machine and a slotting saw of the required thickness is used to form the individual members of the punch. Two cuts are taken; one cut is taken as indicated by the full lines in the illustration, after which the position of the cutter is changed and a second cut is taken. On some types of armature punches where the

slot between the individual members of the punch or prong varies in width at the inner and outer extremities, slotting saws of different thicknesses are used in order to reduce the amount of machining on the sides of the members. When this is necessary, the saw is not inserted as illustrated in Fig. 6, but is raised slightly, and the second saw also raised, the remaining web being machined out with a slotting attachment in the milling machine.

Finish-forming the Individual Members or Prongs

After the individual prongs of the armature punch have been formed by slotting, the next step is to form the inner and outer arcs. This is accomplished as illustrated in Figs. 7 and 8. In Fig. 7 the punch *A* is set up in a vertical position, for machining the inner arc of the prongs. Here it can be seen

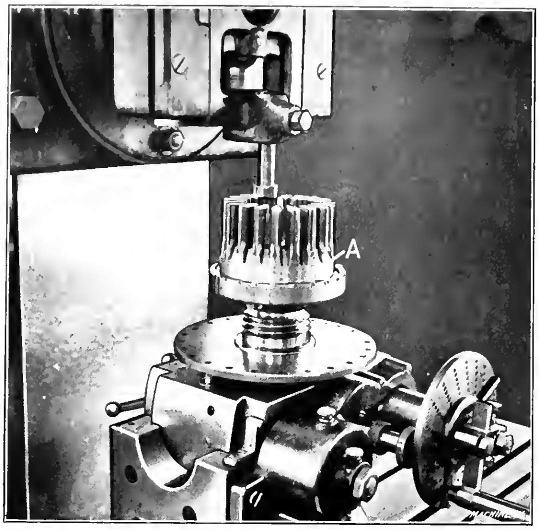

Fig. 7. Final Shaping Operation on the Inner Ends of the Punch Prongs, using a Slotting Attachment and a Dividing Head on the Milling Machine

that the dividing head is used for holding the punch, and the shaping tool is held in the slotting attachment of the milling machine. The shaping tool is so formed that it completes the arc on the inner edge of the prongs in one setting. The outer arc on the prongs is formed with the special milling cutter *B*, as indicated in Fig. 8, with the punch *A* held in a horizontal instead of a vertical plane. The milling cutter, in addition

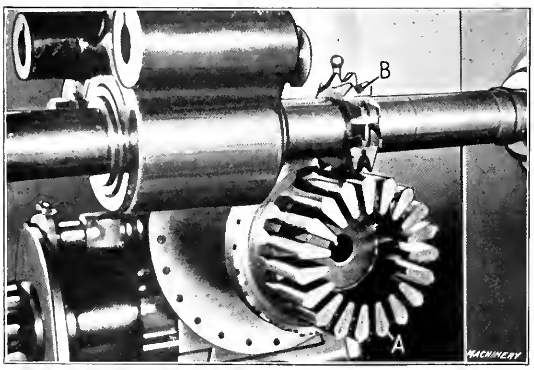

Fig. 8. Finishing the Outer Diameter of the Punch Prongs, using a Formed Milling Cutter

to forming the arc, also produces the slight projections on the punch that cut out the ring that will be left in the armature disk, or in other words, continues the oblong slot to the circumference. The milling cutter as illustrated completes this form of punch in one operation, and at the conclusion, with the exception of a slight touching up with the file, the punch is ready to be sheared into the die to obtain the final shape. The excess stock is filed away, and the punch sheared in several times until the shape has been produced for about 1/4 inch. After this the punch is taken back to the milling machine and the excess amount of stock removed as indicated in Figs. 7 and 8.

Different Types of Armature Disk Tools

Armature and field disks are made of several different shapes to conform with the motor or generator in which they are used. Fig. 9 shows a follow type of armature disk punch and die for producing the disk *A*. The sheet is first perforated

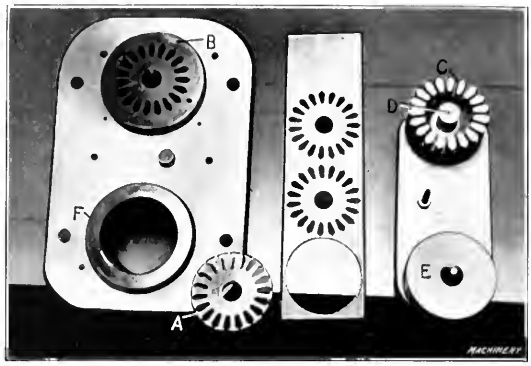

Fig. 9. Follow Type of Punch and Die for completing an Armature Disk in One Operation

by the solid die and punch *B* and *C*, respectively, and at the same time the hole is produced by the inserted punch *D*.

Owing to the relation of the blanking punch and die *E* and *F* to the perforating punch and die *C* and *B*, the punch press makes two strokes before a blank is cut out, when starting a new sheet. The chief reason for laying out the perforating

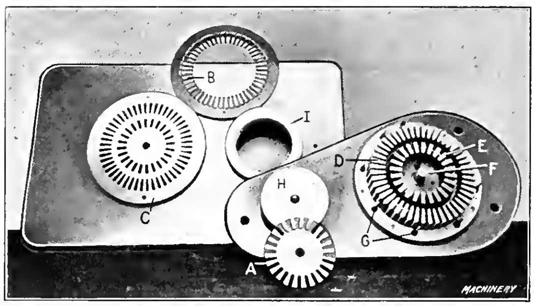

Fig. 10. Combination Follow Type of Punch and Die for completing an Armature Disk and slotting and piercing a Field Disk in One Operation

and blanking dies in this way is that it would be impossible to get them close enough unless made from the same piece of steel. Fig. 10 shows a follow type of die similar to Fig. 9, but of more interesting construction. These tools complete the armature disk *A* and slit and pierce the field disk *B* at each

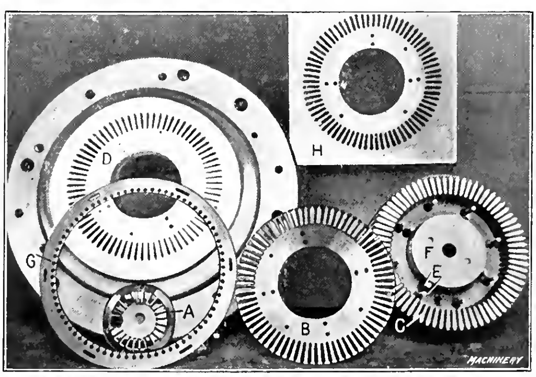

Fig. 11. Punch and Die for a Fan and Starter Field Disk and Other Pieces made from Same Sheet

stroke of the press. The field disk *B* is blanked out in a separate operation. The perforating die *C* is made from one solid piece of steel, while the punches *D* and *E* are made from two solid rings of steel fastened by screws to the punch-holder. The punch *F* which pierces the center hole in the armature

disk *A* is also an individual member. The piercing punches *G* for the field disk *B* are inserted around the outer periphery of the punch-holder as shown. Punch *H* and die *I* blank out the armature disk *A*.

Another interesting example of solid punch and die work is shown in Fig. 11. This illustration shows the punch and die presented in detail in Fig. 2, and also gives some idea of the number of blanks and the character of operations performed by it. The small field disk *A* is only blanked out by these tools and is pierced and slit in a separate operation. The large armature disk *B* is slit by the solid punch *C* and die *D* and is pierced by the inserted punches *E*, the center hole being produced by the separate punch *F*. It is blanked out from the sheet in a separate operation. The field disk *G* is another piece which is produced from the same sheet as the other parts shown in this illustration, but it is completed in a separate operation. The portion of the sheet *H* shows where the disk *G* is obtained.

An armature disk set of tools differing slightly from those previously shown is illustrated in Fig. 12. These tools are used to produce the armature disk *A* which is used in a 5 H. P. motor. The die *B* is one solid piece of steel machined out to the shape shown, while the punch is partly of segment

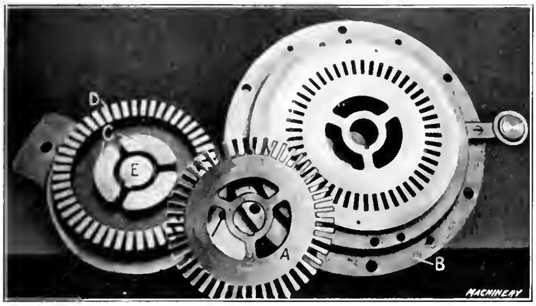

Fig. 12. Five Horsepower Armature Disk Punch and Die of a Semi-solid Construction

construction. Punches *C* for producing the arms are made from three separate pieces of steel let into the main slitting punch *D*, which is made from one solid piece of steel. Punch *E* is also an individual member. This armature disk is blanked out in a separate operation.

Fig. 13 shows an armature disk set of tools set up and in operation in a Toledo punch press. These tools are similar

Fig. 13. Solid Armature Disk Punches and Dies in Operation—Note Method of saving Stock

in construction to those shown in Fig. 10. They produce the armature disk *A*, and pierce and slit the field disk *B*, the scrap being a ring *C*. The field disk *B* is cut out from the sheet in a separate operation. The sheet of stock has been pulled out from beneath the punches to show the operations more clearly. This illustration shows the method used to reduce the scrap to a minimum.

Life of Solid Armature Disk Tools

One remarkable feature that is particularly noteworthy about these solid armature disk tools, and the steel used in making them, is their long life and the large number of blanks which can be produced between grinds. Fig. 14 shows two die blanks; the one to the right has never been used and

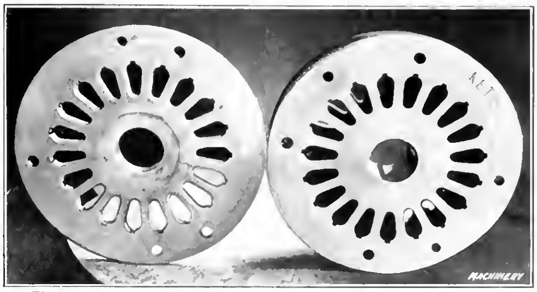

Fig. 14. Comparison of New and Old Armature Disk Dies. The Old Die has blanked 1,344,000 Armature Disks and has been ground down from 1⅛ to 3/16 inch in Thickness

is 1⅛ inch thick, whereas the one to the left has produced 1,344,000 blanks—16,480 blanks between grinds—has been ground eighty times, and reduced from 1⅛ to 3/16 inch in thickness. The solid punch also stands up satisfactorily and is ground an equal number of times. This is a rather unusual performance and is greatly in excess of what would be expected of the solid type of punches and dies as generally made. The clearance, as before mentioned, is only 0.003 inch on a side or 0.006 inch on the diameter of the elongated holes in the die. As the blank always retains the size of the punch—the scrap being the size of the die—the die can be worn down without affecting the character of the work produced by it.

* * *

SPEEDS FOR TURNING UNUSUAL MATERIALS

The *Practical Engineer* gives the following information on turning unusual materials: Slate, on account of its peculiarly stratified formation, is rather difficult to turn, but if handled carefully, can be machined in an ordinary lathe. The cutting speed should be about the same as for cast iron. A sheet of fiber or pressed paper should be interposed between the chuck or steadyrest jaws and the slate, to protect the latter. Slate rolls must not be centered and run on the tailstock. A satisfactory method of supporting a slate roll having journals at the ends is to bore a piece of lignum vitae to receive the turned end of the roll, and center it for the tailstock spindle. Rubber can be turned at a peripheral speed of 200 feet per minute, although it is much easier to grind it with an abrasive wheel that is porous and soft. For cutting a rubber roll in two, the ordinary parting tool should not be used, but a tool shaped like a knife; such a tool severs the rubber without removing any material. Gutta percha can be turned as easily as wood, but the tools must be sharp and a good soap-and-water lubricant used. Copper can be turned easily at 200 feet per minute. When machining commutators that is the speed commonly used. Light cuts are taken with a pointed tool and the surface is finished with a wooden buff lined with glass paper. This buff is in the form of a 90-degree segment and is approximately 1¾ inch thick. It is held against the commutator with the point of an ordinary tool and is fed back and forth across the surface. In this way the segments are gradually ground down until there is not the slightest gap or break between the copper segments and the mica insulation. Bath stone such as is used in the construction of pillars for balconies, etc., can be turned at 150 feet per minute, and the formation of ornamental contours is quite easy. Marble is a treacherous material to turn. It should be cut with a tool such as would be used for brass, but at a speed suitable for cast iron. It must be handled very carefully to prevent flaws in the surface.

AUTOMATIC MACHINERY FOR DANGEROUS WORK

Machinery is designed to function automatically in order to insure uniformity of product and to reduce the cost of attendance. Another reason for designing automatic machines is to save life and limbs. The growing recognition of the fact—chiefly due to liability acts—that employers must bear the responsibility for accidents makes imperative the elimination of dangerous apparatus wherever possible. Some trades are inherently dangerous, and in these, simple automatic machines for performing the operations entailing risk to workmen should effect a considerable reduction of yearly casualties.

There are operations in the manufacture of ammunition which expose the workmen to danger of injury by explosion. They might cost no less if done on automatic machines, because the upkeep of the machines might wipe out the saving of attendance, but the greater safety of operation doubtless would make the change profitable both from a humanitarian and a monetary point of view.

Take, for example, the loading of the cases for a certain powerful explosive shell with cordite. Holes in the sides of the case must be provided, but on account of the difficulty of loading the cordite in cases having holes it seems necessary to load first and drill the holes afterward. Obviously, this is a very dangerous operation. A spark struck by the drill when passing through the wall into the chamber is sure to cause an explosion and probably the death or serious injury of the workman. Granted that the procedure must be as outlined, it seems little less than criminal not to provide automatic drilling machines in bomb-proof inclosures for drilling the holes. Such machines can be readily provided which would work rapidly and as efficiently as hand machines. One life saved by providing automatic drilling machines would be worth all the cost of the equipment.

* * *

BROACHING ROUND HOLES

Broaching keyways and holes of other shapes than round has been practiced many years, but not until the last decade in which automobile manufacturing has developed so greatly did broaching become a commercial practice of widely recognized importance. One of the unexpected applications of the broaching machine is for finishing round holes. The finishing of round holes by broaching instead of by reaming, may seem strange to those unfamiliar with the conditions met with in alloy steel gears, but some alloy steels are extremely difficult to finish satisfactorily by reaming. The steel is tough and the chips have a tendency to catch on the reamer blades and score circumferential grooves in the hole. The cost of reamer upkeep when working on alloy steels is heavy as compared with that for carbon steel.

The broaching process applied to finishing round holes in alloy steel parts is rapid and satisfactory. Not only is the tool upkeep cost lower than with reaming but the finish is superior to that obtained by reaming unless extraordinary care is taken. An advantage of minor importance is that the tool markings appear longitudinal instead of circumferential. This favors proper distribution of the lubricant and insures smooth and long wear of running parts.

* * *

STUDS VS. CAP-SCREWS

An important detail of steam and gas engines, air compressors, hydraulic machinery and other fluid-actuated mechanisms is the means employed for holding cylinder heads and valve covers in place. The choice of the designer lies between studs with nuts and cap-screws. What are the advantages and disadvantages of studs and cap-screws?

Studs are preferred to cap-screws, especially on heavy machinery for the following reasons: 1. A stud and nut can generally be screwed tighter than a cap-screw because of better alignment, smoother threads and reduced effect of torsional elasticity. 2. A stud and nut is less likely to break than a cap-screw when making repairs. In case a nut is rusted fast on a stud it can be split with a cold chisel, but a cap-screw "seized" in the casting is twisted off. This means that the broken part must be drilled out and a new cap-screw provided to take its place. The loss of time and extra labor incident to breakages of cap-screws are important disadvantages when making repairs. 3. Covers secured with nuts and studs can be loosened and tightened without serious deterioration of the fastening means. The nuts on studs can be loosened many times without appreciable wear of the threads, but not so with cap-screws. They soon wear the cast-iron threads and become loose and are likely to strip after being used a few times. 4. Studs have the advantage of holding gaskets in place while a cover is being applied. This is an important advantage in erecting when the parts are heavy and applied with difficulty. 5. A stud made from a round bar is stronger than a cap-screw turned down from a hexagon bar. The latter uses the weakest part of the metal at and near the center for the body.

The Ohio State University department of mechanical engineering will make a series of tests of studs and cap-screws with the view of determining all the advantages of each. Prof. William T. Magruder, head of the mechanical engineering department, will be glad to receive suggestions for the tests and arguments for and against the two types of fastenings.

* * *

ANTIQUATED TOOL-ROOM EQUIPMENT

We are sometimes surprised to find machine shops equipped with first-class tools in every department but the tool-room. In this important department are old lathes and other machines in good condition, but of old design. They did good work, but are too weak to take heavy cuts without excessive vibration and springing out of alignment. The management evidently believed that weak machines were good enough for toolmakers because they are seldom required to do heavy work. This is a mistaken notion. There is no reason why a tool-room lathe should take three or four cuts to reduce a piece when lathes in the main shop are doing the same work in two cuts.

The tool-room should be equipped with strong, heavy machines, for two very good reasons. First, in order to prepare the work quickly for the finishing operation, and second to take heavy reduction cuts when required with a minimum of chatter and spring. Toolmaking is, in the main, nothing more nor less than regular machinists' work with a touch of refinement in the finishing processes. Smoother finish and closer limits are the rule, and they are most efficiently obtained on machines that are sturdy as well as accurate.

STABILITY OF THE MACHINE TOOL BUSINESS

The growth of the machine tool business in the last twenty years has been unprecedented. In 1893 there were comparatively few American builders of lathes, planers, milling machines, boring mills, automatic screw machines, drilling machines, shapers, slotters and other machines for metal working, commonly known as machine tools and their accessories. The number has increased to about two hundred and the capital invested has increased in still greater ratio. At the beginning and during this twenty-year period there have been three distinct dull times, 1893, 1903 and 1907, but within the period the number of failures of machine tool builders was astonishingly small. Probably no other industry consisting of so many actively competing concerns building a long-lived product can show such a record. The record still holds. During the present year, which toward the close undeniably has been a dull time in the machine tool trade, there has not been so far one serious failure. This fact speaks volumes for the stability of the business and the conservatism with which it is conducted.

The last ten years have been marked by the development of a new vehicle—the automobile—and the past six or seven years by the building of enormous plants for its manufacture. The equipping of these plants with standard and special machine tools has created a great market that to a certain degree was unhealthy. It could not last indefinitely. With the slacking of demand for the higher-priced motor cars there have come several failures and discontinuances of automobile concerns which has resulted in throwing a considerable number of second-hand machine tools on the market. These tools have affected the market for new machinery detrimentally, of course. Thus, in the automobile business, the machine tool builders have had an enormous market to supply, for which a number of concerns have perhaps unwisely expanded. Now that the market is restricted and a few of the former buyers are now in a sense competitors, some hardship is inevitable.

The changes in the tariff naturally have caused a tightening of purse strings until such time as the ultimate effect can be seen. German machine tool competition may affect certain lines injuriously for a time, but years will be required for the German manufacturers to obtain a firm foot-hold in this country. During that time our manufacturers will be improving their methods and product so as to keep ahead of foreign countries. The future is full of promise with little to discourage the American machine tool builder. The development of American mechanical appliances for all sorts of purposes must go on, and that progress means unlimited demand for the basic means of production, that is for lathes, planers, drilling machines, milling machines, grinding machines, automatic screw machines, shapers, boring mills, boring machines, slotters and the special machine tools characteristic of modern machine shop equipment.

* * *

SPEEDS AND FEEDS FOR COLD SAWING METALS

The selection of speeds and feeds for cold sawing is one of the many phases of machine shop practice which cannot be regulated by fixed rules. The design and construction of the machine and saw, as well as the grade of material to be cut, cause wide variations in both speed and feed. The average output or number of pieces cut for each grinding of the saw is another factor to be considered. One prominent manufacturer of cold saw cutting-off machines states that for sawing 0.30 carbon, open-hearth machine steel bars 5 inches diameter, a feed of 1 inch per minute and a peripheral speed for the saw of approximately 45 feet per minute would be used. This speed and feed is regarded as economical when using the vanadium steel high-carbon blades. As an example of this rate of cutting, 1600 pieces were sawed off in one machine with an average output of 145 pieces for one grinding of the saw. For some classes of work a feed of 2 inches per minute and a speed of about 45 feet is employed, but under average shop conditions a feed of 3/4 inch per minute is considered conservative when cutting 0.30 open-hearth steel with a saw that is in good condition.

When selecting speeds and feeds, it is important to consider the output for one sharpening of the saw. In one shop 200 pieces of special analysis steel and 800 pieces of open-hearth steel (varying from 3 3/4 to 4 1/4 inches diameter) were cut at one grinding of the saw. While it may be feasible to cut various grades of steel at the rate of 1000 pieces with one grinding of a high-speed steel saw, the experience of the company referred to is that on high-carbon tool steel and special alloy steel, such as chrome-nickel, etc., the best economy in grinding the saw will be obtained by using a feed of about 1/2 inch per minute with a surface speed for the saw of approximately 30 feet per minute. When using the speed and feed mentioned, if the saw averages 100 pieces per grinding the output is considered satisfactory. It has been found that some of the special analysis steels cut quite freely as, for example, 3 1/2 per cent nickel steel which is sawed as easily as open-hearth 0.30 per cent carbon steel. On the other hand, some of the softer grades of stock, such as open-hearth machine steel having about 0.15 per cent carbon, do not cut as freely as stock with a higher percentage of carbon. This is because the softer steel is inclined to roll up into the throats of the saw teeth and, if too much heat is generated in the cutting the chips will fuse more or less to the teeth. A good deal of this soft stock, in bars 8 inches diameter, has been cut with a saw speed of 45 feet per minute and a feed of about 5/8 inch per minute. This rate of cutting is considered the most economical for the saw when using vanadium high-carbon blades. Some grades of chrome-nickel stock seem to cut quite freely, whereas steel of another make is cut with difficulty and, in some instances, the use of a high-speed steel saw is necessary. Moreover, steel of one make may cut quite differently from that of another make, although the analysis in both cases may be the same; consequently, the speed and feed that will prove most economical must finally be determined by actual tests. Of course it will be understood that the size and power of the machine must also be considered. As to phosphor-bronze, some grades can be cut very easily whereas some of the bronzes used for gears, etc., are very hard to cut and the edge of the saw is inclined to glaze over; hence it is difficult to give even a general idea of the speeds and feeds.

Another well-known manufacturer of cutting-off machines gives the following data on the time for cutting various sizes of steel stock: Eighty-one pieces 3 3/8 inches diameter, 2 hours 27 minutes; 210 pieces, 4 inches diameter, 7 hours 27 minutes; 54 pieces, 5 inches diameter, 2 hours 22 minutes; 57 pieces, 6 inches diameter, 2 hours 58 minutes; 684 pieces, varying from 3 3/8 to 6 inches in diameter, 26 1/2 hours. In the last example, the smallest number of pieces of the same size was 2 and the largest 210. The feed was 2 inches per minute and cutting speed 48 feet. The time for cutting 46 pieces of axle steel 7 1/4 inches in diameter was 3 1/4 hours, the feed being 1 3/4 inch per minute. When cutting flat stock 1 1/8 by 9 1/8 inches, several bars were stacked and cut simultaneously, a total of 246 pieces being cut off in 1 hour 37 minutes. The material was low-carbon steel, the feed 3 7/8 inches per minute, and the cutting speed 85 feet per minute.

Still another concern gives time data for various grades of metal: Time for sawing steel forging, 6 1/8 inches in diameter containing 0.74 carbon, 1.12 manganese, 0.30 nickel, 7 1/2 minutes; tool steel bar 2 1/2 inches diameter, 4 minutes; tool steel bar 0.50 per cent carbon, 3 1/2 inches diameter, 3 1/2 minutes; Krupp chrome-nickel steel bar 4 1/2 inches diameter, 5 minutes; Krupp chrome-nickel steel bar 6 inches diameter, 8 to 10 minutes; 6 1/2-inch bar, 0.20 per cent carbon, 5 minutes; 6-inch bar, 0.30 per cent carbon, 4 1/2 to 6 minutes; 8-inch bar of high-carbon steel, 13 minutes; 8-inch diameter hard bronze ingot, 6 minutes.

All these data represent actual practice and are given as a general guide, although it is necessary, of course, to make considerable allowance for the design of the saw as well as the size and power of the machine.

A STUDY OF THE STUB TOOTH SYSTEM OF GEARING*

DETERMINATION OF THE LEWIS FORMULA FACTOR y FOR STUB TOOTH GEARS

BY LLOYD G. SMITH†

Owing to the demand for stronger and smoother running gears in machines where the power transmitted is high and the space limited, there is now coming into common use the stub-tooth system of gearing in which the angle of obliquity is increased to twenty degrees and the length of the teeth decreased to about eight-tenths that of the standard 14½ degree involute tooth. Accurate information regarding the strength of these teeth is lacking and it was the purpose of this investigation to determine correct values of the factor y in the Lewis formula for the strength of gear teeth as applied to this system of gearing. The two forms of stub teeth used in this country—that recommended by the Fellows Gear Shaper Co., 25 Pearl St., Springfield, Vt., and that recommended by the R. D. Nuttall Co., Pittsburg, Pa.—are the ones with which this investigation is concerned.

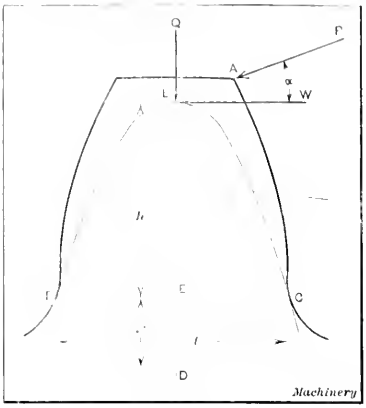

Fig. 1. Diagram illustrating Derivation of the Lewis Formula

The Strength of Gearing—Lewis Assumptions

In 1893, Mr. Wilfred Lewis, after making a considerable study of the subject of the strength of gear teeth, derived a formula for the safe load that could be transmitted by a gear. He was the first investigator to take into consideration the form of the tooth profile and the fact that the line of action of the pressure is always perpendicular to the surface. When gears are cut accurately, his formula gives very satisfactory results and with a few corrections for the number of teeth in contact, etc., it is almost universally used in gear design.

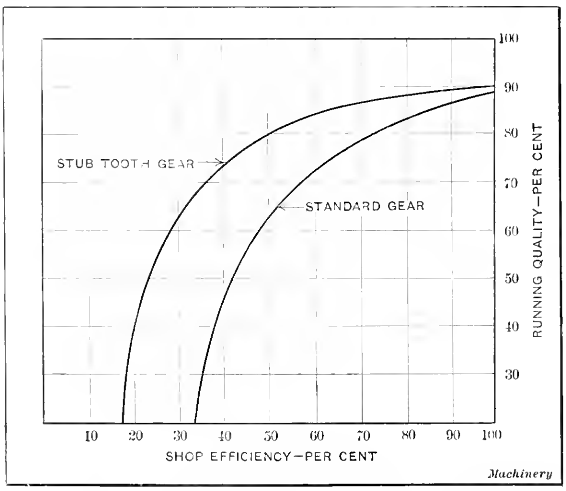

Fig. 2. Diagram from Transactions of A. S. M. E. for 1908 showing Relative Efficiency of Stub Tooth and Standard Gears

Mr. Lewis assumed that all of the load on the gear was concentrated at the end of one tooth, its line of action being perpendicular to the surface AC as shown in Fig. 1. The actual force P was resolved into a tangential force W and a radial force Q. The tangential force produces a bending stress in the tooth, while the radial force produces a uniformly distributed compressive stress. When the material of which the gears are made is stronger in compression than in tension, this radial component is a source of strength, but when the material is of about the same strength in tension and compression it is a source of weakness. For small angles of obliquity α this compression does not amount to more than 10 per cent of the total stress and on this account was neglected by Mr. Lewis. The tangential force W he assumed to be equal to the force transmitted at the pitch circle. This last assumption, although perhaps as much as 10 per cent in error for small pinions, gives values of the stress on the safe side and so may be considered accurate enough for practical purposes.

TABLE I. PROPORTIONS OF FELLOWS STUB TOOTH GEARS

Pitch	Thickness of Tooth, Inches	Addendum, Inches	Clearance, Inches	Whole Depth, Inches
4/5	0.3927	0.2000	0.0500	0.4500

Machinery

Force Analysis

To obtain the weakest section of the tooth, Mr. Lewis constructed a parabola CBF (Fig. 1) passing through B, the application point of the tangential force W, and tangent to the tooth profile at C and F. This parabola encloses a cantilever beam of uniform strength and it can be readily seen that the weakest section of the tooth lies along CF. The resisting moment of this section is:

$$\frac{SI}{C} = \frac{Sft^2}{6} \qquad (1)$$

where S = allowable fiber stress;
f = face width of the gear.

The bending moment is Wh, hence:

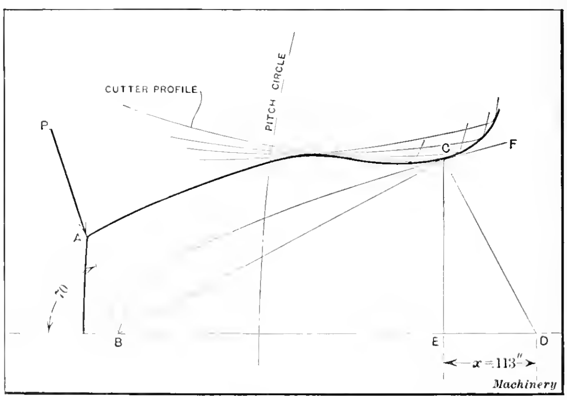

Fig. 3. Method of laying out Gear Teeth to determine Values of x and y

$$Wh = \frac{Sft^2}{6} \qquad (2)$$

From the geometry of the figure:

$$h = \frac{t^2}{4x} \qquad (3)$$

* For further information on the subject of stub tooth gearing see "The Stub Gear-Tooth," published in MACHINERY October, 1911; "Design of Automobile Transmission Gears," October, 1910; "The Stub Tooth Gear," April, 1908; and "Calculations for Short Tooth Gears," July, 1907.

† Address: 5474 Greenwood Ave., Chicago, Ill.

Then $$W = \frac{2Sfx}{3} = Sfp' \times \frac{2x}{3p'}$$
where p' = the circular pitch.

Representing the ratio $\frac{2x}{3p'}$ by the symbol y, we have:

$$W = Sp'fy \qquad (4)$$

The value y is thus seen to be dependent upon the tooth profile and the pitch of the gear. By drawing the tooth pro-

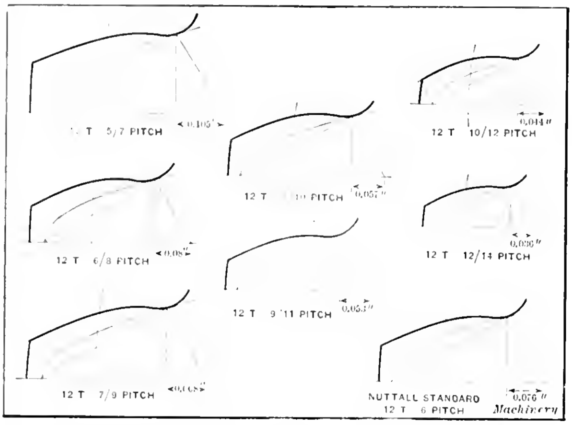

Fig. 4. Tooth Profiles and Values of x for Different Pitches

files for gears with various numbers of teeth, Mr. Lewis was able to calculate the value of y for the standard involute system, and he found that the following equation very closely fitted the values he obtained.

$$y = y_r - \frac{a}{n} \qquad (5)$$

in which y_r = the value of y for rack teeth;

a = constant depending upon angle of obliquity;

n = number of teeth in gear.

A mathematical analysis of a rack tooth outline shows that the value of y_r is given by the following equation:

$$y_r = 0.1273\,p\left(\frac{t}{0.728} - z\right) \qquad (6)$$

in which t = thickness of tooth at pitch line;

z = addendum;

p = diametral pitch.

Stub Tooth Systems

To meet the demand for gear teeth that are stronger than the standard 14½ degree involute, various methods of increasing their strength may be resorted to. Two of these methods are as follows: (1) shortening the addendum and keeping the standard angle of obliquity; and (2) increasing the angle of obliquity and preserving the standard height of the tooth. The stub tooth system is a combination of these two methods, in which the height of the tooth is decreased to about 0.8 the standard height and the angle of obliquity increased to 20 degrees.

The chief advantage of this system is that the teeth will transmit greater loads, and this fact is taken advantage of in the construction of machine tools, hoisting machinery and automobiles, because with the same quality and amount of material, greater strength can be obtained. The stub tooth gears run smoother than gears with the standard 14½ degree involute teeth, due to the decreased impact, because for a given strength and length of face, the pitch is smaller and consequently the number of teeth in mesh is greater. Stub tooth gears are almost universally used by automobile manufacturers, and they report that the action is smoother and the wear less than with standard gears. Mr. Norman Litchfield in the Transactions of the American Society of Mechanical Engineers for 1908 reports that they have given excellent service on the New York subway trains. Mr. E. R. Fellows in the same volume of the Transactions presents the chart shown in Fig. 2, which is based on actual experience. The curves apply to stub tooth and standard gears with "shop efficiency" plotted against "running quality." By shop efficiency he means the relative conditions under which the gears operate and that 100 per cent would only be attained under laboratory conditions, 90 per cent representing first-class commercial conditions and 70 per cent the common conditions in an average shop. By running quality is meant the relative noiselessness of the gears, 100 per cent signifying absolutely noiseless operation and 90 per cent the best condition actually obtainable. The curves show that under the very best conditions the two gears operate about equally well, but under average commercial conditions, the stub tooth gear is decidedly superior.

Forms of the Stub Tooth System

In this country, there are two forms of the stub tooth system in common use, both using an angle of obliquity of 20 degrees, but differing in the length of the addendum. The older of these is that recommended by the Fellows Gear Shaper Co. in which the pitch is designated by two numbers written as a fraction, the numerator of which represents the diametral pitch and the denominator the diametral pitch of

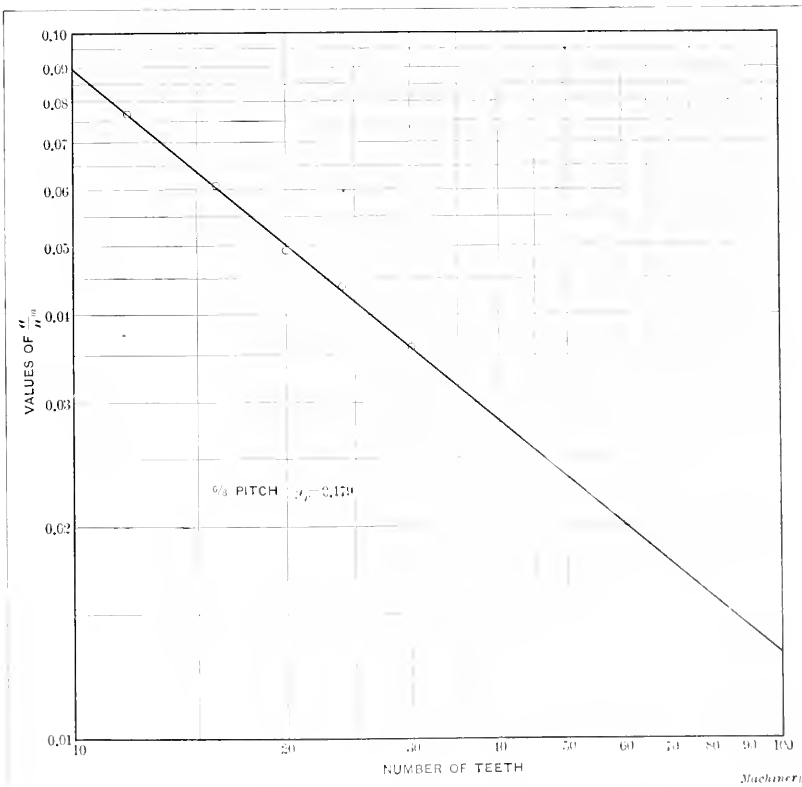

Fig. 5. Diagram showing Values of a ÷ n raised to mth power from which Values of n raised to mth power and Factor y are derived for the 6/8 Pitch Gear

a standard gear having the same addendum. Thus in the 4/5 pitch, the gear would have a diametral pitch of four and an addendum the same as on a standard gear of five pitch, *i. e.*, 1/5 of an inch. Table I gives the proportions of the Fel-

lows stub tooth gears. The other system was originated by Mr. C. H. Logue of the R. D. Nuttall Co., and he uses an addendum equal to 0.25 of the circular pitch and a dedendum of 0.30 of the circular pitch. In the Fellows system the ratio of the addendum to the circular pitch varies from 0.228 to 0.272, and in order to make his system uniform, Mr. Logue took a mean value of 0.25.

Determination of the Strength Factor and Method of Drawing Profiles

In order to determine the value of y for a certain gear of a given pitch, it is necessary to lay out a tooth to some magnified scale in the same manner that Mr. Lewis did (illustrated by Fig. 1) measure the distance x and compute y. In this investigation, this has been done for a great many pitches, using a scale of 10 to 1, except for the large pitches where the drawings would become too large. For pitches 5/7

TABLE II. VALUES OF a AND m

Machinery

and 6/8 a scale of 8 to 1 was used and for 4/5 pitch a scale of 6 to 1. Fig. 3 illustrates the method of laying out the teeth. Before laying out the teeth the profile of the cutter tooth was drawn on tracing paper with the addendum equal to the dedendum of the stub tooth gear, and the diameter equal to that of a 24-tooth gear. The gear cutter was taken this size on the recommendation of the Fellows Gear Shaper Co. The tooth profiles of gears with various numbers of teeth were then drawn accurately on tracing paper, with the face from the base circle out a true involute and the flank and fillet generated by the point of the cutter tooth, as the pitch circles of the gear and cutter were rolled together.

Having thus obtained the profile, the action line AB (Fig. 3) of the force at the end of the tooth was drawn normal to the involute, *i. e.*, at 20 degrees to the vertical. In order to get the parabola BCF passing through B and tangent to the profile, a considerable number of parabolas, differing but slightly from each other, were drawn on cards, so that they could be slipped in under the tracing paper and adjusted to enable the point of tangency C to be determined. The line BC was then drawn and CD and CE drawn perpendicular to BC and BD, respectively. The length x was measured as accurately as possible with a Starrett steel scale and the value of y computed. Two or more profiles of the same tooth were sometimes drawn and it was found that the values of x usually checked within 1 or 2 per cent. Fig. 4 shows the tooth profiles and values of x for various pitches.

Method of Plotting

We have already determined an exact method of computing y_r in Equation (5):

$$y = y_r - \frac{a}{n}$$

If any method could be found for obtaining the value of $\frac{a}{n}$, the problem of determining the value of y would be very simple. The use of logarithmic cross-section paper makes the plotting of all such functions as $y = bx^a$ very simple, because the curve becomes a straight line with a slope a. In Equation (5) $\frac{a}{n}$ is a function of the same character, and when so plotted for different values of n, it should give a straight line with a slope of -1. Advantage was taken of this peculiar property of logarithmic paper by first carefully computing y and y_r for five different gears for each pitch, and then plotting the corresponding values of $\frac{a}{n}$. Due to unavoidable errors in calculating y, the points did not all lie exactly in a straight line, but somewhat as shown in Fig. 5, which gives values of $\frac{a}{n^m}$ for the 6/8 pitch teeth, and so it was considered best to use five points and draw an average line through them instead of drawing a line through just two determined points.

It was found that instead of the function being $\frac{a}{n}$ it was $\frac{a}{n^m}$ for stub tooth gears with the slope of the line, *i. e.*, the value of m, lying between 0.72 and 0.93. Values of a and m are given in Table II.

The values of y in Table III were then obtained by simply subtracting the value of $\frac{a}{n^m}$ obtained by means of the proper chart from y_r. If this method of plotting had not been used, it would have been necessary to lay out gears with from 12 to 200 teeth and measure x on each drawing, a task which would have taken five or six times as long to do.

Conclusions

One of the interesting facts that came out in this investigation was that the function $\frac{a}{n}$ as given by Lewis does not apply to stub tooth gears, and that a function of this nature to be correct should have an exponent other than unity in the denominator. In view of this discovery, it was thought strange that for standard teeth this exponent should be exactly unity and the function be $\frac{a}{n}$, or as Lewis gives it for

20 degree involute teeth $\frac{0.912}{n}$. Consequently Lewis' values of $\frac{a}{n}$, derived from his values of y, were plotted and it was found that the function really is $\frac{0.54}{n^{0.79}}$; but as the function $\frac{0.912}{n}$ is so much simpler to calculate, and is correct within 5 per cent, one might be justified in using it.

Owing to the varying ratio of the addendum to the circular pitch in the Fellows system, the values of y are different for

each pitch, but in the Nuttall system this ratio is constant, y being the same for all pitches. The values of y in Table III indicate that stub tooth pinions with less than 25 teeth are about 25 per cent stronger than the standard 20 degree involute and 40 per cent stronger than the standard 14½ degree involute. For larger gears the difference is in favor of the stub tooth but is not quite so marked.

A table of the values of y for the Fellows stub tooth gears appeared in MACHINERY for October, 1910, computed by Mr. M. Terry. They were derived from Lewis' values for the 20 degree involute tooth by multiplying them by the ratio of the addendum of the standard gear to that of the stub tooth gear. His assumptions, which at first glance seem to be fairly reasonable, are altogether unwarranted when the original method of finding the weakest section of the tooth and computing y is considered. Mr. Terry's values are entirely too high for every gear except the 12-tooth pinions, the values for the larger gears being as much as 10 per cent to 15 per cent too large. The chance for error in determining the distance x would seem to be considerable, since the fillet must be generated by rolling the pitch circles of two gears together, and the point of tangency of the parabola determined by a somewhat approximate method; but as a matter of fact, when two or more lay-outs were made of the some tooth, the values checked very closely.

DIAMETER INDICATOR STOP FOR TURRET LATHES

The usual practice followed in producing duplicate formed work in a turret lathe is to control the movement of the cross-slide by a stop and thus hold the work to the required diameter. An experienced operator with an ordinary cross-slide stop can hold the work to within 0.0005 inch plus or minus limits on the diameter, but when an inexperienced operator is

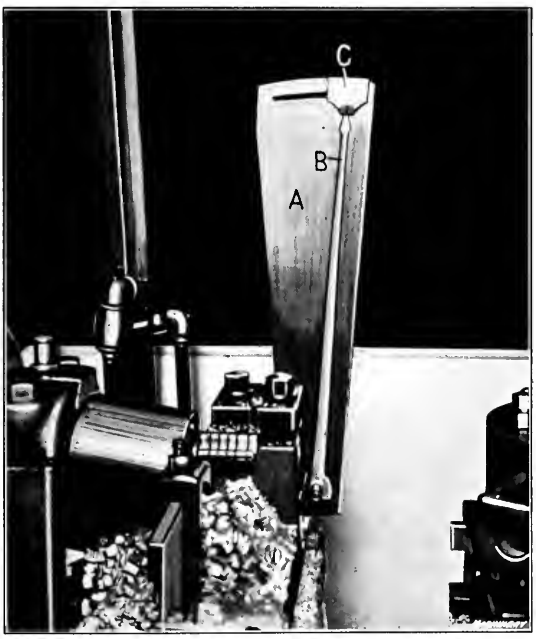

Fig. 1. Diameter Indicator Stop for Turret Lathes

put to work on a turret lathe, these limits are rather close. It takes some time for the inexperienced operator to get just the right feel on the screw of the slide.

In order to eliminate defective work, the Mail-om-eter Co., Detroit, Mich., has worked out an ingenious device which has been applied to all its turret lathes. The device shown in Figs. 1 and 2 comprises a steel plate A which is fastened by cap-screws to the cross-slide and consequently moves with it. This plate carries an indicator needle B and an adjustable datum plate C, the latter being held in place by a thumb-screw shown in Fig. 2. The lower end of the indicator needle B, which is bent at right angles, passes through the plate A and is beveled to an angle of about forty-five degrees in a vertical plane. Working against this vertical beveled face of the indicator needle is a fulcrumed lever D mounted on a bracket fastened to the plate. The lever is kept in contact with the tapered end of the indicator needle by a coil spring E and is operated by an adjustable stop F, which is held in a bracket fastened to the face of the cross-slide carriage.

When in operation the forming tool is advanced toward the work and fed in to the correct depth, the lever D is brought

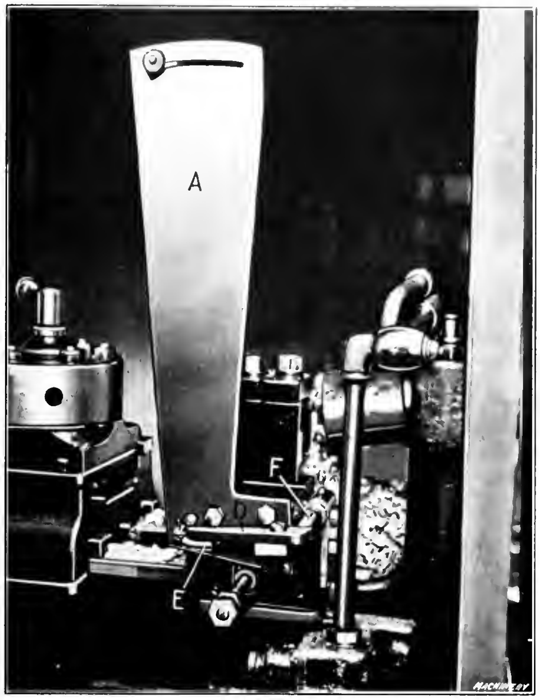

Fig. 2. Rear View of Diameter Indicator Stop showing how it is operated

in contact with the stop F, transmitting a movement to the needle B which moves across the face of the plate indicating when the correct diameter is reached. The movement of the indicator is worked out on a ratio of about 10 to 1, and as a rule where extremely accurate work is required (no limit of variation being allowed) only one line is provided on the adjustable datum plate.

The machine is set up for any particular job by the foreman of the department and then all the operator has to do is to bring the cross-slide forward until the indicator points to the mark indicating the correct diameter. With this arrangement it is easily possible for an inexperienced operator to hold the work within limits of 0.0005 inch, plus or minus, and without any difficulty at all, keep within a variation of 0.001 inch. As soon as the tool becomes dull, which would mean that the work would be made larger in diameter, this condition is easily noted by the finish left on the work. The tool is then taken out, sharpened and the indicator reset. While it would appear that the machine could not be operated as quickly with the indicator needle as with the ordinary cross-slide stop, this is not the fact in actual practice, especially where accurate work is demanded. When nearing the correct diameter, with the ordinary cross-slide stop the operator has to cut slowly so as not to put any unnecessary strain on the slide; while with the indicator stop the slide can be brought forward at an even rate until the needle points to the predetermined point. It is therefore evident that as far as rapidity of operation is concerned, this device does not retard production. D. T. H.

* * *

As a general rule, it seems that there is too much architecture and too little utility about many of our public buildings, and too much utility and too little architecture about most of our factories.

ETHICS OF CONTRIBUTING TO THE TECHNICAL PRESS

SOME OPINIONS OF READERS ON THE RELATIONS OF EMPLOYERS AND EMPLOYES REGARDING PUBLICITY

The article in the November number on "Ethics of Contributing to the Technical Press" brought out several interesting contributions. The opinions of the different writers may be summarized as follows

An employe is not justified in publishing patentable ideas, but it is not wrong to describe general manufacturing methods - publicity would show progressiveness of firm. J. L.

Before making public manufacturing methods, an employe should have an agreement with his employer, provided the methods are special and only used in that particular plant. Workmen should not be barred from describing general methods. Other things being equal, the man who can express his ideas in writing is more valuable to his employer. W. R. H.

When an employe designs improved apparatus for an employer, or offers a valuable suggestion, he should ask permission to publish, even though no compensation has been received. If the suggestion or improvement is ignored by firm, employe has moral right to make public. W. C. B.

The right of an employe to describe manufacturing methods in the technical press depends largely upon the value of the methods. Nothing should be published that would be objectionable to employer. The employe should be competent to exercise his own judgment as to value of methods. N. G. N.

This is not so much a question of ethics as of the attitude of executives. If the article deals with developments of firm, the attitude of those in charge should be ascertained; if it does not, the employer has no moral right to interfere. The liberal-minded employer knows that the subordinate who writes articles is not only interested in his work, but is training himself to think clearly and express his ideas accurately. J. S. M.

The article by Mr. Brickner in the November number of MACHINERY is no doubt interesting to many who have contributed to the technical press. Of course, an employe who worked on certain machinery where patentable ideas were being developed, would not be justified in giving out any information. He would be expected, as a part of his work, to keep in confidence these improvements. As far as general work is concerned, it does not seem that an employe would be doing wrong to write articles describing methods of manufacture and improved tools used. The value to the employer of the methods, tools, etc., would not be impaired by publication, but publicity would rather reflect the efficiency and progressiveness of the firm. The employer may say that the articles would give his competitors an opportunity to apply the ideas developed with his money to their own work. This argument, however, would not hold good, because workmen going from shop to shop to work would prevent methods from being kept private. A certain class of work for which an employer may have spent considerable time and money in designing up-to-date tools, may be handled in another shop in different ways with just as efficient results as to accuracy and rapid production. The question of an employe withholding ideas from an employer would seem to depend upon the nature of the improvements. If they were of a different nature than his regular work, the ideas would, without doubt, be his own property. If his improvements applied directly to the machinery on which he worked, it would seem that his efforts were due largely to the experience and study of his special work. In this case, it would appear that the just thing to do would be to offer his ideas to his employer who should recognize his loyalty and ability in a substantial way. If an employer did not do this, his employes would have no incentive for developing anything of value.

Camden, N. J. JOHN LEAFSTROM

In his communication on the "Ethics of Contributing to the Technical Press," in the November number, Mr. A. J. Brickner is undoubtedly right in assuming that many writers are frequently in doubt as to just what they are privileged to write for publication.

The question, as Mr. Brickner says, is a moral rather than a legal one, but this fact in itself is of slight importance, for an employer has it in his power to make it exceedingly unpleasant, to say the least, for the employe who acts in opposition to his rules or wishes, without the assistance of the law.

It is safe to assume that no contributor cares to antagonize his employer in any way. This being the case, it would seem best in all instances for the employe, if he does not thoroughly understand his employer's views in the matter, to "sound" him and come to some mutually satisfactory agreement, before undertaking to make public methods or processes of manufacture peculiar to his employer's establishment. It makes no difference by whom the methods or processes were devised; if they are a part of the manufacturing system of this particular employer, they belong to him and he alone has the right to publish them or to permit them to be published.

If the employe designs a tool, a fixture, die, or a special machine to perform a certain operation on his employer's product, any new idea incorporated in the tool is universally considered the employer's. As a rule, a workman is asked to sign an agreement to that effect before he is employed, in many manufacturing establishments. This does not mean that an employe is not privileged to write for publication what he pleases when the subject has no exclusive relation to his employer's plant or product. He would be a narrow-minded manufacturer, indeed, who would, on general principles, deny an employe the right to contribute to the technical press. The workman who is not only inventive and original but who can express his ideas in writing, is a more valuable man, other things being equal, than the man who cannot, and writing for the technical press is of great value in helping a man to express his thoughts clearly.

If an employe has original ideas or knows of methods in use in more than one establishment which have not been described, he has as much right to make them public as he would have to publish his personal views in a local newspaper. In other words, if the idea is wholly his, or belongs to no one in particular, there can be no question at all in the matter, either legal or moral. If the employe, in the course of his work, applies some device or idea of his own to a machine or process of his employer's and if the same device or idea could be applied generally to similar machines or processes and does not have any particular relation to the employer's plant, then the employe might consider himself free to write on the subject. Still, as previously remarked, if there is the slightest doubt on the contributor's part as to his employer's attitude on the subject of contributing, the wise course naturally would be to settle the doubt before it is too late.

Rochester, N. Y. W. R. HUMELBAUGH

When an employe makes a suggestion, or designs an improved apparatus for a manufacturer, even though no material compensation has been received by the person making the suggestion or design, it is advisable to ask permission to submit it for publication. If no compensation has been given, permission to publish would probably be granted, but if a firm accepts a suggestion or design and pays something for it, then the one making the suggestion has no right to submit it for publication or even ask such a privilege, as it is then the firm's property. Again, suppose John Henry makes a suggestion and it is not accepted or is totally ignored (this has been done by the officials of some concerns), although John knows it to be a big improvement over the method in use; then he has a moral right to publish the information and Blank & Co. have no "kick."

The writer would like to narrate an incident which occurred in a place where he was once employed. John Henry was a young draftsman, who got the writing "bee in his bonnet" and started out to write up the whole equipment of the shop. Early in the game one of his articles came under the superintendent's notice, whereupon John received a summons to his sanctum, where he received a lecture and advice. On another occasion, John wrote an article by permission of the superintendent, which came under the president's notice. The article was of an unimportant nature and John told the head of the firm that he had permission to write it and wanted to know what harm had been done. The president remarked that he did not believe in the "education of the masses." This gives an idea of the sentiment of at least one firm in regard to writing for the technical press. As a rule, the officials of concerns do not like to have anything pertaining to the equipment published, even though it is generally known.

New Britain, Conn. W. C. Betz

Concerning A. J. Brickner's queries in the November number, the writer has made it a point to contribute nothing that, in his opinion, an employer might find objectionable or harmful. Permission of my superiors to make "kinks" public is rarely requested, on the grounds that in my regular everyday work I am given credit for being able to exercise judgment in the company's interests and, therefore, am certainly competent to use that same judgment in matters that are less difficult to decide.

Much depends upon the value of the method to the employer. For example, my company makes use of a process of machining that no one else, to my knowledge, uses. The method is quicker, more economical, and more accurate than the usual methods, yet the company is not keeping it in strict secrecy. We are simply given to understand that the method is "new" and that it is one of the reasons why the company is able to maintain its present good scale of wages. Would I write a description of this process for the technical press? No, I did not have a hand in its development. We give our chief engineer credit for the method, and I feel that if anyone has a right to make it public he has. As the company is honest and square, the employes should be just as honest and square in return. The company and the chief engineer would have good grounds for objecting to the exploitation of this process, although, in my opinion, competitors would be rather slow to adopt it because of the expense that would necessarily be entailed in changing from old to new methods.

An associate once described a manufacturing method in detail, giving cost figures, test data, and every point of importance. He had first obtained his employer's permission. A competitor read the article, was naturally much interested, and managed to secure an interview with my friend. He seemed much surprised that his competitor would consent to the publication of matter of such seemingly vital importance. As it happened, however, the manufacturing costs of the two companies were about the same, so the only thing they had to fear was the small competitor who might be able to undersell the larger concerns by getting a line on costs through such publicity. The second large competitor sent a verbal message through my associate to the first competitor, to the effect that he "admired his nerve," but believed it better policy to keep certain things under cover, especially costs. Both of these companies are still the largest in their line of manufacture.

Another friend recently described an improved method for tabulating and plotting data, and in the article he gave credit to no one but himself, incidentally mentioning the fact that a large corporation was using the system with success. Because he did not ask permission and give his superiors due credit, he was rather severely censured, but it was admitted that the publication of the article would do the company no harm and perhaps would be beneficial to other companies that might be looking for more efficient tabulating and plotting methods. My friend still insists that he had a moral right to do as he did. As he expressed it, "——— is sore because I beat him to it. He would have written it up himself had he thought of it first." He assumed all credit because he believed the article would thus receive better editorial attention.

An employer certainly has a right to refuse publicity of his methods. The government recognizes the right of privacy in taking census data, in assessing, and in other ways, but if an employe chooses to make public what he knows about his employer's business there is usually nothing to stop him but his own conscience or his own judgment. So, according to my way of thinking, the whole matter hinges on personalities and conditions. No fixed rule can be made.

N. G. Near

The articles on "System Carried to Extremes" and "The Ethics of Contributing to the Technical Press" in Machinery for November, each seem to call for some comment. While these subjects appear to be widely separated they are often really correlative, because much which is wrong in the attitude of many concerns on both subjects is traceable to the same causes, *viz.*, lack of cooperation, hence lack of understanding or *vice versa*, and incompetence. Lack of proper understanding of motives, aims and purposes is probably responsible for more that is deplorable than any other single cause.

It is the plain duty of any department head to cooperate with the other department heads and rectify anything wrong in mutual relations which may come to his notice. The chief engineer who permits a rule that there should be at least three views on all drawings, no matter how simple the part, is certainly not cooperating with the one who established the rule. If he was, there would be no such rule. The person who established the rule had a lack of understanding as to what constitutes a good and sufficient drawing. In this respect at least he appears to have been incompetent and to have failed to ask the advice of someone who was.

A man once dreamed that he was pursued by the "Evil One" and was making a hasty flight across fields. He impatiently kicked a jack-rabbit to one side saying, "Get out of my way and let someone run who can." Systematizers and others establishing rules often have such dreams in regard to their own ability, it would appear, and, being over self-confident, fail to cooperate.

The episode of the time cards also indicates a lack of understanding. Two of the main objects of such cards are to secure fairly accurate costs and to show up things which are abnormal and therefore require attention. In the case cited, a draftsman charged time spent in studying up improvements on a small detail to another larger job because he feared the time actually spent would be criticised. He thus defeated the purposes for which the cards were intended. Now if the results obtained were worth the time expended he should have charged all the time to the job. If the correct record on the cards was the means of starting an investigation he could have frankly stated his case, which, being creditable, should do him no harm.

The foregoing is based upon the idea that the right should prevail, as it does under fair-minded, honest and competent executives. Of course, we all know that there is the other variety and most of us have, at times, been hampered and annoyed by their short-sighted tactics, until it sometimes seems that too much honesty is not always the best policy, especially if it causes things to move with more friction.

It would seem from M. T.'s story that the troubles observed were mainly due to foolish rules, probably established by incompetents, or what amounts to about the same thing, good rules foolishly interpreted or too inflexibly applied. A little cooperation between fair-minded competent men should speedily adjust such matters. In the absence of such cooperation the best attitude toward such rules is often to believe in the old saw, "rules are made but to be broken," and when it seems justifiable consider yourself at liberty to break them with impunity. The establishing of rules is not the office or aim of system, and the establishing of a rule fixing a limit to salaries for any class of work (which is mentioned by M. T.) is not only in direct opposition to the ideas upon which most modern systems are based, but seems both foolish and uncalled for, because it serves no good purpose and does much

to discourage the employes. What is the use of establishing such a rule when it may be found both expedient and highly desirable to break it? To be consistent, if you limit the earning power of your employes you should also limit your own earning power and say: This concern will not earn over ten per cent of the capital invested per annum. Anything over this amount earned will be returned, pro rata, to the customers. If you consider an employe as a mere machine, do you imagine that the cost of developing this machine to its present state of perfection when taken as capital invested can be multiplied by a percentage of profit and by adding the proper cost of maintenance thus arrive at a just limit to salaries? If you do you have neglected to take into account that the probable duration of the mechanism has, in this case, a value to the machine itself. Even if you tried to be fair in this particular your ideas of proper maintenance and those of the machine are very likely to vary widely. Modern system may attempt to fix the rate for the performance of a certain amount of work but it should not attempt to limit the earning power of the individual if he gives value received in what he produces, whereas the fixing of a limit to salaries is an attempt in this direction.

Now regarding the ethics of contributing to the technical press, this is also a matter run largely by rules and in its practical workings is often not so much a real matter of ethics as of the attitude of the officers of the concern, their personality and the rules they may have established. The main difference between such rules and the variety mentioned in the foregoing, is that a rule regarding the publishing of matter is an arbitrary statement of the concern's policy in this respect and the breaking of such a rule would probably be classed as insubordination—an offense calling for reprimand or discharge. When no such rule exists the only logical thing to do is to ascertain the attitude of those in charge, if the proposed article deals with their work. If it does not, and is not prepared on the employer's time, the writer fails to see wherein the employer is concerned. There is, however, a class of executives who seem to think that if a man is on a salary basis instead of an hourly rating, his entire time belongs to the company. This class looks with a jealous eye upon any activities other than those from which they can see a direct benefit to the concern. The writer does not believe an employer has any moral right to assume this attitude unless he clearly states it before engaging the employe, and even then, unless the emoluments are so exceptional as to justify such an attitude, its ethical aspect is cloudy because it is an unnatural restriction upon the personal liberty of the employe.

The attitude of employers on the subject presents many inconsistencies, personality entering as a dominant factor in many cases. Some cases within the writer's experience are given in the following:

Mr. A is a public spirited citizen of the type who says he can get all the office boys he wants at three dollars a week but that he knows a boy cannot live on three per, so he pays him five. A's chief engineer, C, is the sort who raises a man's salary before asking for it. Says he does not believe it should be necessary for a man to use "a better position proffered" as a club to secure an advance.

Now C promised B a photo-print of a cut from A's catalogue, to illustrate an article B proposed publishing. A would not permit this, saying that it was the general policy of the company to have nothing published relative to their work excepting what was used in connection with their advertising literature. Whether A feared the use of the picture in question would rob his publicity experts of some of their fire, or whether he doubted the ability of B to write a creditable article is unknown, but some weeks later halftones of the device appeared in the dailies in connection with a discussion of labor troubles. B published his article minus the desired illustration, as he was bound to do under the circumstances, while the reporter for the daily, not being in A's employ, simply used his camera. Both A and C were liberal minded men, yet the ruling seemed narrow to B.

Another example: Concern D maintains an expensive bureau of safety, employs two physicians (one always on the job), equips wash rooms, furnishes storm coats for outside work, etc., "for the good of the service," but the concern is so secretive about its business that any information whatever about the equipment is absolutely refused. Even a twist drill salesman could not find out approximately how many drills they used a year as a basis upon which to quote prices. An employe publishing an article dealing with their work would undoubtedly be discharged. With this concern one need not be in doubt as to their attitude, but whether they gain or lose by it is problematical.

Another sidelight on the subject is illustrated by the following: Draftsman E had done considerable work on a special machine for chief engineer F. In the course of developing the designs, E learned a number of interesting things about the practical application of theory to design which would have made a good article. E proposed writing such an article but F said he, himself, wished to read a paper on the subject before a society of engineers, after which he had no objection to E's proposed handling of the subject. However, F never prepared the paper, E finally lost interest in the matter and the readers of MACHINERY lost a good article. Frequently the officers of a concern have no objection to the proper variety of articles, but the man who could and would prepare them is prevented by someone a little higher up, who thinks he himself should have the glory, but who actually does nothing; a sort of bow-wow-in-the-manger's attitude whether so intended or not.

Sometimes the official who passes upon the desirability of publishing articles mistrusts the ability of the one proposing to prepare it. Therefore, for an initial attempt it is probably best to prepare the article before asking permission, then submit it to your immediate superior with a request for his opinion. By this procedure you can demonstrate your ability and probably secure his cooperation. The liberal-minded man is glad to know that his subordinates are taking an intelligent interest in things, and he knows that the writing of articles is a mighty good training toward clear thinking and concise expression, as well as a means of developing correct ideas instead of erroneous ones; and, knowing that the old days of the trade secret bunco-game are gone forever, he generally lends a helping hand instead of placing obstacles in the way of the aspiring technical writer.

Some concerns are as hungry for free advertising as an opera star and, if permitted to do so, would monopolize much space in the technical journals by laudatory descriptions of their methods and product. Now properly managed periodicals do not cater to this spirit. They are looking for articles of merit only, which, in their judgment, will interest and benefit their readers. If an article incidentally reflects credit upon a concern or an individual, they are fair minded and desirous that all credit should be given where due, and occasionally make favorable editorial comment; but it is on a basis of what appeals to them as being meritorious. In view of this, it is desirous in the preparation of articles to eliminate as much as possible, mention of the men or concern where the work is done and stick closely to the development of the subject in an impersonal manner, which lessens the chance of giving offense to anyone's ideas on the ethics of the matter.

If an article is properly prepared, does not deal in personalities, violates no confidences, does not hand out "back door information," and presents matter worth while in a readable form, the author's own judgment as to the ethics involved in publishing it should be as good as anyones, but he should remember that the attitude of his superiors is very likely to be an arbitrarily assumed one instead of being based upon ethical considerations.

Philadelphia, Pa. JOHN S. MYERS

* * *

A furnace lining which will resist very high heat may be made from 40 parts, by weight, of fine asbestos, and 60 parts of water glass. The asbestos and water glass are mixed with enough water to make the whole pasty so that it can be worked. This mixture, says the *Brass World*, is useful for patching or plugging cracks, as it does not crumble as readily as other compositions made from fire-clay.

LUBRICATING SYSTEMS FOR CUTTING TOOLS—1

VARIOUS METHODS OF SUPPLYING AND DISTRIBUTING LUBRICANT TO CUTTING TOOLS

BY JOSEPH G. HORNER*

The lubrication of cutting tools, like many other details of machine tool practice, has made great advances during recent years. Systems and methods that were at one period considered special and adapted only to a certain class of machine, are now applied commonly to various other types. New developments have also had their effect in increasing the demand for better methods of lubrication. There is considerable variation in the methods of lubricating tools, not only on different classes of machines, but on machines of the same type, the reason being two-fold: Either the work does not require the application of a lubricant, or the amount and manner of supplying the lubricant varies, ranging from a slight drip to a profuse flooding under pressure; this depends upon the nature and extent of the cut. For example, a light milling operation with a single cutter may need no more than a small supply from a drip-can, whereas, on the same machine, the operation of a gang of cutters for deep roughing cuts will require a large stream to flood the work thoroughly and wash the chips away. Some machine tools, such as brass-finishers' machines of many types, cylinder-boring machines, some lathes for machining castings only, and some

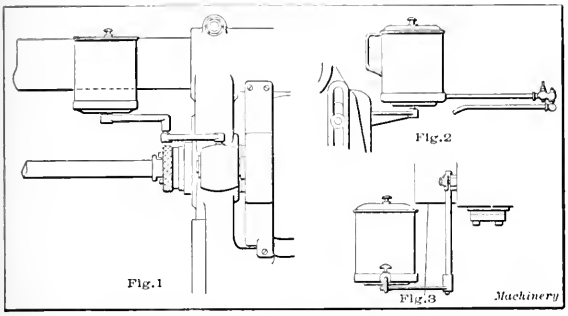

Fig. 1. Drip-can mounted on Pivoted Bracket. Fig. 2. Drip-can with Jointed Delivery Pipe. Fig. 3. Drip-can arranged for Vertical Adjustment

of the reciprocating types of machines for brass or cast iron only, have no arrangements for lubrication of the tools. In many, a compromise is made so that the addition of a lubricating system is easily effected. In order to avoid a multiplicity of designs, some firms build certain of their machines with the channels, trays, etc., essential to the flooded system, and omit or supply the pump and piping as wanted.

The Amount of Lubricant

There are three principal reasons for the adoption of a lubricating system: One is to cool the tool or cutter, another

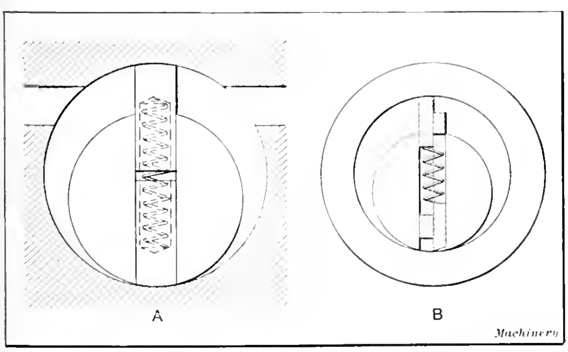

Fig. 4. Two Types of Wing Pumps for Cutting Lubricant

to impart a smooth surface to the work, the third to wash away the chips. The first-named is frequently the only reason for the application of a lubricant. For instance, in many operations on brass and other alloys the surfaces would be tooled just as smoothly without the lubricant, but the tools would heat up, and the work would also become too warm if the operation were long-continued; hence the accuracy would be impaired, while the cutting edges would not endure for a sufficient length of time. On the other hand, drilling, particularly in deep holes, sometimes cannot be done at all unless the lubricant is fed with sufficient force to eject the chips as fast as they form. A quantity much in excess of the requirements for cooling alone is therefore required.

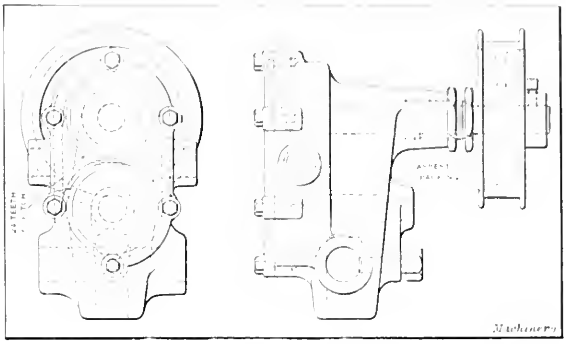

Fig. 5. Rotary Pump of Gear Type

When a metal or alloy cannot be tooled with a smooth finish unless lubricant is employed, it may not be necessary to use a large quantity, so long as the edges of the tool and the portion of the work adjacent thereto are covered. The necessity for an increased supply soon arises, however, as speeds and feeds are increased; otherwise the film of lubricant will be too attenuated to spread as fast as the metal is cut into, and the result will be that intervals of dry cutting will occur, and the heat will evaporate the film to such an extent that it becomes useless. A further development is reached when the heat, caused by cutting, raises the temperature of the cooling medium to such an extent that the latter ceases to act effectually. This happens when the total amount of

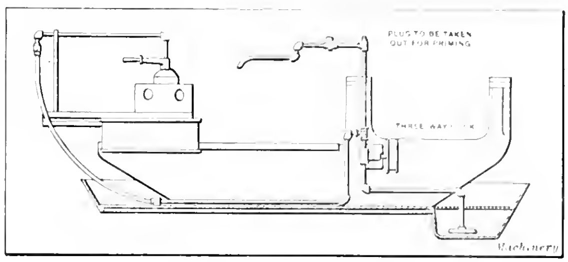

Fig. 6. Lubricating Arrangement of Bardons & Oliver Turret Lathe

liquid is not large enough to provide for cooling in the intervals between successive applications to the cutting tool. The remedy is a much larger amount of liquid, and preferably a return tray of ample surface area, so that the maximum amount of area shall be exposed to the air. In extreme instances, two tanks may be utilized, each holding a large body of lubricant, which are drawn from alternately, thus affording intervals for each to cool somewhat.

The essentials involved in any system of lubrication are the supply, collection and separation from cuttings, and method of return. The first two requirements include many devices and modifications, ranging from the time-honored drip-can to elaborate pump and piping arrangements, and from a simple can hung beneath a table to a complete series of rims, chutes, troughs, pipes and strainers. The distinction between the two extremes is due to the quantity of lubricant required, since a simple system that is capable of feeding and collecting a few pints of liquid used at a slow rate is totally inadequate for the flooding method; neither is it automatic in action but necessitates frequent attention.

The amount and nature of the chips also materially affects the mode of collection and one method is not suitable for

* Address: 45 Sydney Bldgs., Bath, England.

all cases. Large curling chips, and fine swarf (such as from a hacksaw) are very different as regards the separation of the lubricant from them, the swarf being much more difficult to separate. The bulk of the chips is also important in considering the method of collection and separation. If they occur in small quantities, very little extra accommodation beyond that necessitated by the liquid is wanted, but if there is a large bulk of chips to be received, the sizes of pans and trays must be varied accordingly and supplementary boxes or trays on wheels are essential for frequent removal.

Drip-can Method of Supplying Lubricant

Various methods of supply and collection are illustrated in connection with this article by drawings of various machines, but these are only a fraction of the immense number of modifications which exist in practice. The drip-can is the oldest form of continuous supply and is still employed extensively for operations where its limited feed is suitable and sufficient. It is often included on machines which have a pump outfit as well, for use when the ample flow provided by a pump is unnecessary, the can being preferred when the class of work for which it is suited has to be done for a considerable time. The usual design is that of a cylindrical vessel, preferably with a cover, and an inside strainer of gauze (unless the liquid is strained previously). The can body is made of either sheet metal or cast iron. If the capacity of a cylindrical can is insufficient, a rectangular tank is sometimes used instead, as on some shafting lathes with multiple rests. Variations occur in the manner of holding the can, and the position and number of outlets. As a can, in most cases, is placed quite close to the point of application of the liquid, a short pipe is all that is necessary; this may be single- or double-jointed, to bring the spout to the location desired. The can is either placed upon a flanged tray, supported upon a pillar fixed in any convenient position, or it is held either by a band, or stem and wing-nut on a slotted arm beneath, to permit of radial or vertical adjustment. The vertical adjustment is not of so much importance because the lubricant can be directed to fall on the work, but considerable adjustment in a horizontal direction is desirable, especially in machines where the cutters or tools occupy varied positions. Figs. 1, 2 and 3 illustrate common methods of adjustment. Fig. 1 shows pivoted arms, on the outer one of which the can is held; Fig. 2, a fixed bracket with jointed pipe, which gives much the same result; and Fig. 3, a suspension rod. The latter is employed on vertical milling machines, etc., to permit radial and vertical adjustments.

When the construction of a machine will not permit placing a can close to the tool, use is often made of flexible tubing of rubber or metal for connecting the can and spout.

Pumps for Cutting-tool Lubricating Systems

The drip-can ceases to meet requirements when the quantity of lubricant that must be delivered exhausts the contents of the can in a few moments. A pump which is automatic and under the control of the attendant, is then the only method of providing a sufficient supply. Four types of pumps are in use: Centrifugal, plunger, wing, and geared, the latter being in the majority. The centrifugal pump is not used to any great extent but is sometimes preferable when there is grit in the lubricant. The plunger pump is employed only to a limited extent, although in the early days it was probably the only kind used for supplying drills and boring tools for deep-hole work in lathes. Where a large supply is desired or where the parts of the machine run at such a slow speed that there is no opportunity for drawing a rotary pump at a proper speed, the plunger type is still used, the most notable example being that of certain bolt-threading machines.

The construction of the wing type of pump comprises a casing with a chamber bored eccentrically (see Fig. 4) with relation to the spindle bearing. The enlarged head of the spindle is slotted to receive a pair of flat plates or wings, pressed apart by a brass spring or springs, so that as the spindle rotates, the ends of the plates maintain contact all around inside the chamber, thus drawing the liquid in and discharging it in one direction or the other according to the way in which the spindle rotates. These pumps will lift the lubricant a slight distance, but it is better to submerge them to avoid priming. A modification of the ordinary method of making the wings as illustrated at *A*, is shown at *B*. The latter type is manufactured by Messrs. C. Wicksteed & Co., Ltd., of Kettering (England) for use with their hacksawing machines. The wings, instead of meeting at the center, are thinner and pass right through the spindle head. Slots are cut in each section, as shown, so that a single spring presses the halves apart equally. The wings are tapered at the ends so that when a full discharge is not required, the pressure of the liquid will press the wings back. This renders the use of a relief or overflow valve unnecessary.

The geared pump, a type employed to a far greater extent than any other, is of simpler construction, the essential parts being a pair of spur gears revolving inside a closely

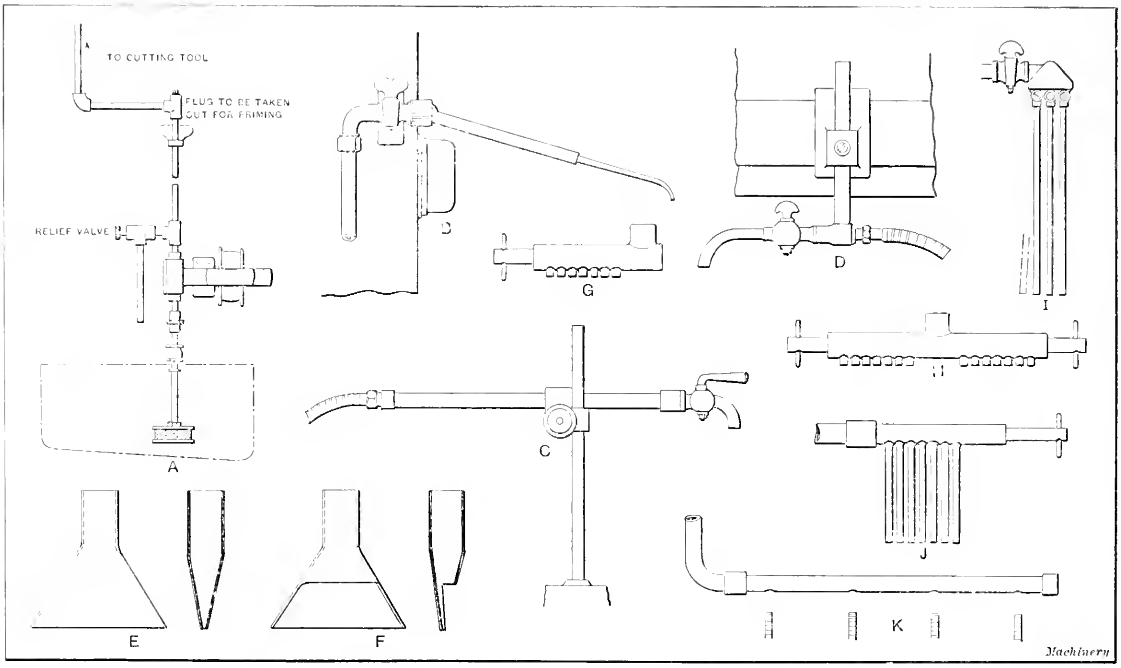

Fig. 7. Various Arrangements of Piping and Nozzles for distributing Lubricant to Cutting Tools

fitting case and drawing the liquid around in the tooth spaces. This type has no delicate parts to get out of order, and if properly built, enables high pressures—up to 1000 pounds per square inch—to be obtained. These high pressures are, of course, not necessary for feeding to external cutting tools, but for deep-hole drilling, in which great force is necessary to remove the chips, they are utilized. The low pressure pumps work to 100 pounds per square inch or less. For the average machine, it is merely necessary to raise the liquid and overcome the friction in the pipes and distributor; any surplus pressure is only useful for washing away chips, the need for which varies with the class of operation. Some kinds of chips fall naturally out of the way whereas others tend to clog the work and the cutters. Some materials will stick to the cutters or work if lubricated to a moderate extent, and may require a larger stream and greater pressure to dislodge them. The removal of long curling chips, especially heavy ones, is not facilitated by the force of the stream, unless they are forced out of a hole.

The geared pump, an example of which is seen in Fig. 5, is rated to deliver a certain quantity at a definite number of revolutions per minute, and it may be run at higher or lower speeds if desired, with a varying output. The pump shown is made by Messrs. H. W. Ward & Co., Ltd., of Birmingham, (England). In place of the usual foot, it has holes to slip over a piece of shaft secured to the machine in any convenient location. This permits of setting the pump in three different positions, according to the belt location. The following table gives the capacities of two sizes of Brown & Sharpe geared pumps, with driving pulleys of 3½ inches and 5 inches diameter, respectively:

	Revs. per Min.	Capacity, Quarts per Min.	Suction	Discharge
No. 1	300	4	$\frac{3}{8}$ inch	$\frac{1}{4}$ inch or $\frac{3}{8}$ inch
	500	8		
No. 3	300	20	$\frac{3}{4}$ inch	$\frac{1}{2}$ inch or $\frac{3}{4}$ inch
	500	40		

The lift ranges up to 20 feet, but it is preferable to put the pump as near the level of the tank as it convenient, the exact location depending upon the type of machine and the facilities for attachment to the side of the framing or the edge of the tank or pan. The method of driving depends partly upon the position of the pump and partly upon the designer's ideas. The belt or cord drive is the most common. Spur gearing and chains are also used to a lesser extent, the advantage of these being that there is no bother with slipping belts nor trouble due to the splashing of oil. It is often more convenient to drive the pump by gears or chain from some constant-speed shaft on the machine, than

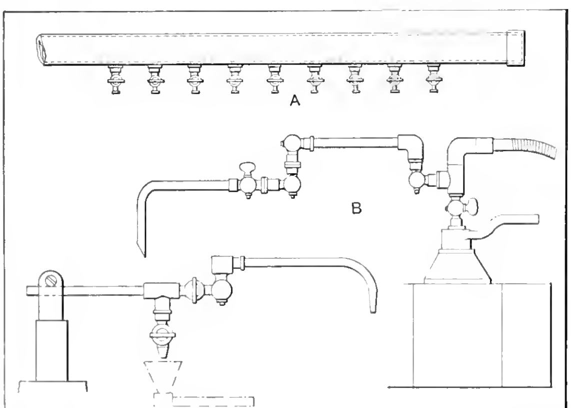

Fig. 8. A. Distributor with Row of Taps. B. Combined Supply Pipe for Interior of Turret and External Tools. C. Supply Pipe feeding into Funnel on Box-tool

by a belt from the countershaft; when a motor drive is installed, the gear or chain method is especially applicable. The pump is thrown out when necessary, by sliding the gears out of mesh or by disengaging a clutch, if a chain is used. Generally, pumps run in one direction, provision being made to drive them from a shaft or countershaft which does not reverse, but when the machine reverses at intervals, as with certain automatic screw machines, the pump is slightly modified to enable it to run in either direction.

The fittings which are directly connected with the pump system include a strainer, which is submerged in the liquid and prevents access of grit or chips, and a relief valve, which is closed by spring pressure but opens when the flow is reduced or stopped at the delivery outlet, allowing the lubricant to run back to the tank through a by-pass. Sometimes a check valve is placed between the pump and the tank, but not invariably. Fig. 6 shows the piping for a Bardons & Oliver turret lathe, including a flexible supply pipe to the turret center for feeding hollow tools, and the diagram A, Fig. 7, shows the piping for a Brown & Sharpe milling machine. These two views represent, in principle, the arrangement of many machines. A pump for each unit is dispensed with in certain cases, as, for example, "batteries" of automatics or of sensitive drills, which are fed from a common supply instead of having a pump for each machine.

Methods of Distribution

The two points which we now have to consider are: (1) The means of distributing the lubricant to the tool or tools;

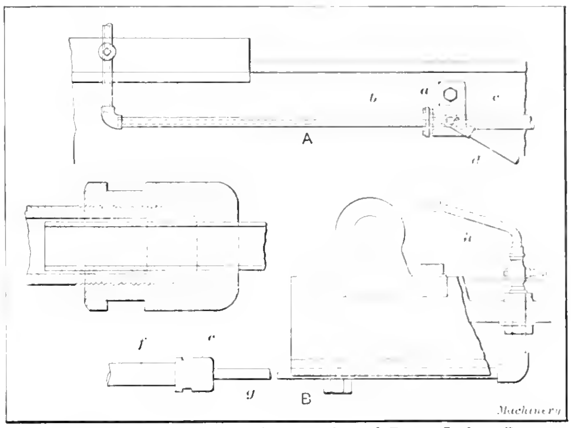

Fig. 9. A. Sliding Pipe and Stuffing-box of Turret Lathe. B. Telescopic Pipe Connection for Carriage of Gear-cutting Machine

and (2) the means for catching the lubricant and returning it to the tank. The methods of distributing and returning the lubricant vary greatly on account of the varying conditions of cutting and different arrangements of tools, slides, machine framings, etc.

In regard to the method of distribution, the choice lies between rigid pipes, flexible pipes, and jointed pipes; between a single outlet, two or more outlets, a perforated distributor, a pipe with a number of taps or pipes leading from it, or an overhead reservoir fitted with outlet pipes. Means may be provided in the case of multiple outlets to shut off any or all of these according to the amount of lubricant desired and its place of delivery. The flow may be allowed to fall from above, or it may be directed precisely to a certain spot by a pipe, or through a hollow tool or spindle, or a spout or chute may catch the lubricant and pour it onto a precise location.

Rigid pipes are chiefly applicable to machines which have no great changes of tools or adjustments of slides, so that a fixed position of the pipes is suitable, but these are the exception, and it is better to have an adjustable pipe, for convenience in moving it out of the way if necessary. The degree of movement depends on the range of possible locations of the cutting tools. Piping with three or four joints is frequently necessary, including horizontal and vertical swivel adjustments. The alternative is the flexible pipe, which however, is likely to be in the way in many instances. A flexible pipe is more useful as a means of connecting rigid or jointed pipes to the supply or drawing-off arrangements.

A single outlet is all that is necessary for most of the single-point cutting tools, for narrow milling cutters, drills, and similar tools, but two or more outlets are required for pairs or gangs of cutters and multiple tools, unless the

alternative of a single wide spout is utilized. The main support of a jointed pipe is placed according to circumstances, sometimes consisting of the supply pipe itself, sometimes of a separate rod to which it is attached, the rod being bolted or screwed in any convenient position. The main pipe or rod must be put where it is not likely to be in the way of large work, jigs or fixtures; in some cases, a portable fitting may be necessary to meet these requirements. An alternative to the gas-bracket type of jointed pipe is one having a ball-joint and telescopic second tube (see *B*, Fig. 7).

A preferable method of securing flexibility is to use a short piece of pipe equipped with a tap, and hold this in a clip against a part of the machine or on a rod, and connect to the pump with flexible tubing. This arrangement is useful when no great range of adjustability is essential and also when considerable horizontal or vertical range is required. In the first case, it obviates the use of a jointed pipe, and in the second it enables adjustments of several feet to be obtained without encumbering the tool with three or four jointed pipes. Typical examples are shown at *C* and *D*, Fig. 7, *C* showing a rigid pipe held by a split clamp to a rod screwed into a machine boss and connected to a flexible tube, and *D* a stem extending from the connection and clamped in a bracket horizontally adjustable along a slide. As the flexible pipe can be carried down at the rear or side of the machine, it need not interfere with the operation of the machine; moreover, if cutting is done without lubricant, the clamps may be released and the piping laid out of the way altogether. Arbor ful for gang mills on an arbor which is steadied by a central support) and *J* has extension tubes hanging down to reach in between tools which interfere during part of their stroke, with a directly vertical flow. This type of distributor is also used where the air from a belt or other rapidly moving part would disturb the vertical stream of lubricant and blow it out of its proper path. At *I* the tubes are pivoted to swivel to one side and direct the liquid to a particular place. A shut-off may or may not be provided for each tube.

The standard distributing pipes occasionally fail to meet special conditions, and it becomes necessary to cut a piece of tubing and drill it specially, as at *K*, where four slitting saws are set rather far apart and a pipe is drilled with holes to suit. If much of this class of work is likely to be done, it may be preferable to drill a larger number of holes in the pipe and plug up those not wanted. Long distributing pipes are sometimes provided with holes drilled fairly close together and having spring bands which are partly rotated to block those holes which are not required. Another special arrangement for some classes of work where a guard is fitted over the cutters is to use the hollow top of the guard for conducting the lubricant directly upon the cutters. Box-tools are also sometimes made with hollow frames, with an outlet close to the cutters, giving a broad stream at the best possible location. This is a mode of distribution that must be designed to suit the tools, and is not of general application.

An alternative to the practice of stopping off or plugging up unused holes in a distributing pipe, is to provide

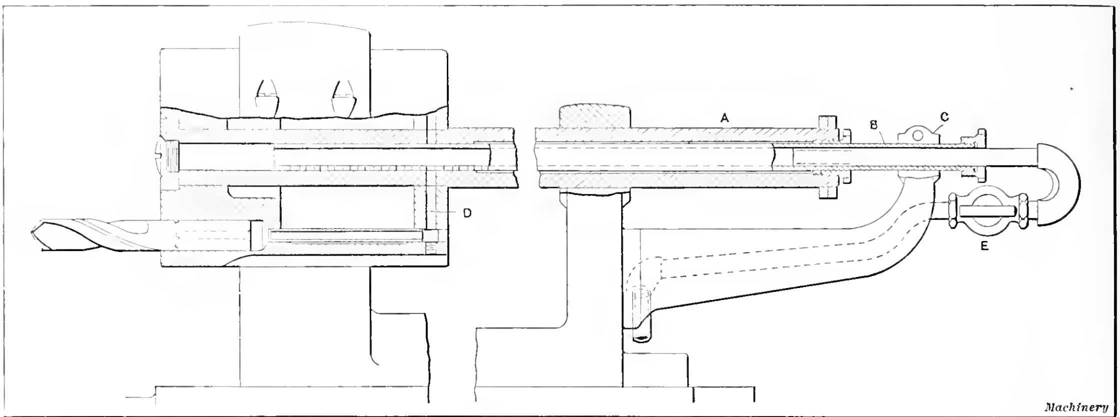

Fig. 10. Sectional View showing Method of supplying Oil to Turret of Cleveland Automatic

supports or overhanging arms on the machine are often used for attaching pipe clamps.

A cutter of considerable width, or a hob, must have an ample supply of lubricant along its entire length, if lubrication is to be effective and even, and cooling uniform. A good device for hobs and cutters for heavy duty is the fan nozzle. This is set vertically, or at an angle, just above the cutter, and delivers a broad copious stream. The closed type *E*, Fig. 7, is employed in the case of slab millers having the cross-slide face set at an angle, the nozzle being pointed inward or toward the back of the machine. The partly open kind *F*, is suitable for horizontal delivery or delivery at a slight angle. These nozzles are attached to the delivery pipe, but in a few instances the nozzle is used separately, being clamped to a part of the machine or to the tool itself and fed by a flexible pipe brought over it, thus affording a wide stream without modifying the outlet for ordinary operations.

Adjustment for width of flow is provided for in some nozzles, the opening being blocked to any desired extent by sliding a plug along to suit the width of the cutter. When there is no adjustment to the supply pipe to accommodate the varying lateral positions of cutters on their arbors, the nozzles may be pointed to right or left, as desired, by fitting it with a swivel joint. Perforated distributing pipes which give a flow of lubricant to suit the length of work or cutter are shown at *G*, *H* and *J*, Fig. 7. They have sliding plugs to shut off some of the holes, thus reducing the supply. Pipe *G* is an ordinary form, *H* is double-ended (a type use- regular taps for turning off the lubricant. This method is common to slab or "plano-millers" on which a pipe of ample capacity is secured to the cross-rail and has a number of taps screwed in at close intervals, as shown at *A*, Fig. 8. If the pipe runs along at the back of a machine or below a cross-rail, as in many multiple-spindle drilling machines, pipes connected to each tap will be essential in order to bring the oil to the drills, a swivel-joint permitting each pipe to be placed in the position desired.

The case of two or more pipes having outlets separated more widely than in the distributors referred to, is often met with, such as when two tools or cutters are working on different parts of a piece or on two pieces of work. Either rigid or swiveling pipes are used, according to requirements, or provision for variation between the outlets is made by a length of flexible pipe. Certain multi-spindle drilling machines and multi-spindle automatic screw machines carry a pipe partly around the spindles or around the turret, and various bent pipes or distributors lead off from this common supply pipe to feed each drill or turret tool. At *B*, Fig. 8, is an example of a double supply, one pipe leading to the center of the turret for lubricating hollow tools, and the other continuing for feeding external tools held in the turret. A somewhat similar arrangement is shown at *C*; the tap nearest the turret feeds into a funnel which is connected to a slot distributor attached to one of the box-tools having a long cutter for forming steel taper pins; this arrangement insures a proper flow all along the broad-faced cutter.

Portions of machines which move intermittently or continuously along a bed, and must be fed with lubricant in any position they occupy, require the use either of jointed pipes, flexible connections, or telescopic tubes. Both of the latter are used largely. The flexible tubes are likely to get in the way and become a nuisance, while the telescopic pipes can be arranged in snug fashion and occupy a minimum of space; moreover, they are not as liable to become damaged as flexible tubes. It is chiefly in those types of machines where the tool has a horizontal feeding movement, that the provision of adjustable piping is required. Gear-cutting machines and turret lathes are the most frequent examples, the cutter-slide of the one, and the turret-slide of the other requiring a supply of lubricant at all working positions. Certain other machines of less importance in point of numbers, such as horizontal drilling machines and slot-drills with traveling cutter-heads, also require adjustable piping. The telescopic device *A*, Fig. 9, which also shows the back of a turret lathe with a portion of the turret saddle, has a fixed bracket *a*, fitted with a stuffing-box through which the sliding pipe *b* is free to move. The latter passes into the closed end of pipe *c*, which is fed by the pipe *d*, from the pump.

Connection to the sliding cutter-carriage of a gear-cutting machine is made either by the somewhat clumsy means of a flexible pipe, or by a sliding pipe which is arranged, preferably, below the base, as at *B*. (From the practice of Messrs. J. Parkinson & Son, Shipley, Yorkshire.) The packed gland *e* (shown enlarged in section above) is screwed on the end of the stationary pipe *f*, and admits the sliding pipe *g*, which is united to a short vertical pipe fixed to the cutter-carriage. From this vertical pipe the short length of flexible steel tube *h*, directs the stream onto the cutter.

Another system of distribution for movable parts is that requiring a supply to tools in a turret, one or perhaps two or more of which may require the lubricant to be fed through their hollow bodies during their period of operation only. This is effected by causing the rotation of the turret to turn on and cut off the oil as the tools come into their working position. The arrangement for the Cleveland automatic screw machines is shown in Fig. 10, and will serve to illustrate the principle. The feed takes place when the drill shown is at the lowest or working position. The turret shaft *A*, in its to-and-fro movements, controls the feed in the following manner: An oil tube *B* extends inside the shaft and can be clamped in the bracket *C*, wherever desired. This tube has a series of holes in its lower side, continuing for a distance equal to the turret stroke. These holes communicate with a single hole *D* connecting with a tube inserted in the turret hole which carries the tool. The position of tube *B* determines when the oil will begin to flow; it can be adjusted to start at the beginning of the stroke, or later. Valve *E* is to regulate or shut off the oil. Can action is employed in some machines to turn the oil on and off.

BUILT-UP UNIVERSAL GEAR PATTERNS

One of the problems confronting a manufacturer of gears, especially when he makes a practice of furnishing gears of all shapes, types and sizes, is the tying up of a large amount of his capital in patterns. Of course, it is evident that where the sizes are close to some standard, slight alterations can be made in the mold before the gear is cast, but where the difference exceeds limits greater than those which can be handled in this manner it is necessary to make a pattern in each case.

The Foote Gear & Machine Co., Chicago, Ill., has worked out a system of built-up interchangeable patterns which reduces the number of patterns made to a minimum. These patterns are built up from a number of standard parts, and as shown in Figs. 1 and 2 the only part common to all is the center *A*. This center portion is made from a cast-iron shell to prevent the pattern from being wrecked in the foundry, and is arranged with projecting bosses, equal in number to the arms required in the gear. In these projections the removable arms *B* are held, simply being pointed and driven in place and then fastened by screws. The arms can be procured in strips machined to the required shape and it is only necessary for the patternmaker to cut them off to the required lengths. The rim *C* of the pattern is made from two circular members consisting of segments which are provided with holes clear through. These holes are formed by the halves of each groove in the circular segments, which are parted at the center so that the arms can stick out, thus enabling gears of various outside diameters to be cast from the same pattern by simply shifting the position of the rim on the arms. Six inches is about the maximum projection that can be allowed without interfering with molding. The hub of the gear pattern consists of two circular blocks which have projecting bosses that fit in the hole in the center portion of the pattern. The core prints *E* are then screwed to the built-up hubs, and the pattern is complete.

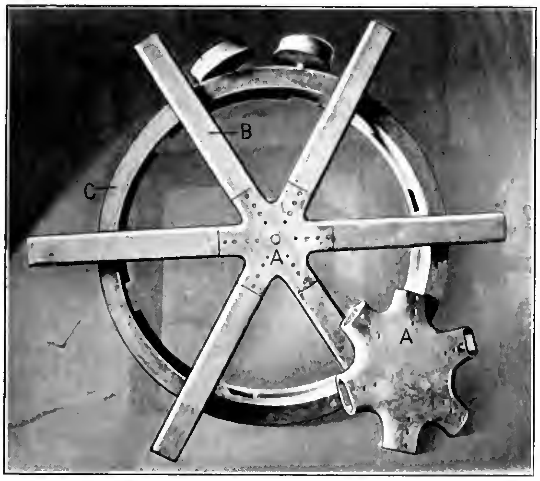

Fig. 1. Component Parts of Built-up Universal Gear Pattern

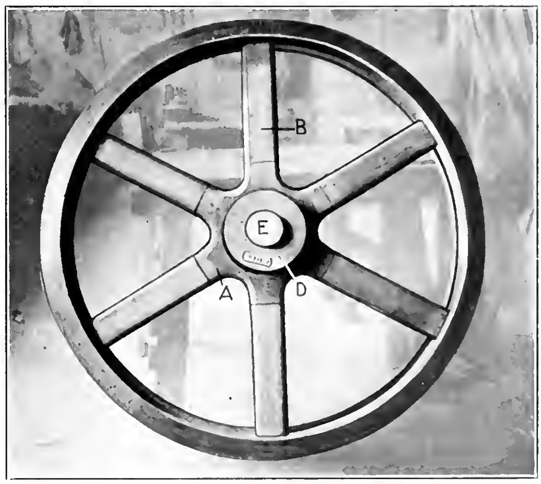

Fig. 2. Pattern assembled and ready for use

This standard pattern, by the addition of the built-up portion previously mentioned, can be used for practically any special gear that comes into the plant, and the number of parts are so few that the problem of storing is greatly simplified. When an order comes in for a gear for which no pattern is made up, it is only necessary for the patternmaker to look through his stock of hubs, rims, arms, etc., and pick out those which approximate the requirements. This not only makes it possible for the manufacturer to produce a cheaper gear, especially when ordered in small lots, but it also enables him to fill the order much more quickly than if it were necessary for him to make up a pattern for each size of gear.

A lining for plating tanks, to protect them from the influence of acids, is made from a mixture consisting of 75 parts, by weight, of pitch; 9 parts plaster-of-paris; 9 parts ocher; 15 parts beeswax, and 3 parts litharge.

AN EFFICIENT FILING SYSTEM FOR THE DRAFTING ROOM

BY G. E. CAMPBELL*

Considering the number of questions the engineering department is called upon to answer daily, and the numerous drawings which have to be referred to in order to give correct information, the necessity of an efficient system for filing drawings and keeping a record of blueprints that are given out is apparent. In this day when sectional filing cabinets with drawers of convenient size can be bought ready for use, it is possible for a drafting-room of any size to have a first-class and efficient filing system which will enable the draftsman to find any drawings in the room immediately and keep a complete record of all blueprints given out. The system which the writer is about to describe has been installed in two different manufacturing plants and both are pleased with the results obtained.

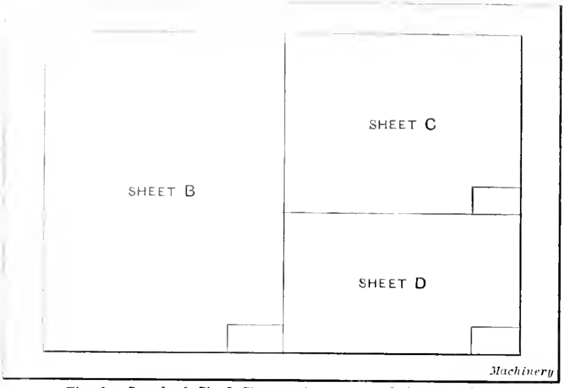

Fig. 1. Standard Sized Sheets of Paper used for Drawings

Size of Drawings

The first thing necessary is to adopt standard sized sheets for drawings, and these sizes will depend upon the material used in making the drawings. As a general proposition, it is preferable to make new drawings on Crane's No. 25 bond paper, as they can be inked directly on this paper, thereby saving considerable time and avoiding the mistakes made in tracing drawings. This quality of paper also makes excellent blueprints. Paper without the "water mark" comes in sheets 27 by 40 inches in size and this will be known as sheet *A*. By cutting the sheet in the center, two sheets 27 by 20 inches in size are made, and each of these will be known as sheet *B*. Again cutting sheet *B* we get sheets *C*, 15 by 20, and *D*, 12 by 20 inches in size. Every sheet has a title in the lower right-hand corner, as shown in Fig. 1, and if the inside measurements of the drawers in filing cases are 31 by 41 inches there will be just enough room for partitions between the different sized sheets.

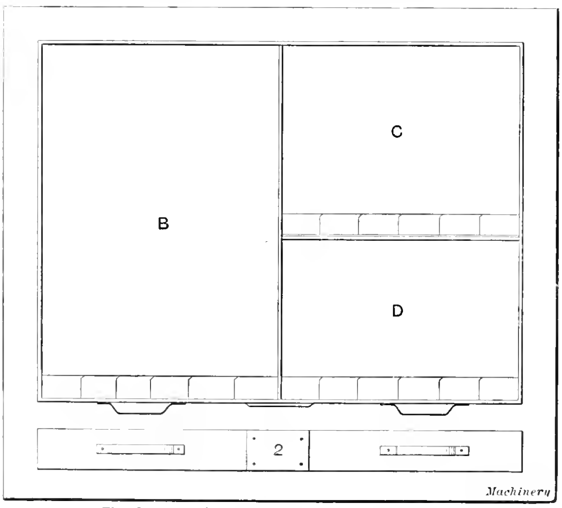

Fig. 2. One of the Drawers in the Filing Cabinet

* Address: 606 Ivy St., Chattanooga, Tenn.

The System

Let us suppose a line of standard machines of different sizes is being manufactured and that each machine requires drawings of the different sizes previously mentioned. It is very convenient to have all the drawings of each machine filed together, and in order to do this, each drawer in the filing cabinet should be provided with partitions of heavy manilla paper or light cardboard. Those partitions should have tabs bearing the name of the machine contained therein, as illustrated in Fig. 2. The drawers are then numbered consecutively on the front.

Numbering the Drawings

Each drawing bears a number just under the title and this number consists of a letter denoting size of sheet, number of drawer in which sheet is filed, and number of sheet in the drawer. For instance, the number *B* 232 means that the sheet is size *B*, or 27 by 20 inches, that it is filed in drawer No. 2 and is the thirty-second drawing filed in this drawer. It will be filed under the tab bearing the name of the machine for which the drawing was made. If the drawing happens to be a detail drawing of a part used on more than one machine, blueprints are made and marked "Record Prints," and these prints are filed under the tab for the machine intended. In this way, a complete set of drawings for each machine is always at hand and filed together for ready reference.

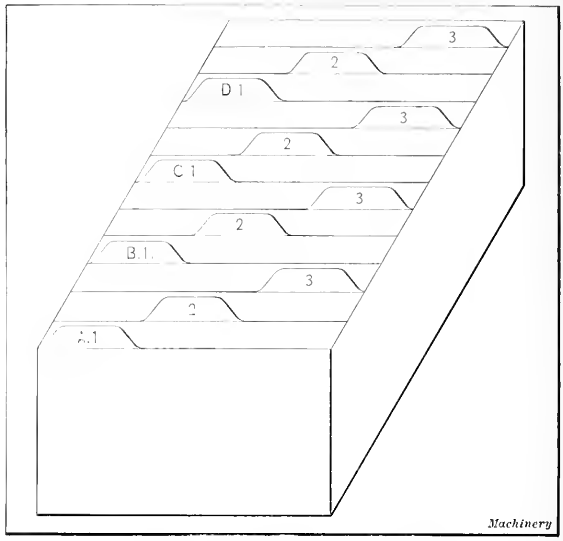

Fig. 3. The Numerical Index of Drawings

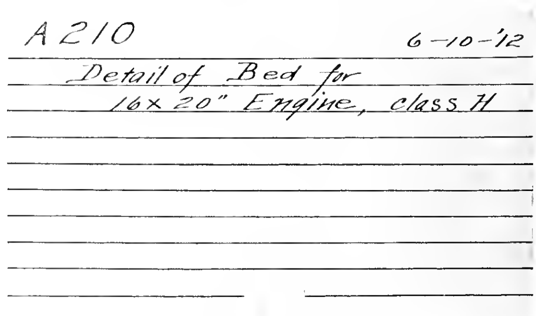

Fig. 4. Card used in the Numerical Index

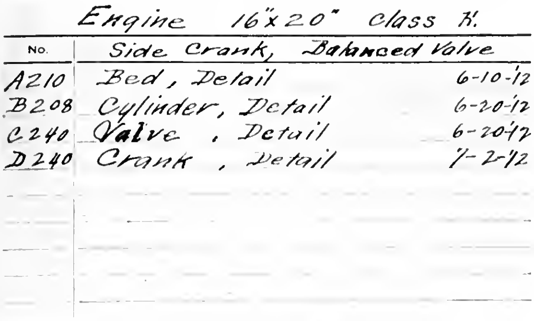
The Card System

As a check against mistakes, and to complete the record, three sets of cards are kept, each under a different head, *viz.*,

"Numerical Index," "Machine Index" and "Customer's Index." The numerical index cards should be made before drawings are filed and the finished index will appear as shown in Fig. 3.

One of the individual cards is shown in Fig. 4. This card would be filed in section A after 2, and by numbering these cards consecutively and in advance there is no danger of having the same number on any two drawings, as this index must be referred to before numbering a drawing. For example, a size A drawing for drawer 2 is to be numbered, and



Engine 16"x20" Class K.

No.	Side Crank, Balanced Valve	
A210	Bed, Detail	6-10-12
B208	Cylinder, Detail	6-20-12
C240	Valve, Detail	6-20-12
D240	Crank, Detail	7-2-12

Fig. 5. Card used in the Machine Index

by referring to index under A 2 we see that A 210 is the last number used; therefore we use blank card A 211 and put this number on the drawing. The title of the drawing is also written on this card. Frequently only the number of the drawing is referred to and in order to locate and identify the drawing, this index is very valuable.

The machine index is simply an index bearing the name of machines alphabetically arranged, the cards being ruled as shown in Fig. 5. The advantage of this card is chiefly as a check, and when all of the drawings for a machine are wanted, it is well to refer to this card for the complete list, as there is always a chance of someone putting a drawing away in the wrong place. By referring to the card, you

Fig. 6. Card used in the Customer's Index

know that you have a complete set of drawings. It is also handy for the man getting up a complete set of blueprints for a machine.

The customer's index is a record of blueprints mailed to the customer. The cards are ruled as shown in Fig. 6 and are filed in an index which is arranged with the customers' names in alphabetical order. This will be found valuable in order to locate the exact blueprint mailed to a customer.

* * *

Effective ventilation means first of all that the air in a room is kept in motion. It does not necessarily mean that the air is being rapidly displaced by the outer atmosphere. Workmen will be comfortable in a warm shop if the air is kept in motion so that a perceptible breeze is felt. To merely change the air is not enough. For this reason, it is a mistake to design a shop, especially a blacksmith shop, with the window openings six or seven feet above the floor. At this height, the direct effect of the air coming in is not felt by the men, who, as a result, are likely to suffer severely, notwithstanding the fact that the air is constantly changing. They do not feel the breezes and the drying of perspiration is slow.

STRESSES IN BRICK PRESS MOLD BOXES

BY SAMUEL B KANOWITZ*

In the design of mold boxes for repressing clay products to their required form, designers have not had any rational formula to follow, since the stresses transmitted to the frame vary with the plasticity of the clay. As the writer has had occasion to use various sized mold boxes, the following formulas were developed, the coefficients given having been derived from experimental tests. For all practical purposes, we may consider that each side of the frame of the mold box (see Fig. 1) is subjected to two stresses—one a bending stress due to the distributed load acting on the side direct, and the other a tensile stress due to the reactions of the adjacent ends, as shown in Fig. 2.

The bending stress can be found from the formula for a uniformly loaded beam fixed at the ends, or

$$p_1 = \frac{Pl}{12Z} \tag{1}$$

where p_1 = stress per square inch;
P = total load on beam;
l = length of beam;
Z = section modulus.

In the case under consideration let

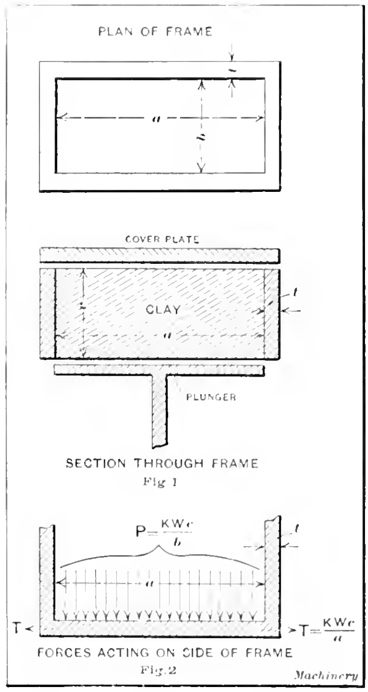
W = total upward force of plunger;
a = inside length of frame;
b = inside width of frame;
c = depth of frame;
t = thickness of metal.

In the case of a fluid where the pressure is distributed uniformly in all directions, we have the following formula;

$$p_2 = \frac{W}{ab} \tag{2}$$

where p_2 = pressure per square inch in all directions.

In dealing with a clay, however, we find that the pressure is not distributed equally in all directions and that the unit pressure on sides and ends can best be expressed by the following formula



Diagrams illustrating Brick Press Molds

$$p_2 = \frac{KW}{ab} \tag{3}$$

In this formula, K is a constant depending on the nature of the clay and amount of moisture in the material to be repressed. The following values of constant K were obtained from experiments on brick at different stages of drying:

Nature of Material	Percentage of Moisture 10	15	25	35	50
	Values of K				
Soft plastic clay	0.68	0.73	0.82	0.90	0.91
Medium plastic clay....	0.62	0.68	0.78	0.85	0.90
Coarse plastic clay	0.58	0.65	0.76	0.84	0.90
Fireclay, kaolin........	0.50	0.55	0.64	0.72	0.80

The area of side A of the frame = ac (see Fig. 1); there-

* Address: 114 S. Broadway, Baltimore, Md.

fore, the total load on side A equals $\frac{KW}{ab} \times ac$, or,

$$P = \frac{KWc}{b} \quad (4)$$

The section modulus of side A about the neutral axis is equal to $Z = \frac{1}{6} ct^2$. Substituting the values of P and Z in Equation (1) and noting that $l = a$, we have the following result:

$$p_1 = \frac{KWa}{2\,bt^2} \quad (5)$$

From this equation we note that the bending stress varies with values a, b and t but is independent of the values c.

The tensile stress on side A is due to the outward pull exerted upon it by the load on the two adjacent ends. The area of each of these equals $b \times c$, and the load per square inch from Equation (3) equals $\frac{KW}{ab}$; therefore, the total load on each end equals $\frac{KW}{ab} \times bc = \frac{KWc}{a}$ or, calling the tensile force that pulls on side A, T, then

$$T = \frac{KWc}{a} \quad (6)$$

The area over which T acts equals $c \times t$; therefore, we have

$$p_3 = \frac{T}{tc} = \frac{KWc}{atc} = \frac{KW}{at} \quad (7)$$

where p_3 = the direct tensile stress.

Combining Equations (5) and (7) we obtain

$$p = p_3 + p_1 = \frac{KWa}{2\,bt^2} + \frac{KW}{at} \quad (8a)$$

where p = the resultant stress in the frame due to flexure and tension. Equation (8a) can be reduced to the following form:

$$p = \frac{KW}{ab}\left(\frac{a^2 + 2\,bt}{2\,t^2}\right) \quad (8)$$

In designing a frame, the combined stress in the longer side only is considered, since the combined stress in the longer side is greater than the combined stress in the shorter side. The bending stress in the longer side is also greater than the bending stress in the shorter side, since their ratio is, from Equation (5),

$$\frac{KWa}{2bt^2} \div \frac{KWb}{2at^2} = \frac{a^2}{b^2}$$

Although the tensile stress in the shorter side is greater than the tensile stress in the longer side, still their ratio is, from Equation (7),

$$\frac{KW}{bt} \div \frac{KW}{at} = \frac{a}{b}$$

From the above equations, we see that the ratio of the bending stresses in the longer to the shorter side, varies as the square of $\frac{a}{b}$, while the ratio of the tensile stress in the smaller to the longer side, varies as the first power only, so that the sum of the combined stresses in the longer side is greater than the sum of the combined stresses in the shorter side.

Solving Equation (8) for t we obtain

$$t = \frac{KW}{2\,ap} + \sqrt{\left(\frac{KW}{2\,ap}\right)^2 + \frac{KWa}{2\,pb}} \quad (9)$$

In the above equation, if a is much longer than b, the quantity $\frac{KW}{2\,ap}$ can be neglected and Equation (9) reduced to the following form:

$$t = \sqrt{\frac{KWa}{2pb}} \quad (10)$$

This same result can be obtained by solving Equation (5) for t, thus showing that under the above conditions, the tensile stress can be neglected in comparison with the bending stress.

The data given in the foregoing is applicable not only to ordinary hand and power re-presses, but also to brick-forming machinery such as soft-mud machines and dry-press machines; in the latter type, the forces required are enormous. The question of brick machinery design and installation has been very much neglected, due particularly to the general inefficiency of the average brick plant but, principally, because the average brick machinery designer has a very meager knowledge of clays and depends mostly upon guesswork. The stresses to which the mold box of a press is subjected, especially when comparatively dry clay is compressed to the form of a brick, are much greater than is generally supposed. Take the case of a "face brick" made on a dry press. Dry pulverized clay is used, and, after being poured into the mold boxes of the press, enough power has to be applied to compress this clay into bricks having smooth surfaces and sharp edges; these bricks must also be hard enough to allow stacking them in a kiln thirty high, without losing their shape. Certain clays require a pressure of from 40,000 to 50,000 pounds per square inch, before these results can be obtained.

An idea of the stresses set up and the forces that have to be applied in brickmaking, may be obtained from the following quotation taken from the catalogue of a well-known manufacturer of brick machinery. "A press that will turn out 2800 dry pressed bricks per hour, weighs 51,000 pounds, requires 25 H. P., and the guides which receive the thrust of the plungers are built to withstand a tensile strain of 6,078,000 pounds." Re-presses which are used to press bricks after they are already formed, also require very high pressures in order to press out all cavities and produce bricks having smooth surfaces and well defined edges. For some clays a unit pressure of 2000 to 3000 pounds is required.

DON'TS FOR DRILLING MACHINE OPERATORS*

BY JAMES E. COOLEY†

Don't forget when using a head counterbore to try the head of the screw in a hole often, to see if it is cutting the right depth.

Don't take it for granted that the drill you called for at the tool-room has been given you; look at it and see if it is the right size.

Don't brush cast-iron chips off the table onto the floor but catch them in a box; this action raises a dust which gets into the machine bearings.

Don't run a tap in a hole with the tapping fixtures, unless you have first measured the hole to see if it is drilled large enough.

Don't use a knee or angle-plate or parallels without first assuring yourself there are no nicks in them to make the work out of true.

Don't forget to slightly prick several places around on a scribed circle with the center punch; they will show after the circle has become rubbed out.

Don't push down hard when tapping a hole but give the fixture time to feed the tap in; tapping fixtures are broken by forcing and not because they won't work.

Don't use a drift that passes entirely through the broach in the spindle, because the hammer will strike the spindle on the last stroke or when the drift passes through.

Don't, when using several drills, let a drill follow a very small one or *vice versa* if you can avoid it; use the drills in the order of their nearest diameters if possible.

Don't ever fail to look at the opposite end of a drilled hole to see if there is a ridge on one side of the edge; if there is, it shows that the drill has been ground off the center.

Don't forget to watch and see if the drill is sending up solid or powdered chips; if the latter, the feed is not on tight enough, or the feed belt is loose, or the drill is dull.

* See "Don'ts" for Drilling Machine Operators," published in the November, 1913, number of MACHINERY.

GRINDING WHEEL PROTECTION DEVICES*

REPORT ON INVESTIGATION OF DEVICES MADE BY THE NORTON CO.

BY R. G. WILLIAMS†

Recent discussions in the technical press and publications devoted to industrial safety and welfare work, have forcibly brought to the attention of those most interested, the fact that there is no uniformity or standardization of grinding wheel protection devices. This lack of uniformity has been a serious handicap in the development of safer manufacturing conditions. Attention has also been drawn to the fact that there are no recorded data or observations on which standardization and safety rules can be based. For the purpose of obtaining data and observations on the relative protection offered by an approved type of protection hood and approved beveled steel flanges, the Norton Co., through its research laboratories, conducted a series of tests.

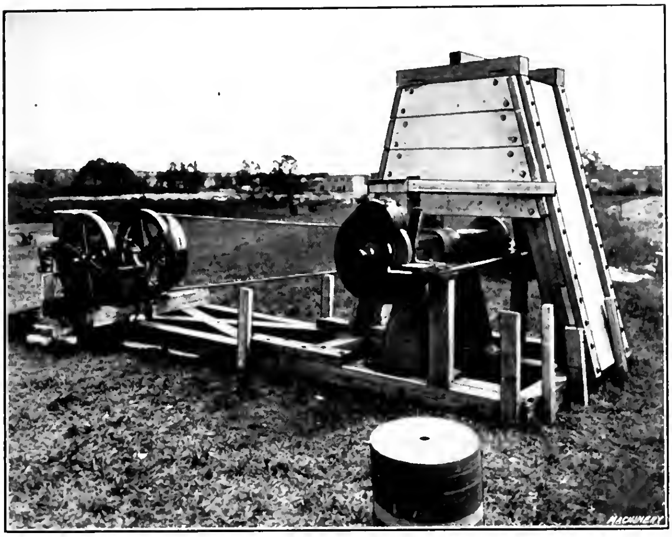

Fig. 1. Testing Equipment consisting of Norton Floor Stand operated at a Speed of 6000 Surface Feet per Minute for All Tests

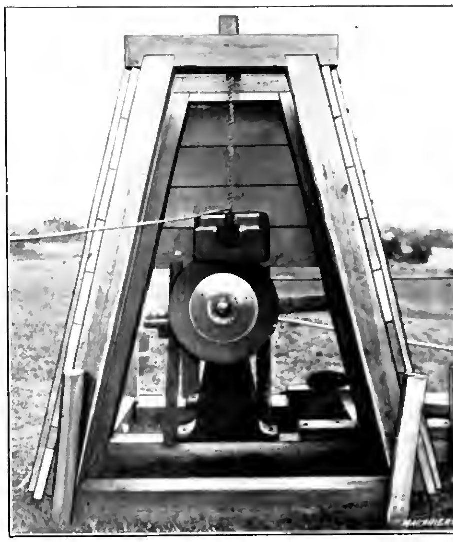

Fig. 2. Wheels broken by swinging 130-pound Weight against the Side

The testing equipment consisted of an up-to-date grinding wheel stand driven by a 7½ horsepower gasoline engine (see Fig. 1). A wooden framework of heavy timbers was built over the side on which the flanges were tested, to intercept pieces of the wheels which might possibly break off outside the flanges. In all tests, the wheels were operated at 6000 peripheral feet per minute, the speed being very carefully regulated immediately before each test.

*Paper presented before the American Society of Mechanical Engineers at New Haven, Conn., November 21, 1913.
† Safety Engineer, Norton Co., Worcester, Mass.

Hood Tests

The wheels used for the hood tests were 16 by 2 by 1¾-inch, alundum, vitrified, of various grains and grades and had parallel sides. The hood was a modern type, and the wheels were mounted between relieved cast-iron flanges 8 inches in diameter. One layer of blotting paper of standard thickness was used between the wheel and each flange. The nut on the spindle was not tightened excessively, but drawn up enough to hold the wheel firmly. The wheels in the hood tests were broken by dropping a steel wedge between the rest and the side of the wheel, in such a manner as to provide a severe blow. The object was to duplicate, as nearly as possible, one of the most frequent causes of accident, *viz.*, that of the work being caught between the rest and the wheel.

Flange Tests

The wheels used were all 24 by 2½ by 1¾-inch alundum, vitrified, grain 14, Grade O, tapered both sides ¾ inch to the foot, with a flat at the center of 4 inches diameter. One thickness of standard blotting paper was used between the wheel and each flange. In these tests, five sets of relieved steel flanges, tapered ¾ inch to the foot, were used, the diameters being 12, 14, 16, 18 and 20 inches, respectively.

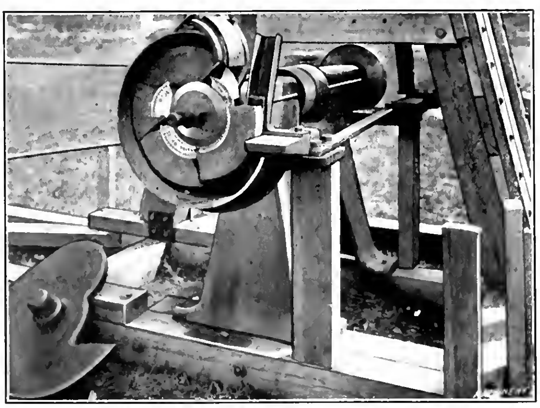

Fig. 3. Wheel; 16- by 2- by 1¾-inch Alundum, 20-K Vitrified; Speed, 6000 Surface Feet. None of the Broken Pieces escaped from the Hood

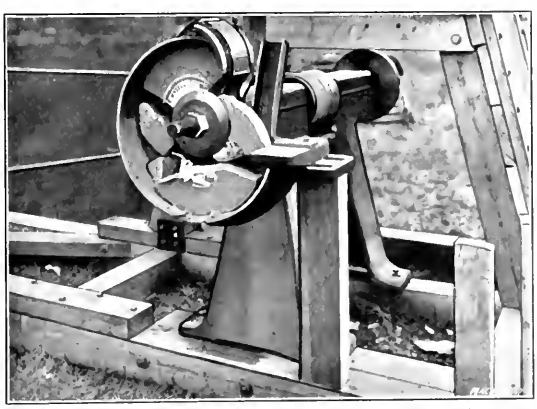

Fig. 4. Wheel; 16- by 2- by 1¾-inch, Alundum, 30-K Silicate; Speed, 6000 Surface Feet. None of the Broken Pieces escaped from the Hood

The wheels in these tests were broken by swinging a 130-

pound cast iron weight against the side of the wheel (see Fig. 2). This method of breakage corresponds to a common cause of accident when heavy castings, which are suspended by tackle above the wheel, are carelessly allowed to strike the side of the wheel with enough force to cause breakage. The manner in which a wheel is broken is not important when pro-

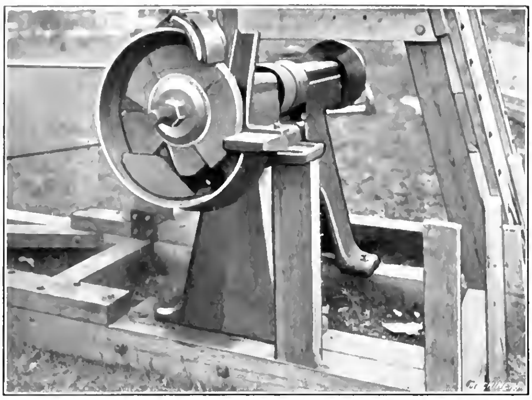

Fig. 5. Wheel; 16- by 2- by 1¾-inch, Alundum, 24-K Vitrified; Speed 6000 Surface Feet. None of the Broken Pieces escaped from the Hood

tection devices for grinding wheels are being studied, so even though the wheels were broken by different methods in the hood tests and the flange tests, the results obtained are comparative from the point of view of protection to an operator.

Observations

In none of the hood tests did a piece of the wheel leave the hood in a way that could have caused damage. The tests show conclusively that a well designed protection hood, made of the right material and properly adjusted, affords ample protection for straight-side wheels even when they are mounted between standard straight relieved flanges having a diameter equal to one-half the diameter of the wheel.

It is possible to break pieces from a wheel by a severe blow when there is only 2 inches of the wheel projecting beyond

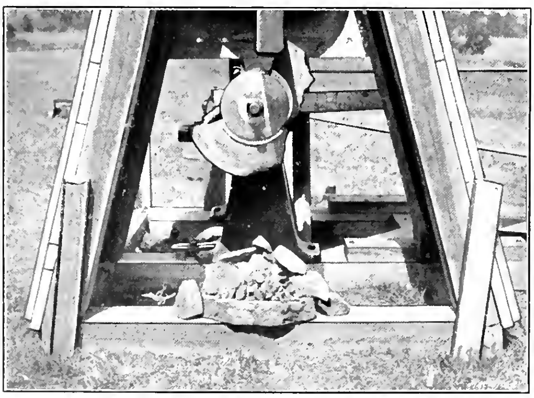

Fig. 6. Wheel; 24- by 2½- by 1¾-Inch, Tapered ¾ Inch to Foot, Alundum, 14-0, Vitrified; Speed, 6000 Surface Feet. Flanges; Steel, 12 Inches Diameter, Relieved, Tapered ¾ Inch to Foot. Wheel broke into Forty-two Pieces and approximately Two-thirds of Wheel escaped from Flanges

the flanges. With protection flanges, no matter how little the wheel projects beyond the flanges, an operator has no protection from injury in case a piece of the wheel breaks off outside of the flanges, whereas with a hood, protection is almost absolute.

Requirements for Hoods and Flanges

It was not the intention to obtain data from which standard specifications for hoods and flanges could be drawn; nevertheless, the tests as a whole brought out a number of points which could be so used. Specifications for hoods for rough grinding should not only require a certain strength, as determined by the design and material used, but they should also require that the top end of hoods have some sliding-tongue device, which can be adjusted as the grinding wheel wears, and thus offer at all times the maximum protection possible. They should also contain a definite statement as to the maximum exposed grinding surface allowable for the common varieties of grinding. For example: Can 60, 70 or 80 degrees of grinding surface be exposed on the type of machine known as the floor stand? Such specifications should also state the minimum size wheel allowable in a hood of given dimensions.

In a majority of instances where protection flanges are now used, ample protection can be obtained by means of hoods without such flanges. However, there are conditions where a hood is not practical and where flanges offer the next best method of protection. The amount of protection offered by flanges is dependent upon the following:

1. The capacity of the flanges to resist the wedging action of a broken piece of the wheel.

Fig. 7. Wheel; Same as Fig. 6. Flanges; Steel, 14 Inches Diameter, Relieved, Tapered ¾ Inch to Foot. Wheel did not break into as many Pieces as One in 12-inch Flanges. Approximately Three-fourths of Wheel escaped from Flanges

2. The size of flanges.
3. Bevel of the wheel.
4. Peripheral velocity of the wheel.
5. Mass of the wheel.
6. Degree of safety.

Degree of safety, as here used, expresses the relationship between the thickness of the wheel at the hub and the thickness of the wheel at the point where the outer edge of the flanges bears on the wheel. In other words, it is an expression which indicates how much the flanges must spread in order to let out a broken sector of the wheel. If the force acting upon the

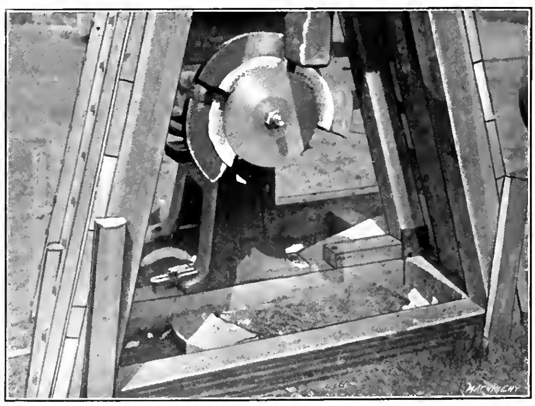

Fig. 8. Wheel; Same as Fig. 6. Flanges; Steel, 16 Inches Diameter, Relieved, Tapered ¾ Inch to Foot. Blow of Weight was not on Piece of Wheel which left Flanges and dropped to Ground. The Part of Wheel struck by Weight was held in Flanges

sector of a broken wheel is great enough to spread the protection flanges a distance equal to B minus A inches (see Fig. 11), then there is not adequate protection. Sufficient protection can be obtained by (*a*) increasing the thickness of the flanges, (*b*) using flanges of a material with a greater modulus of elasticity, (*c*) increasing the diameter of the flanges, (*d*) increasing the taper per foot of the wheel.

Some figures obtained from the 16-inch diameter flange test, give a basis on which standard specifications may be formulated. The combination of factors present in this case resulted in what could be termed a critical condition. The wheel broke into four almost equal pieces, the weights of which were about 23½ pounds. The peripheral velocity of the wheel was 6000 feet per minute. The wheel was tapered ¾ inch to the foot, the taper ending 2 inches from the center of the wheel. In order for a sector to fly out of the 16-inch flanges, they had to spread a total of ¾ inch. After the breakage, it was found that the sectors had moved out a little over 5½ inches and the flanges had spread a little over 11/16 inch, or nearly the required distance to let out the sectors.

The shape of the flanges used was such that it has been found impractical to consider them as cantilevers of the same cross-sectional area, and, therefore, the acting forces in the above case, and the exact factor of safety, cannot be calculated readily. For this reason we cannot deduce definite formula relations between the several factors involved. We can, however, find a proportional relation which expresses the relative degree of safety with different size wheels and flanges.

Fig. 9. Wheel; Same as Fig. 6. Flanges; Steel, 18 Inches Diameter, Relieved, Tapered ¾ Inch to Foot. The Piece of Wheel on the Ground was not knocked off by Blow of Weight, but thrown from Flanges by Centrifugal Force and hurled through Opening at Top of Framework into Air about 50 Feet

Flanges 20 inches in diameter must open one inch to let out a sector. This distance is 33 1/3 per cent more than in the case previously cited, so that 20-inch flanges of the same stiffness as the 16-inch flanges would just about hold the quarter sector of a wheel of 33 1/3 per cent greater mass.

Fig. 10. Wheel; Same as Fig. 6. Flanges; Steel, 20 Inches Diameter, Relieved, Tapered ¾ Inch to Foot. All Segments were retained by Flanges which are only 4 Inches less than Wheel Diameter

The size of a 24-inch wheel of 33 1/3 per cent more mass than a 24 by 2½-inch wheel, would be about 24 by 3⅜ inches. Since 20-inch flanges are as large as is practical to use on wheels 24 inches in diameter, it is quite obvious that 24-inch wheels of a thickness greater than 3½ inches are not safely guarded by means of ¾-inch taper protection flanges, unless the flanges are made more rigid than most existing flanges. Standard specifications should require a factor of safety of at least 2. This requires a greater taper than ¾ inch to the foot, or the use of very heavy steel flanges.

Conclusions from Tests

The tests conducted and the mathematical deductions given above, show that protection hoods provide greater safety than do safety flanges. The protection offered by any given taper decreases with decreased diameter of the wheel. To provide equal safety on all sizes of wheels would require, therefore, a graduated difference in taper. A hood with an adjustable tongue furnishes equal protection for a wide range in the diameter of wheels.

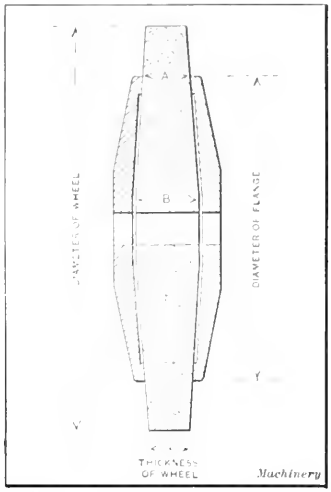

Fig. 11. Sectional View of Tapering Grinding Wheel and Protection Flange

Second to safety, the cost of operating a given grinding machine is of vital interest. In this respect, adjustable hoods have the better of the argument for, as the wheel wears, protection flanges must be changed frequently. Such change involves the removal and remounting of the two flanges and wheel, whereas, in the case of a hood, the change would merely involve set-screw adjustment.

To provide adequate protection for wheels 3 inches and thicker, the thickness (hence the weight) of flanges would have to be increased beyond that of any flange now on the market. This would mean added momentum to the revolving spindle, which, in turn, would require greater rigidity and strength than is to be found in the majority of present-day grinding machines.

Since the face of a tapered wheel becomes wider as the diameter decreases, serious inconvenience is caused in all grinding where the wheel must work in a slot. Tapered wheels do not permit the grinding of right-angle shoulders as do straight wheels. Laws in almost every country require the removal of dust from grinding. This requires the use of a hood, and if a hood must be used, it might just as well be strong enough to offer protection in case of accident. A proper hood offers complete protection. Protection flanges cannot offer this complete protection, but in instances where a hood would interfere with the proper use of the wheel, flanges offer the next best method.

* * *

RUSSIAN EXPORT TRADE

Are American machine builders who are looking for an export trade fully aware of the fact that Russia, at the present time, offers one of the greatest opportunities for trade expansion? Germany is working this field very diligently and has a firm grasp on the Russian machine trade. Russia, in fact, is one of Germany's most important customers in the machine field. Sweden also exports to Russia a large percentage of the machinery built in that country, and many of the machine industries in Sweden depend largely upon the Russian market. Whether or not the abrogation of the treaty between the United States and Russia would have any influence on the conditions of trade between the two countries is difficult to say; but there seems to be no reason why Russia should not be just as willing to do business with American exporters as with Germans, unless the absence of the treaty makes a material difference in our trade with Russia. Germany and Sweden have no advantage except the proximity of territory. This, of course, counts for something, but in these days of rapid transportation, the odds against American manufacturers on this account should not be insurmountable.

GEARS FOR MACHINE TOOL DRIVES*

MATERIALS RECOMMENDED FOR THE VARIOUS GEAR COMBINATIONS MET WITH IN MACHINE TOOL DESIGN

BY JOHN PARKER†

The basis of this paper is the consideration of the six following questions relating to the use of gears for driving machine tools:

1. Under what conditions is it advisable to use cast-iron or steel gears for machine-tool drives?

2. Are the objections to cast iron on the ground of wear or breakage?

3. What tooth pressure is safe for cast-iron gears?

4. What grades of steel give best results and how should they be treated?

5. How hard is it advisable to make steel gears before machining them?

6. Are they to be hardened after machining, and if so, to what scleroscope test?

Conditions Governing use of Cast-iron and Steel Gears

There are a number of well established gear conditions that are common to the majority of machine tools, which, if noted, may prove somewhat of a guide in selecting the proper material for the gears, considered from the standpoints of economy, efficiency and durability. The conditions may be classified, as in the accompanying table.

GEAR CONDITIONS COMMON IN MACHINE TOOLS

		Material
A Gears always in mesh, the wear on the teeth being constant	(a) Slow speeds, light duty	Cast Iron
	(b) Slow speeds, heavy duty	Machine steel
	(c) Fast speeds, light duty	Machine steel
	(d) Fast speeds, heavy duty	Machine steel, casehardened
B Gears in sets that are removable and interchangeable with each other, distributing the wear over a number of gears	These are change gears used in thread cutting on lathes, spiral cutting on milling machines, indexing on automatic gear cutters and feed and speed change gears; speeds and pressures are generally moderate	Cast iron, excepting the smallest, which may require to be of steel
C Gears in sets that are non-removable and partially interchangeable, distributing the wear over a number of gears. Changes made while gears are in motion*	Used as quick-change feed gears —changes made by levers; speeds and pressures moderate	Machine steel, casehardened
D Gears in sets that are non-removable and partially interchangeable, distributing the wear over a number of gears. Changes made when gears are at rest†	Used as quick-change speed gears — changes made by levers; high speeds and heavy pressure	Machine steel, casehardened
E Gears that are employed only part of the time the machine is working, and are engaged and disengaged when the machine is stopped	This condition applies to back-gears for the spindle drive. Gears are made large diameter, coarse pitch and wide face; speeds moderate and heavy pressure	Hard, close-grained cast iron

* If the changes were made when the machine was at rest, the gears would not require hardening. But custom demands that changes be made while the machine is running.

† Although the changes are supposed to be made when gears are at rest, careless workmen will violate this rule, with the possibility of breaking the engaging gears. Some makers use an alloy steel in their spindle train to prevent breakage, but a better way is to provide means whereby it is necessary to stop the machine before throwing in the gears. This applies to the tumbler type of change gearing.

The objections to cast iron cover both wear and breakage. If the speed is excessive, say about 500 feet per minute, they are likely to wear quite rapidly; and on slow speeds and heavy pressure breakage will occur, unless they can be made of adequate size, as in the case *E*, where the back-gears are so located in the machine that it is possible to employ large diameters, coarse pitches and wide faces.

Safe Tooth Pressure for Cast-iron Gears

The question of tooth pressures in cast-iron gears is somewhat problematical. The Brown & Sharpe Mfg. Co. has in successful operation a gear in the spindle drive of its largest milling machine, made from a hard, close-grained cast iron having a tensile strength of 23,000 pounds per square inch, which, when running at the slowest speed, sustains a pressure on the teeth of 8250 pounds. It is calculated that two teeth are always in contact, which gives 4125 pounds pressure per tooth. The area in cross-section of each tooth is 1¼ square inch, equaling 3300 pounds per square inch. When the gear runs at the fastest speed the pressure is about 1000 pounds per square inch. It is not known whether the pressure could be increased to any considerable extent, but it has been overloaded to at least 30 per cent without injuring it; this was when testing out the machine and the overload was of short duration. It might be said that this gear is not subjected to any sudden shock; if it were, the allowable tooth pressure would be considerably less.

Grades of Steel that give Best Results and Heat-treatment

For gears that are of small proportions and yet are subjected to heavy duty, it has been found that in cases where the more common steels have failed, excellent results have been obtained from using a 5 per cent nickel steel. This steel casehardens with a very hard surface and still has a strong and tough core, making it an ideal steel to use where the pressure is heavy or the gear is subjected to shock. Experience shows that drop-forgings are more uniform in texture than bar stock. This grade of steel is given an oil treatment and is also annealed before machining. The oil treatment is as follows: heat to 1550 degrees F. and quench in oil. To anneal, reheat to 1350 degrees F. and cool very slowly. The steel is then ready to machine.

After machining, it is carbonized as follows: Pack in any good carbonizing material and cover very carefully to exclude air; place in furnace and heat to 1700 degrees F., and hold long enough to get the desired depth of casing. Care should be taken to have the steel heated entirely through. Ordinarily from three to four hours is sufficient. Then remove the steel from the furnace and cool in the boxes; then remove from the boxes and place in a furnace or bath; reheat to 1550 degrees F. and quench in oil. Again reheat to about 1380 degrees F. and quench in oil or water, according to the size and shape of gear. If the gear is of generous dimensions and free from sharp corners, water is preferable. Small slender gears are quenched in oil, on account of the liability of cracking if water is used. For ordinary gears the scleroscope test should show 80 to 85 points of hardness. If the gears are used as clash gears they should be drawn to 475 degrees F., or about 70 to 75 points of hardness, by scleroscope test, to avoid chipping.

Hardness Advisable for Steel Gears before Machining

The kinds of steels used for gears are of such a nature that they do not call for heat-treating before machining, but where extra toughness in shafts is required to withstand torsion and bending strains, 3½ per cent nickel steel is satisfactory and is heat-treated as follows, after being rough-machined: Place in an open furnace or bath, heat to 1500 degrees F. and quench in oil. It is advisable to experiment with a small quantity in each batch, before subjecting a whole lot to the drawing out heat, which should begin at about 700 degrees F. If the scleroscope registers between 50 and 58, the correct hardness has been obtained; if higher than 58, the parts should be reheated to a higher temperature than before; if lower than 50, the parts must be rehardened. After this treatment,

* Paper presented before the American Society of Mechanical Engineers, December, 1913.

† Address: Brown & Sharpe Mfg. Co., Providence, R. I.

the pieces are finish-machined. No further hardening is necessary. When machining, slow speeds and feeds must be used.

Hardening after Machining, and the Scleroscope Test

Practically all alloy and all low-carbon steels are hardened after machining and finished by grinding after hardening. About 0.010 inch on the diameter is left for this operation. All gears should run true, and to obtain this result not only are the holes ground true with the pitch circle, but the hubs are ground on their faces so they will set square with their shafts when tightened up by nuts. The scleroscope test for 30 to 35 point carbon machine steel is anywhere from 80 to 90, and for 5 per cent nickel steel for ordinary gears, 80 to 85, and for clash gears, 70 to 75. All steels are tested by the file in addition to the scleroscope. The file test by an expert is very reliable and some feel that possibly more confidence can be placed on his judgment than on any testing instrument.

The above notes apply to spur and bevel gears. For worm and worm-wheel drives, the worm should be made of machine steel, casehardened, and the wheel of a hard bronze. Both should run in a bath of oil, especially if under high speed and heavy duty. Spiral gears should be used only where the duty is light. The material should be the same as for a worm and worm-wheel, and they should also run in oil to avoid cutting.

For index mechanisms where accuracy is essential, if the worm is hardened, the thread must be ground afterwards. This is done in all the spiral heads of Brown & Sharpe's make. Generally, the worm, which is made of tool steel, is left soft. Worm-wheels used for indexing purposes only are usually made of cast iron, and invariably if of large diameter. High-multiple threaded worms for indexing mechanisms should not be used; a double thread can be tolerated, but not more, if accurate indexings are required.

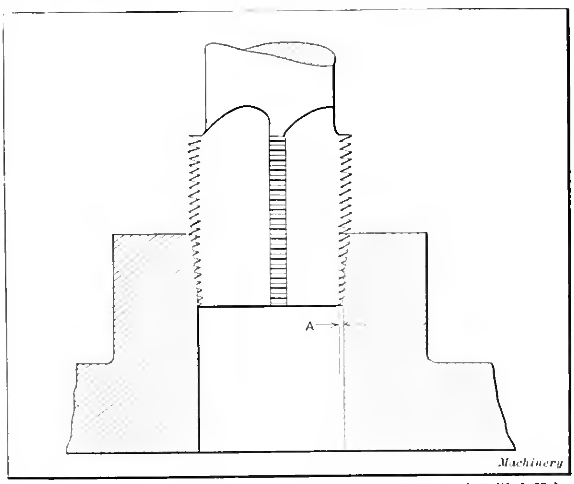
TAP DRILL SIZES

BY ALBERT A. DOWD*

The correct size of drill which should be used for a hole that is to be tapped subsequently, seems to be somewhat variable, and the result of this uncertainty is that the amount of thread remaining after the hole has been finished is sometimes insufficient to perform its function. Nearly all factories have tabulated lists for reference in the "tool crib," giving correct tap drill sizes for standard holes. These are of great value in the general run of manufacturing where the tapping is to be done on a tapping machine or by means of a tapping attachment. There are cases, however, where the



Illustrating Clearance between Thread Root of Tap and Wall of Drilled Hole

drill sizes given are so proportioned that the tap clearance at the root of the thread is insufficient for machine tapping, although it may be all right for hand tapping. When this is the case, taps are frequently broken. In other instances the tap drill size specified is too large, resulting in the saving of taps but giving an inferior product on account of lack of thread surface.

The illustration shows a drilled hole with the tap in position, indicating at A the amount of clearance between the thread root of the tap and the wall of the drilled hole. This clearance should vary in proportion to the pitch of the thread, for if not so proportioned the relative strength of the different pitches will not be the same. In determining this clearance, two points must be considered, *viz.*, the diameter of the hole and the strength of the tap. For example, a ½-inch tap, 40 pitch, is obviously much stronger than a ⅛-inch tap of the same pitch. We must also bear in mind that for machine tapping the clearance should be greater than for hand tapping, in order to avoid the breaking of taps as much as possible. The formulas given herewith are proportioned for both machine and hand tapping and will be found of considerable assistance in determining drill sizes.

Formulas for Tap Drill Sizes

T = tap size specified;
MTD = tap drill size for machine tapping;
HTD = tap drill size for hand tapping.

Then

$$MTD = T - 0.8\left(\frac{1.299}{\text{pitch}}\right)$$

$$HTD = T - 0.9\left(\frac{1.299}{\text{pitch}}\right)$$

For example, let it be required to ascertain the correct tap drill size for a ⅜ 16-pitch thread, for machine tapping. Applying the formula we have:

$$0.375 - \frac{0.8 \times 1.299}{16} = 0.31005,$$ and the nearest drill size is 5/16, or 0.3125 inch.

CONSTANTS FOR TAP DRILL SIZES

Machinery

The formulas given above will take care of any condition or pitch of thread, but for small diameters, say from ⅛ to ¼ inch, it is advisable to select a drill from 0.002 to 0.004 inch larger than the figured dimensions.

Formulas for Tap Drill Sizes using Constant Table

The table gives constants which may be used for the more frequently used pitches and will be found convenient. These are subtracted from the outside diameter of the tap or screw to find the diameter of the tap drill for machine tapping and hand tapping.

T = nominal size of tap specified;
C = double depth of thread;
MD = constant for machine tapping;
HD = constant for hand tapping;
MTD = tap drill size for machine tapping;
HTD = tap drill size for hand tapping.

Theoretical size of tap drill required = $T - C$

$$MTD = T - MD$$
$$HTD = T - HD$$

* No set before breaking.

These tests represent average results obtained from a considerable number of test pieces subjected to the different heat-treatments specified in the table. The test pieces were spur pinions having fourteen teeth of six pitch, 2 1/3 inches pitch diameter, 1-inch face width and 1-inch bore. All teeth were of standard depth and shape. During the tests the pinions were held in a special chuck as shown in the accompanying illustrations, the load being applied to the edge of the teeth as indicated in Fig. 1. The initial displacement or elastic limit was determined by following up the load with a vernier tooth caliper which showed when permanent set had occurred (see Fig. 2). All carbonizing was 1/32 inch deep, and the furnace temperature varied from 1450 to 1500 degrees F., for eight hours, and was held at 1600 degrees for from three to five hours—a total of eleven to thirteen hours.

It will be noted that the increased strength, as a result of the double heat-treatment after carbonizing, is comparatively slight, particularly in the nickel-alloy steels. This is undoubtedly due to the long and low carbonizing heats and the low hardening heats. The various hardened test pieces of the "straight-carbon" steel showed a variation in strength of 10 per cent above and below the records given. This stock was selected especially for casehardening and, according to our experience, the ordinary run of machine steel of the same carbon content would vary, in some cases, twice as much as this. The same may be said of the so-called "natural nickel-alloy steels," as we find that they vary as much as the straight-carbon steels. The higher grade of alloy steels did not vary more than 10 per cent either way, and the average was closer.

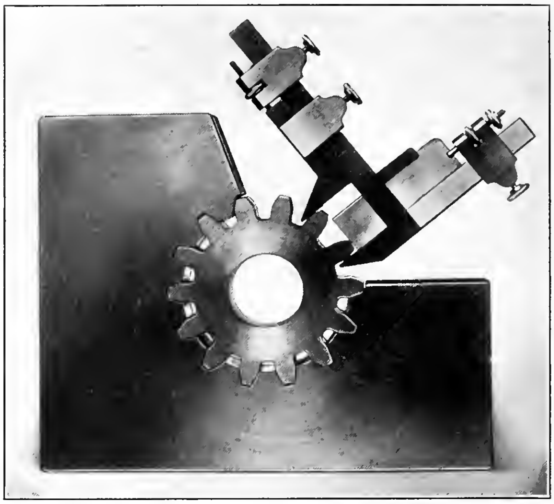

Fig. 2. Gear Tooth Caliper used to determine when Permanent Set occurred

LOOK OUT FOR THE "BORROWER"

Some time ago we were favored with a visit from a man claiming to be C. E. Watson who was connected with the Case Crane & Engineering Co., Columbus, Ohio to whom we recently made shipment of a machine. He knew all about some minor defects of the machine and we had no reason to question his integrity, and as he was short of funds, we cashed a check for $35 on one of the Columbus banks. The check was returned protested "Not Known." Since that time we have received letters from the Laughlin-Barney Machinery Co., of Pittsburg and the Detrick & Harvey Machine Co., of Baltimore, advising us that the same man had obtained money from them, in the same manner, only that he claimed to be connected with the Babcock & Wilcox Co., of Barberton, Ohio. This "worthy" gentleman was connected with the Case Crane & Engineering Co., as we found out from them and was formerly connected with the Crucible Steel Company of America and we believe he was at one time an engineer in the Navy. We think it is high time that notice was given, so that other people will not be duped the same as we were.

A STUDY OF FOUNDRY MIXTURES USED AND RECOMMENDED BY MACHINE TOOL BUILDERS

BY HENRY M WOOD†

When considering what sort of iron to use for various purposes, the machine tool manufacturer is interested chiefly in the results attained by the foundryman, *i. e.*, the strength, soundness, hardness, etc., of the casting, rather than the foundry methods used in accomplishing such results. Nevertheless as an investigation of the character of the casting is made through chemical analysis, it is well first to consider the effect of each of the elements usually present in cast iron.

Influence of Chemical Elements

The five elements present in ordinary cast iron are carbon (both free as graphite and combined), silicon, sulphur, manganese, and phosphorus.

Carbon. Carbon exerts a more important and direct influence on the quality of the metal than does any other element. The percentage of carbon in the casting and the form in which it exists are dependent upon the melting conditions, the thermal treatment, and the amounts of other elements present. Therefore it is necessary to take account of the effects of the carbon itself and the way its influence is modified by the presence of varying quantities of other elements. To obtain a proper relation between combined and free carbon is the most important point. The percentage of total carbon usually ranges from 3.5 to 4 per cent.

Graphitic Carbon. Graphite is merely mixed with the iron instead of being in chemical combination. Since it is only mixed with the metal it cannot exert any direct influence upon the properties of the molecules of the iron. So far as the graphite itself is concerned, the toughness, hardness and melting point of the grains of the iron will not be altered. The tensile strength will, however, be greatly affected, since the interposition of the flakes of graphite will act as partings between the grains of the metal and reduce the cohesion. Iron high in graphite is soft and can be machined readily, but is of low tensile strength.

Combined Carbon. The carbon which is in chemical combination affects directly and greatly the properties of ordinary cast iron. It is the principal factor in determining the hardness, tenacity, soundness, and freedom from internal stresses of the castings. In general, the percentage of combined carbon ranges from 0.05 in the softest cast iron to about 0.60 in iron of the highest elasticity. With suitable iron mixtures the amount of silicon and sulphur present, regulates the separation of carbon as graphite so that the amount of silicon present is an index of the relation between the free and combined carbon. Many analyses submitted do not state the percentage of carbon, perhaps because the foundrymen do not appreciate the importance of it, or perhaps because they consider the quantities of silicon, manganese and sulphur, which influence the quantity of combined carbon, make it unnecessary to determine the latter.

Silicon. Silicon tends to cause separation of the carbon as graphite. As the hardening effect of the silicon necessary to do this, is less than that of the combined carbon converted into free carbon, the net result of adding silicon is softer iron. Under conditions which are easily regulated by selection of materials and in other convenient ways, the general influence of silicon can be utilized to render the cast iron suitable for various purposes, but it must be used with due regard to the other constituents of the metal.

Sulphur. The influence of sulphur is opposite to silicon, in that it makes the iron harder and more brittle. It makes the iron more sluggish when pouring and is liable to cause unsound castings. Sulphur increases shrinkage, resulting in internal stresses of unknown value and sometimes producing distorted castings. This element should be kept low, especially in small castings.

Manganese. One effect of manganese is to combine with sulphur and go off in the slag. Another is to retard the separation of graphite by combining with carbon, and in this its influence is opposite to that of silicon, rendering the iron harder, stronger and perhaps closer.

Phosphorus. Phosphorus lowers the melting point and increases the fluidity of the molten iron. On the other hand, phosphorus makes the casting harder, more crystalline and brittle, and reduces the tensile strength.

Special Mixtures

Semi-Steel. This mixture is obtained by charging mild steel scrap into the cupola. It is common practice to use about 20 per cent steel, but any amount up to 70 per cent may be used. The 20 per cent mixture usually gives the desired results for machine tool work. Semi-steel is lower in total carbon than cast iron, seldom having more than 3 per cent. The fine grain of semi-steel is due to low percentage and fineness of graphite. It is used for parts requiring good appearance, tensile strength, and ability to resist shock. It is often used for large gear blank castings for various machine tools, for milling-machine tables, knees, and saddles, for lathe reverse plates, compound rests, etc. The tensile strength is relatively high and the grain of the casting is close.

Alloys. Elements sometimes introduced into cast iron for special purposes are vanadium, titanium, nickel and chromium. Vanadium increases the resistance of the casting to wear. Titanium combines with nitrogen and goes off in the slag, thus acting as a scavenger and making closer and cleaner iron. While nickel and chromium are now used to a limited extent in heavy chilled castings such as car wheels and rolling-mill rolls, the writer has been unable to find instances of the use of these metals in cast iron for machine tool parts.

Mixtures used by Representative Machine Tool Makers

In the belief that valuable information could be secured by a comparison of the present practices of representative machine tool manufacturers, the writer asked a number of machine tool makers in different lines and in different sections of the country if they would be willing to submit an outline of their practice. The following is quoted from their replies:

Two Plain	
Manganese	0.60 to 0.90
Phosphorus	0.50 to 0.80
Sulphur	0.05 and under
No. 3	
Silicon	1.00 to 1.50
Manganese	0.50 and over
Phosphorus	0.50 to 0.80
Sulphur	0.07 and under

In addition to the above we use materials as follows: No. 1 machinery scrap, mild steel scrap, manganese steel scrap. The last carries 12 per cent of manganese with quantities of the other elements so small that they are negligible in gray iron foundry work. Our mixtures are figured out on the actual analysis of each car, insuring in the castings uniformity of analysis and consequently of physical characteristics, such as strength, density, and machining qualities. In general practice we use three different mixtures suited to our needs.

In our first mixture we include our lighter castings such as pulleys, small gears, washers, handwheels, brackets, and the like. In this mixture we try to have the following analysis:

Silicon	1.90
Manganese	0.60
Phosphorus	0.70
Sulphur	0.08

This is usually secured by the use of a mixture of 50 per cent of two or three lots of "two plain" iron and 50 per cent of scrap. The proportions of the different pig irons are adjusted to produce the proper analysis in the mixture, and the scrap is partly our own foundry return, the balance being No. 1 machinery scrap.

Our second mixture covers all our heavy work, such as planer beds, posts, tables, faceplates, frames, etc. These castings require strength and sufficient density to permit the

* Paper presented before the American Society of Mechanical Engineers, December, 1913.

† Lodge & Shipley Machine Tool Co., Cincinnati, Ohio.

machined surface to take a high polish. The analysis is:

Silicon	1.40
Manganese	0.60
Phosphorus	0.60
Sulphur	0.09

This mixture consists of 45 per cent of two or more "No. 3 irons" and 55 per cent total scrap, shop and No. 1 machinery together. Should this mixture fail to yield sufficient manganese, the addition of 1 to 2 per cent of manganese steel scrap is made to correct it.

The third mixture is semi-steel, used principally for large blank gears and castings requiring special strength. Its analysis is:

Silicon	1.20
Manganese	0.90
Phosphorus	0.45
Sulphur	0.09

Its average makeup is:

Machinery scrap	30 per cent
Mild steel scrap	20 per cent
Manganese steel scrap	5 per cent
No. 3 pig iron	45 per cent

All materials are weighed before charging into the cupola and all due precautions are taken to insure proper melting conditions and perfect mixtures of the various materials.

A Manufacturer of Precision Machinery: In our work we run various grades of iron to meet the conditions existing in the machines or in the parts of machines under consideration. In a general way our mixtures, in per cent, run as follows:

Silicon	Manganese	Phosphorus
3.00	0.60	0.08
2.40	0.65	0.70
2.00	0.65	0.60

The first is for the average run of castings of smaller size; the second for the larger castings. Where we need a special close-grain iron we use the third mixture.

A Manufacturer of Milling Machines: We have never carried on any extensive experiments to learn the best mixtures of cast iron for our purposes. We use in the tables, knees, saddles and vises about 20 per cent of steel with a view to obtaining a close-grain casting, and increasing somewhat its strength. We use practically no cast iron for gears or small parts, these being made of steel, drop-forged in the case of larger parts, and also in the case of smaller parts when not adapted for manufacture from the bar. The subject of gray-iron castings is, we believe, one of the most annoying to be found in connection with the manufacture of machine tools. Customers are not satisfied to accept machines with defective castings even though the deficiency is of such a nature as to, in no wise, impair the life or efficiency of the machine. The ideal casting is, of course, one that is so close as not to show any grain when finished and at the same time, just as hard as it can be, and be worked into shape. The question of strength is probably not so important, as there is opportunity to use sufficient bulk to obtain strength. At any rate this is true of the parts that we make of cast iron, for, as stated above, all our gears, etc., are made from casehardened steel.

A Manufacturer of Heavy Lathes: With the heavier castings we are using a semi-steel mixture with about 20 per cent of steel. The analysis of this iron shows 1.60 to 1.70 silicon, 0.65 to 0.75 manganese, 0.40 phosphorus, 0.8 to 0.10 sulphur. While our carbons are not noted as a rule, we get a check on these every once in a while, showing the total carbons about 3.50 to 3.60. Our iron for smaller pieces runs from 1.80 to 1.90 in silicon, 0.40 to 0.50 in phosphorus, 0.65 to 0.70 manganese, 0.07 to 0.10 in sulphur. The total carbon shows up practically the same in both mixtures. Our test bars on the first mixture break at from 2800 to 3200 and on the latter mixtures at about 2600. This refers to 1 inch by 1 inch standard bars supported on 12-inch centers.

A Manufacturer of Grinding Machines: We use castings with various proportions of steel according to the size of the casting and the place where it is to be used, so that we have very bright lustrous surfaces.

Practice with Reference to Chilling Castings

There is a wide difference of opinion among machine tool manufacturers as to the desirability of chilling surfaces of castings. The writer asked some of the representative manufacturers of various classes of machine tools for their experience. The quotations state both sides of the case:

A Manufacturer of Milling Machines: We are not using any chills at this time, though we have experimented with these from time to time but have reached no satisfactory conclusion.

A Lathe Manufacturer: We have not used chills on any parts of our machines, which, we must concede, is from many points of view, not a very satisfactory admission to make.

A Manufacturer of Heavy Machine Tools: For quite a period, about nine or ten years ago, we chilled the ways on our lathes and also the rails on our boring mills. We found, however, after they had been out some time that there was considerable trouble owing to the chilled surfaces scratching. It was hard to find exactly the root of the trouble and we finally gave it up. The effect of the scratching of the chilled ways was a most peculiar one, and we sometimes observed on a machine, even before it had gone out, that some little particle of material had settled on the way and scratched it badly.

A Manufacturer of Grinding Machines: In regard to chilled iron, of course, you know that chilled iron means iron that cannot be filed, planed or scraped. At least any mechanic understands "chilled iron" to mean a surface that cannot be cut with tools. Now such a surface makes it impossible to get practical aligning ways on machine tools. It might just barely be possible to grind them accurately, but probably not practicable to do so. We use an iron with steel mixture, and vary the mixture according to the size of the casting, and we produce a casting as dense and as hard as we can possibly plane and scrape with any surety of getting perfect alignment, because imperfect bearing and imperfect alignment are just as bad as iron that is too soft.

Another Manufacturer of Grinding Machines: The main reason for chilling the different parts of our work is to increase the wearing durability and, at the same time, secure the advantage of refined metal and a clean surface. The parts chilled are the guides of the carriage and the surface of the table upon which the head and tailstocks are mounted. Our method of chilling is to place plates 5/8 inch thick in the mold; these give a depth of chill of about 1/2 inch and a degree of hardness to the point where the machining can be done readily. It would be natural to suppose that this chilling would produce or increase internal strains, but on our work, such conditions have not given any trouble.

Our work is not of such a nature that hammering upon it or peening is necessary; therefore, we are unable to state just what action would take place as the result of hammer blows and peening. The chilled surfaces are very much more durable than metal in the ordinary condition, and we believe by the chilling process, the durability of the surface upon which wear comes is increased at least from 300 to 400 per cent.

A Builder of Heavy Machine Tools: In 1888 we began the practice of solidifying cast-iron surfaces by introducing chill blocks in the molds, and we have continued the practice ever since. Answering your questions specifically, first, we have not discontinued the use of chilled surfaces because of any difficulty in oiling. We have never found that the fine grain of the chilled iron prevented the oil from sticking. There is no truth in the statement. We have not found any increase in internal strains due to the use of chills. On the contrary, when chills are properly placed they equalize the cooling of the heavy parts adjacent to lighter portions and reduce the internal stresses which would naturally result from the difference in time of cooling. If the chills are improperly used it would be possible, especially in thin castings, to cool the entire mass too rapidly and produce internal stresses. We have not found that the proper use of chills makes the iron more sensitive to a peening action; in fact, we have evidence to the contrary. The chilled surface we believe to be more durable. Gearing made in this way has outlasted several sets made in the old manner. The success or failure of this process depends upon the ability to produce, day in and day out, the kind of metal required, and, further, the intelligent designing of chills of iron molds so that a proper relation may always be observed between the size and shape of the casting and the thickness of the mold or chill block.

A Boring-Mill Manufacturer: We are chilling certain sur-

faces on our boring-mill spindles with good success, but have found no occasion for chilling any other surfaces. If we experienced difficulty due to undue wear on sliding surfaces, we would increase the area of the surfaces and supply better lubrication and protection from dirt rather than to try to chill the surfaces of these parts. The chills which we use on our spindles serve two purposes: First, by securing closer grained metal; second, by improving the quality of the wearing surfaces. We found that it was difficult to get good castings of these spindles until we used chills.

A Builder of Special Machine Tools: Concerning chills, we would say that to some extent we are now using these on the surfaces of beds and similar castings.

Chilled Lathe Beds

Analysis of Iron: In view of the considerable differences in opinions of the value of chilled surfaces and the idea held by some that it is impossible to chill an iron of high tensile strength without making it so hard that it cannot be machined, the practice of the Lodge & Shipley Machine Tool Co., with which the writer is connected, is here outlined.

Three average analyses are as follows:

Silicon	Sulphur	Phosphorus	Manganese	Tensile Strength
2.16	0.065	1.01	0.40	22,310
2.17	0.065	1.01	0.39	24,840
2.45	0.076	0.63	0.71	24,195

The first analysis is of a specimen taken in January, 1913, from the first iron run in a heat; the second, from the last iron of the same heat; the third, from the average iron of a heat in September, 1913. This iron is used for lathe beds of which the ways are chilled; it is also used for other cast-iron parts which do not require the high tensile strength of semi-steel. For parts, such as compound rest top slides and reverse plates, we use semi-steel. Parts subject to greater stress or to severe shock are made of steel.

A cross-sectional fracture through the finished ways and a portion of the side wall of a chilled bed for a 30-inch lathe, clearly shows that the iron, even far away from the chill in the side wall of the casting, is dense and of as close grain as other good cast iron; it also shows the much closer grain of the iron below the finished surface, as a result of the chill in closing up the iron and making it harder and more durable. In the 30-inch bed, the close iron produced by the chill extends to a depth of 1½ inch to 2 inches below the finished surface of the ways, thus proving that the chilled iron is not all removed in the planing.

Degree of Hardness

Scleroscope tests on chilled beds finish-planed but not scraped, gave as a result of eight different tests on four different beds, scleroscope readings of 40 to 42 with an average of 41. Similar tests on chilled beds which had been planed and then scraped gave a practically constant scleroscope reading of 42. Comparative scleroscope tests on a heavy section of unchilled cast iron which would give as nearly as possible conditions parallel to those just quoted gave readings ranging from 18 to 22, with an average of 20.

In addition to the advantage gained by the hardness, the chilled beds are, if anything, more uniform than the unchilled. The rough beds as received from the foundry are quite straight, so that the amount of metal removed all along the ways in planing is as nearly uniform as is practicable. Then, too, the scleroscope readings indicated a more nearly constant degree of hardness on the chilled beds than on the unchilled. Fewer castings are unsound than before chills were used.

Action of the Chill

The chilled surface is produced by a series of cast-iron chill plates, each about 6 inches long, placed end to end in the mold. The use of separate short plates eliminates much of the warping and twisting which would occur in a long chill plate. If a thick chill plate is used with a low-silicon iron, the surface of the casting is chilled so hard that it cannot be machined. The desired result is attained by regulating the thickness of the chill plate to suit the size of the casting for which it is used; then a low-silicon iron of high tensile strength can be poured successfully. The heavier the casting, the thicker the chill plate. The action in the mold is that when the molten iron strikes the cold plate it is chilled and hardened; then the heat in the mass of iron forming the body of the bed casting gradually warms the chilled surface and the chill plate, thus annealing the casting or "drawing the chill," just as when in tempering a chisel, the heat in the shank of the chisel "draws the temper" of the cutting edge to the proper point after the cutting edge has been hardened by quenching in water. This annealing of the chilled surface of the casting produces the desired form of hard, close-grained gray iron. The thickness of the chill plate used is such that the heat in the casting will anneal the surface sufficiently to permit planing, although at a greatly reduced cutting speed, and yet retain the benefits of the chill.

Value of Chilled Surfaces

The advantages of chilled wearing surfaces for machine tools are:

1. Much harder surfaces, which experience has proved are vastly more durable than similar unchilled surfaces.
2. A hard guiding surface with a relatively soft carriage, bringing the bulk of the wear on the carriage and thus maintaining the alignment of the guide.
3. A denser and much more closely grained surface of the casting, giving better appearance.
4. An exceptionally smooth finished surface, in which there are no pores where dirt and grit may become imbedded to cause rapid abrasion of the other bearing surface.

There are several ways of increasing the durability of working parts, such as by increasing the area of the bearing, by providing more complete lubrication, and by hardening the surfaces. All are successfully used. In general, each method may be used independently of the others. If the areas of the surfaces are as large as special conditions permit, and if the lubrication is thoroughly efficient, there would seem to be no objection to still further increasing the durability by the use of chills. Chilled surfaces are more advantageous on some machines and some parts than on others. In the case of a lathe the carriage will often be used for long periods of time on chuck work or on short jobs between centers which brings all of the wear on a comparatively short length of the bed just in front of the headstock; such uneven wear on the unchilled bed destroys the accuracy of the alignment for long work. Chilling the ways brings the wear principally upon the carriage, and even if the carriage is worn, the alignment at all points along the bed will remain relatively true.

Only one manufacturer of all who were kind enough to reply on this subject, had discontinued the use of chills; the others who are using chills do not report any trouble due to scratching. The objections to the use of chills, aside from the one instance quoted, have come from foundrymen who do not and have not used chills. Our own experience, based on the use of chilled ways on beds of all sizes of our lathes for more than two years, is that no internal stresses are created by the chilling; that the surface is not made more susceptible to a peening action; that the surface can be equally as well lubricated as before; that iron of high tensile strength is used; and that the increased hardness and closeness of grain of the chilled surface vastly increases the durability and permanency of alignment. We find no disadvantage except a somewhat increased cost.

Tensile Strengths of Various Irons

As the letters received from other machine tool manufacturers do not state tensile strengths, the following statements regarding the general practice of Cincinnati manufacturers are quoted:

A Professor of Mechanical Engineering and Testing: I believe the general Cincinnati machine tool practice for good castings runs from 22,000 to 24,000 pounds per square inch, tensile strength, but owing to the great variety I would not wish to commit myself to any particular figures.

A Cincinnati Chemist: After tabulating the results of my tests of the tensile strength of cast iron from various sources, I pick some at random to show the average run of machine tool iron in pounds per square inch in this locality: 22,962; 21,090; 24,522; 23,197; 23,260.

This will give an idea of what the general run is. Good machineable iron, where the grain does not have to be too close for machine tool work, should run from 20,000 to 26,000 pounds per square inch. Low tensile strength is due to too much silicon, sulphur, or phosphorus.

PRINCIPLES OF BAND-BRAKE DESIGN*

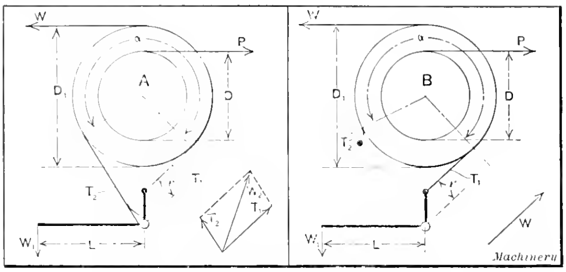
FORMULAS AND DATA WHICH SIMPLIFY THE CALCULATIONS INVOLVED

BY G. M. DAHL†

The purpose of this article is to deal very briefly with the fundamental principles of band-brake design. The brakes considered are classified under two general headings: 1, single-acting brakes, the most important feature of which is that they are good lowering brakes; 2, differential brakes, the most important feature of which is that they are good holding brakes but are liable to give a jerky lowering action, especially when the ratio $\frac{r}{r_1}$ is close to the locking ratio. Bearing in mind the features of these two classes of band-brakes, it will be evident that a single-acting brake should be used when a safe and steady lowering of the load is essential, but when the object is simply to hold a heavy load, a differential brake will be found most satisfactory. It must not be inferred from this statement that a single-acting brake cannot be made to hold a heavy load. From the formula,

$$\frac{L}{r} = \frac{FW}{W_1}$$

it will be easily seen that it is merely a question of making



Figs. 1 and 2. Single-acting Band-brakes; A, One End Loose on Shaft; B, One End Fastened

the ratio $\frac{L}{r}$ sufficiently large, and when this is done any kind of brake can be made to hold the required load. The ratio $\frac{L}{r}$ will, however, be limited by practical considerations in most cases of band-brake design.

Another important consideration is the bending stress on the drum-shaft that is produced by setting the brake. The bending stress on the brake-shaft is not of such importance because the brake-shaft can easily be supported by brackets on the bed plate of the hoist, thus reducing the bending moment to a minimum. In the case of the drum-shaft, however, this cannot be effected without considerably increasing the cost of the hoist and complicating its design. It is therefore essential to reduce the bending stress on the drum-shaft to a minimum. This result is obtained by increasing the arc of contact and the coefficient of friction, and also by locating the brake-shaft in such a way that the resultant bending stress produced by the brake acts in the opposite direction to the rope pull. Even though the location of the brake-shaft may be determined by the general design of the hoist, it is always well to remember that the location of the shaft within these fixed limits is a matter of importance.

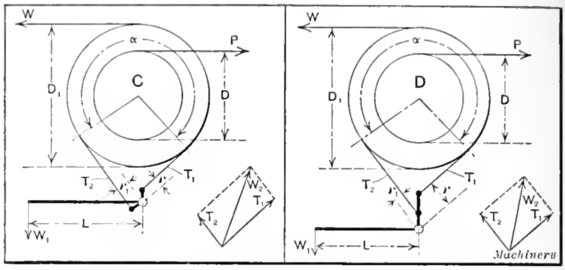


Fig. 3. Single-acting Band-brake C with Both Ends pulling.
Fig. 4. Differential Band-brake D

In order t ofacilitate calculations in the design of band-brakes, the following formulas are given:

$$F = \frac{W_1 \frac{L}{r}}{W} \qquad (1) \qquad\qquad W = \frac{W_1 \frac{L}{r}}{F} \qquad (2)$$

$$W_1 = \frac{FW}{\frac{L}{r}} \qquad (3) \qquad\qquad \frac{L}{r} = \frac{FW}{W_1} \qquad (4)$$

Examples illustrating the use of these formulas are given in subsequent paragraphs, which make the method of procedure quite clear. Figs. 1, 2 and 3 show different arrangements of single-acting band-brakes, while Fig. 4 illustrates the differential type of band-brake. The following explains the notation used in these illustrations:

P = rope pull in pounds = $\frac{WD_1}{D}$;

W = load on brake ring in pounds = $\frac{PD}{D_1}$;

D = diameter of rope circle in inches = $\frac{WD_1}{P}$;

Machinery

* For further information on the subject of band brake design, see "Band and Block Brakes," by A. L. Campbell, published in MACHINERY, October, 1908; "Friction Brakes," by H. D. James, August, 1908; "Brakes," by C. F. Blake, August, September, October and November, 1906; and "Notes on Band Brake Design," by C. F. Blake, March, 1905.

† Address: 588 Henry St., Brooklyn, N. Y.

D_1 = diameter of brake ring in inches $= \dfrac{PD}{W}$;

r = distance from center of brake-shaft to slack side of brake-band in inches $= \dfrac{W_1 L}{FW}$;

r_1 = distance from center of brake-shaft to taut side of brake-band in inches;

L = length of brake-lever in inches $= \dfrac{FrW}{W_1}$;

F = force required at radius r to hold a load W of 1 pound on the brake ring;

$F = T_1$ for a nsigle-acting brake with one end pulling;

$F = T_1$ for a single-acting brake with one end pulling;

$F = T_1 - \dfrac{T_2}{\dfrac{r}{r_1}}$ for differential brakes;

T_1 = tension in slack end of band in pounds $= \dfrac{W}{N-1}$
$= T_2 - W$;

T_2 = tension in taut end of band in pounds $= \dfrac{WN}{N-1}$
$= W + T_1$;

W_2 = load on brake-shaft in pounds. This quantity is the resultant of T_1 and T_2 which is shown graphically in the illustration of the different styles of brakes.

$N = \dfrac{T_2}{T_1}$ = locking ratio of $\dfrac{r}{r_1}$. The ratio $\dfrac{r}{r_1}$ must be at least 1.5 N to prevent differential brakes from locking themselves. Log $N = Cf$. Values of the constant C for various arcs of contact and coefficients of friction are given in Table I.

f = coefficient of friction. For maple in contact with cast iron, the coefficient of friction $f = 0.18$; for a 75-degree V-brake with plain maple blocks, $f = 0.30$ = cosecant $\dfrac{75 \text{ degrees}}{2} \times f = 1.6427 \times 0.18 = 0.296$; for cork on cast iron $f = 0.35$; for a 75-degrees V-brake with cork inserts f 0.57.

A = minimum area of cross-section of wrought iron brake-band in square inches calculated for a fiber stress of 8000 pounds per square inch. This value of the fiber stress ought not to be exceeded for wrought-iron brake-bands.

The values of T_1 and T_2 and A are given in Table I for a load W of one pound on the brake ring. For any other load, the values given in the table are multiplied by that load. The force F required at a radius r to hold a load W of one pound on the brake ring is given in Tables II, III and IV, for different arcs of contact, coefficients of friction, and ratios $\dfrac{r}{r_1}$ for differential brakes. For any other arc of contact or ratios $\dfrac{r}{r_1}$, it will be accurate enough to interpolate between the values given in the table, although it is not strictly correct. It is important to observe at this point that it is not advisable to interpolate for coefficients of friction lying between the values given in the table.

In order to illustrate the use of the formulas and tables presented in this article, the following problems are worked out. These problems cover the different cases which may occur in band-brake design.

Example 1. To determine the most suitable style of brake to use for a given class of service. Consider a case in which the brake-ring load $W = 30{,}000$ pounds; the brake-lever load $W_1 = 150$ pounds; the ratio $\dfrac{L}{r} = 20$; and the arc of contact = 280 degrees. For these conditions:

$$F = \frac{W_1 \dfrac{L}{r}}{W} = \frac{150 \times 20}{30{,}000} = 0.10.$$

The only suitable brakes for this case are found in Tables

Machinery

II, III and IV, for an arc of contact of 280 degrees, and $F = 0.10$. In Table II, for a single-acting V-brake with cork inserts and one end pulling, $f = 0.57$ and $F = 0.066$. This brake will hold the load with a load on the brake-lever:

$$W_1 = \frac{FW}{\frac{L}{r}} = \frac{0.066 \times 30{,}000}{20} = 99 \text{ pounds}$$

By making the load on the brake-lever $W_1 = 150$ pounds, the load can be held by proportioning the brake mechanism so that ratio $\frac{L}{r} = \frac{FW}{W_1} = \frac{0.066 \times 30{,}000}{150} = 13.2$. Referring to Table I, for an arc of contact of 280 degrees and a coefficient of friction $f = 0.57$, the value of A is found to be 0.000133. Multiplying this value by 30,000 for the case under consideration, the minimum cross-sectional area of the brake-band is found to be $0.000133 \times 30{,}000 = 3.99$ square inches. It is evident that a single-acting band-brake with both ends pulling cannot be used in this case because the minimum value of F for $f = 0.57$ is found to be 1.132, which is greater than the previously determined maximum value of 0.10.

Next consider the case of a differential brake in which $F = 0.10$; $f = 0.18$ and $\frac{r}{r_1} = 2.8$. The ratio $\frac{r}{r_1}$ is seen to be too close to the locking ratio 2.41 given in Table I, for it will be remembered that the value of this ratio for differential brakes must be at least 1.5 times the locking ratio in order to prevent the brake from locking itself. For a brake with $F = 0.10$, $f = 0.30$ and $\frac{r}{r_1} = 6.5$, the locking ratio given in Table I is found to be 4.34. This brake may be used, as the ratio $\frac{r}{r_1} = 6.5 = 1.5 \times 4.34$. The value of A in Table I is found to be 0.000163. Multiplying this value by 30,000 gives $0.000163 \times 30{,}000 = 4.89$ square inches, as the minimum cross-sectional area of the brake-band. For a differential brake with $F = 0.10$, $f = 0.35$ and $\frac{r}{r_1} = 11.0$, the locking ratio given in Table I is 5.54. This brake may be used, as the ratio $\frac{r}{r_1}$ is greater than 1.5 times the locking ratio. The value of A given in Table I is found to be 0.000153. Multiplying this coefficient by the load gives $0.000153 \times 30{,}000 = 4.59$ square inches as the minimum value of the cross-sectional area of the brake-band.

Example 2. For a given brake, to determine the load that may be held on the brake ring with a given load on the lever. Consider the case of a single-acting V-brake with both ends pulling, arc of contact 260 degrees; $\frac{L}{r} = 25$; $W_1 = 100$ pounds; $f = 0.30$. Referring to Table II, the value of F is found to be 1.69. The load that can be held is:

$$W = \frac{W_1 \frac{L}{r}}{F} = \frac{100 \times 25}{1.69} = 1480 \text{ pounds}$$

The value of A in Table I is found to be 0.000168. Multiplying this value by the load gives $1480 \times 0.000168 = 0.249$ square inches as the minimum cross-sectional area of the brake-band.

Example 3. For a given brake, to determine the load required on the lever to hold a specified load on the brake ring. As an example, consider a single-acting brake with one end pulling; arc of contact 270 degrees; coefficient of friction $f = 0.35$; ratio $\frac{L}{r} = 20$; $W = 12{,}000$ pounds. Referring to Table II, we find $F = 0.238$.

$$W_1 = \frac{FW}{\frac{L}{r}} = \frac{0.238 \times 12{,}000}{20} = 143 \text{ pounds.}$$

The value of the coefficient A given in Table I is found to be 0.000154. Multi-

plying this value by the load gives $0.000154 \times 12{,}000 = 1.848$ square inches as the minimum cross-sectional area for the brake-band.

Example 4. For a given brake, to determine the value of the ratio $\frac{L}{r}$ that is necessary to hold a specified load on the brake ring with a given load on the brake-lever. Consider the case of a differential brake with the ratio $\frac{r}{r_1} = 5$; the coefficient of friction $f = 0.18$; the arc of contact = 290 degrees; the load on the brake ring $W = 15{,}000$ pounds. The load on the brake-lever $W_1 = 150$ pounds. Referring to Table III, we find $F = 0.337$. The ratio is then found to be:

$$\frac{L}{r} = \frac{FW}{W_1} = \frac{0.337 \times 15{,}000}{150} = 33.7$$

The coefficient A found in Table I is 0.000209. Multiplying this value by the load gives $0.000209 \times 15{,}000 = 3.135$ square inches, as the minimum value of the cross-sectional area for the brake-band.

In order to show the effect of changing the arc of contact and coefficient of friction, Tables V and VI have been prepared for two brakes with arcs of contact of 220 and 320 degrees, respectively, and coefficients of friction ranging from 0.18 to 0.57. The load on the brake ring W is 10,000 pounds and the ratio $\frac{L}{r}$ is 20. The values of T_1 and T_2 are obtained from Table I, the values of the coefficients obtained from this table being multiplied by 10,000 in order to secure the correct values for the case under consideration. The bending force on the brake-shaft produced by setting the brake is found by constructing a parallelogram of forces on T_1 and T_2 to some convenient scale. The resultant of this parallelogram is the required bending force.

The method of calculating the load required on the brake lever has already been illustrated by following through a problem. In Table VI values of the brake-lever load W_1 have been calculated for the two brakes referred to in the preceding paragraph, for arcs of contact of 220 and 320 degrees, respectively, and coefficients of friction f ranging from 0.18 to 0.57. It will be readily seen from these results that a single-acting brake with both ends pulling is a very poor holding brake. It will also be seen that for a single-acting brake with one end pulling, the load required on the brake lever varies from 500 to 21 pounds as the result of increasing the arc of contact from 220 to 320 degrees, and increasing the coefficient of friction from 0.18 to 0.57. Of course the figures in Tables V and VI give a somewhat exaggerated idea of the difference between good and poor examples of band-brake design, but they emphasize the point that it is possible to materially reduce the strains and increase the holding power of the brake by proportioning its members properly.

By way of conclusion, the following may be said to constitute the underlying principles of band-brake design. Make the arc of contact as large as possible; locate the brake-shaft where the bending stress in the drum-shaft produced by setting the brake is counteracted by the rope pull; and, if necessary, increase the coefficient of friction to give the required holding power.

CALCULATION OF STRESSES IN AUTOMOBILE FRONT AXLES

BY JOHN L. ALDEN*

Automobile front axles are made of steel or bronze forgings, steel castings, or steel tubing, although bronze is seldom used except for emergency or experimental purposes. Steel castings are frequently used for truck axles, but axles of this material are seldom found in pleasure cars to-day. Steel tubing was also one of the favorite materials of the earlier designers, and is still successfully used on many light- and medium-weight cars. It has the advantage of being readily obtainable in its finished form, needs little or no machining, and the only forgings required are those for the steering heads and spring seats. By far the greater number of pleasure cars in operation to-day carry drop-forged front axles, and thus far no other type has even threatened their supremacy. Both carbon and alloy steels are being used with success. Carbon steels of 0.25 to 0.30 per cent have an elastic limit of from 40,000 to 80,000 pounds per square inch when heat-treated according to the recommendation of the Society of Automobile Engineers. Steel of this character may be allowed a fiber stress of 10,000 pounds per square inch, but this value may be safely raised to 15,000 pounds per square inch if the specifications are rigidly adhered to and if great care is taken in the forging and heat-treatment. The elastic limit of 0.30 to 0.35 per cent carbon nickel steel lies between 65,000 and 160,000 pounds per square inch when the S. A. E. recommendations are followed. Chrome-nickel steel with 0.25 to 0.40 per cent carbon has an elastic limit ranging from 50,000 to 125,000 pounds per square inch for low chrome-nickel and from 65,000 to 200,000 pounds per square inch for high chrome-nickel steel. The elastic limit of 0.25 to 0.45 per cent carbon, chrome-vanadium steel may vary from 55,000 to 200,000 pounds per square inch. Any of these alloy steels are suitable for structural drop-forgings, and when used for axles, an average working stress of 15,000 pounds per square inch, with a limit of 20,000 for exceptionally favorable conditions, is allowable. The lower value is more suitable for cars for quantity production or for any case where the greatest care cannot be taken in manufacture, as under these circumstances, the elastic limit of the material will be found to be in the neighborhood of the lower figures given for the metal under consideration.

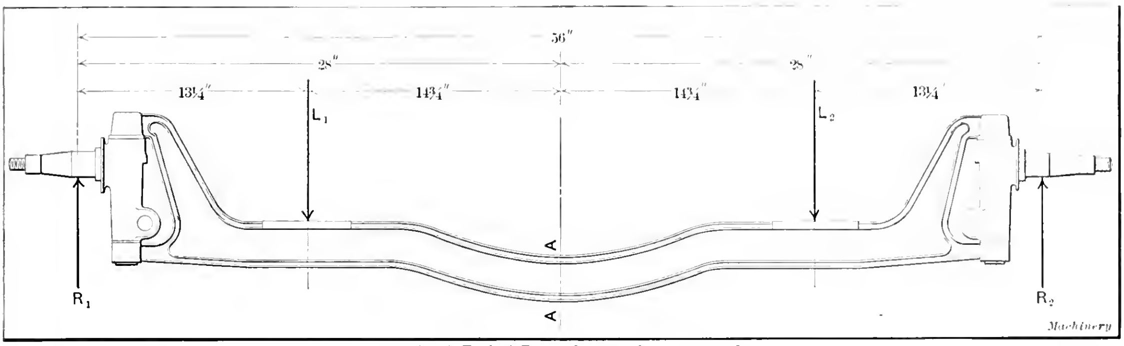

Fig. 1. A Typical Form of Automobile Front Axle

A typical front axle for a pleasure car is shown in Fig. 1. This is a drop-forging of an I-section similar to the one outlined in Fig. 2. The design shown is that of a well-known make equipped with Elliott type steering heads, and with the spring seats forged integral with the upper flange of the section. The I-shape is carried uniformly from spring seat to spring seat, as the bending moments due to the spring loads are equal at all points from L_1 to L_2. The top flange is flared from the width of the steering head bosses to the full width of the spring seat. When the car is in motion there are two sets of independent forces acting upon the axle—those caused by the weight of the car and those caused by the resistance of the road, due to striking obstacles, etc. The former are obviously vertical in direction, while the latter

* Address 701 Green Ave., Champaign, Ill.

have both vertical and horizontal components. It is evident that the maximum horizontal force which the axle will be called upon to resist is indeterminate. The same is true of the vertical component of the collision force. The factors upon which this force depends are the velocity of the car, the size and shape of the obstruction, the depression of the tire due to impact, and the unsprung weight of the axle, wheels, etc. The determination of the horizontal resisting moment of the axle is, therefore, largely a matter of judgment and experience on the part of the designer. Any calculation of the vertical resisting moment must also be incomplete, since we have no means of determining the limiting value of the collision force. If we calculate our section to carry the static load of the vehicle, using the values for the allowable fiber stress previously given, we will be sure of a reasonable result, as the large factor of safety is expressly intended to cover the stresses which we are unable to estimate. Consequently, if we select a section whose proportions have proved satisfactory in actual service, we will not go far wrong in the relation between our horizontal and vertical resisting moments. The section shown in Fig. 2 is an average of a number of successful designs used on modern cars, covering a wide range of weight, speed and price. Therefore, if the section of Fig. 2 is selected and we calculate its dimensions, using the spring seat loads, we may expect to be reasonably close to modern practice. We will now assume the necessary data and carry through a typical example, in which we shall consider the axle as a simple beam, supported at the wheel centers and symmetrically loaded at the spring seats.

We will consider the case of a 3600-pound touring car which, when loaded with five passengers, will weigh about 4350 pounds. In general, about 0.4 of the weight of a pleasure car is borne on the front axle, one-half of this being carried by each front spring. Thus the front axle load of our hypothetical car is $0.4 \times 4350 = 1740$ pounds and the load at each spring seat is 870 pounds. As the weight of the axle itself rarely exceeds 80 or 85 pounds, we may safely neglect this item. The principal dimensions will be assumed to be as given in Fig. 1. The statement has already been made that the bending moment due to the static load is maximum and equal at all points from L_1 to L_2. Hence the critical section may be chosen anywhere between the spring seats. Then, taking our section at A–A, we have the maximum bending moment:

$M_a = 28 \times 870 - 14.75 \times 870 = 13.25 \times 870 = 11{,}528$ inch-pounds.

Using the formula for beams:

$$M = SZ$$

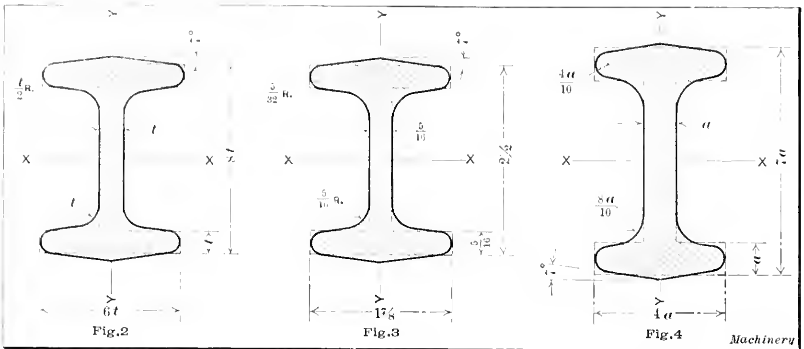
where M = maximum bending moment;

S = fiber stress due to the maximum bending moment;

Z = the section modulus.

We may solve for Z and the dimensions of the section, providing we assume a suitable fiber stress. Let us assign to S a value of 10,000 pounds per square inch. Then our flexure equation, when transposed, becomes:

$$Z = \frac{M}{S} = \frac{11{,}528}{10{,}000} = 1.15.$$



Figs. 2, 3 and 4. Two Forms of Sections used for Automobile Front Axles

Returning now to our average section, Fig. 2, it will be found much more simple and sufficiently accurate to base our calculations upon the equivalent section whose outline is shown dotted. The moment of inertia about the axis X–X is:

$$I_x = \frac{6\,t \times (8\,t)^3 - 2 \times 2.5\,t \times (6\,t)^3}{12} = 166\,t^4$$

$$Z_x = \frac{166\,t^4}{4\,t} = 41.5\,t^3$$

In the same manner:

$$I_y = \frac{2\,t \times (6\,t)^3 + 6\,t \times t^3}{12} = 36.5t^4$$

$$Z_y = \frac{36.5\,t^4}{3\,t} = 12.2t^3$$

$$\frac{Z_x}{Z_y} = \frac{41.5t^3}{12.2\,t^3} = 3.41$$

This signifies that the axle is 3.41 times as strong vertically as horizontally. The Z_x of our typical section is, according to the preceding calculations, $41.5\,t^3$; and the required value of Z_x of our axle is 1.15. Equating these, we have:

$$41.5\,t^3 = 1.15$$

$$t^3 = \frac{1.15}{41.5} = 0.0277.$$

$t = 0.3025$ inch or, to the nearest fraction, 5/16 inch.

From the value for t thus obtained all other dimensions for the section may be readily found. These are given in Fig. 3 for the case just discussed. By using these proportions, with the known section modulus, the cut-and-try methods commonly used are eliminated. It is evident that the calculations are thus much simplified.

Another section at one time in common use is shown in Fig. 4. The moments of inertia and section moduli are:

$$I_x = 83.1\,t^4; \qquad Z_x = 23.75\,t^3$$
$$I_y = 11.1\,t^4, \qquad Z_y = 5.56\,t^3$$
$$\frac{Z_x}{Z_y} = 4.27$$

This axle is, therefore, weaker in a horizontal plane than the one shown in Fig. 2. This would seem reasonable, as the horizontal force is due largely to shock and is proportional to the square of the velocity. Consequently, as the speed requirements increase, so should the horizontal resisting moment of the axle increase, which accounts for the gradual strengthening in this direction from year to year.

WOODEN SHOES MADE IN THE UNITED STATES

In this country beech is the favorite material for wooden shoes, the manufacture of which has reached considerable proportions in the United States according to the Department of Agriculture, which has just issued a bulletin on the use of the wood. These shoes, the department says, cost from sixty to seventy-five cents a pair and are good for two years. They are worn by those who have to work in cold or wet places, such as tanneries, breweries, and livery stables, and by workmen in steel mills and glass factories who must walk on hot grates or floors. Farmers, too, are classed among the users.

* * *

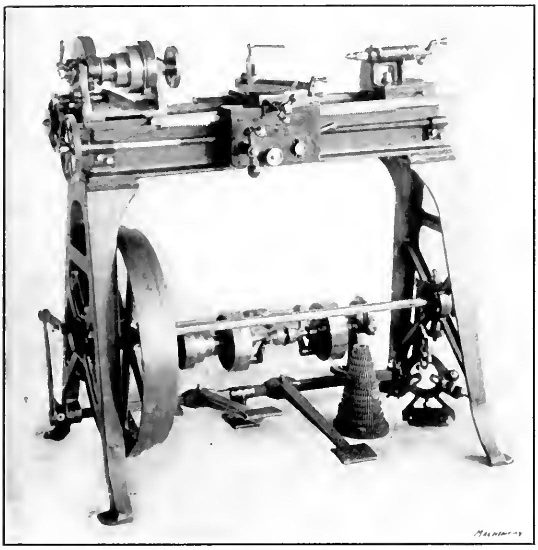
The melting points of some metals which fuse at very high temperatures are published by G. K. Burgess and R. G. Waltenberg in the *Journal of the Washington Academy of Science.* The melting points are as follows: Titanium, 1795 degrees C. (3263 degrees F.); vanadium, 1720 degrees C. (3128 degrees F.); chromium, 1520 degrees C. (2768 degrees F.); manganese, 1260 degrees C. (2300 degrees F.); iron, 1530 degrees C. (2786 degrees F.); cobalt, 1478 degrees C. (2692 degrees F.); nickel, 1452 degrees C. (2545 degrees F.)

A TRADE SCHOOL PRODUCT*

BY JAMES F. JOHNSON†

A commercial product of the State Trade Education Shop of Bridgeport, Conn., is shown in the accompanying illustration. The machine is a 9-inch screw-cutting lathe designed to cut from four to forty threads per inch. It is fitted with steady-rest, follow-rest, and attachments for taper turning, and has a compound rest graduated to 180 degrees. The carriage is fitted with a power cross-feed and a micrometer collar reading to thousandths. In case the countershaft drive is not desired, the lathe is made convertible so that foot power drive may be substituted, as the illustration indicates.

These lathes are constructed for the purpose of giving the apprentice definite training along just such lines as he will encounter when he has completed his trade school work, as he performs a variety of work involving many operations. The fact that it is a commercial product, requires a degree of accuracy that the apprentice would not find in other work. The delivery being promised at a certain date, keeps the boys on the alert, and with a careful system of time keeping and job cards, the apprentice is placed under the same conditions as exist in modern machine shops, while, at the same time, he is receiving definite instruction in his particular trade. To enable him to better understand the work and make him a more thorough mechanic, there is taught in connection with shop work, practical shop mechanics and shop mathematics.



Nine-inch Screw Cutting Lathe built by Apprentice Boys at State Trade Education Shop, Bridgeport, Conn.

The boy who cuts a lead-screw for a lathe has a mathematical understanding of screw threads, including the Acme thread and the square thread; the depth of the cut for this particular pitch as well as other pitches; the area of the section across the bottom of the screw, as well as problems relating to the time element in cutting the screw. In shop mechanics, the apprentice learns about gear combinations for cutting this particular pitch thread in the lead-screw; how speeds are effected by compounding gear trains; and similar problems.

The boys that cut the gears used on the lathe are taught in their shop mathematics the method of finding the diameter of the gear blanks for this particular pitch gear and for other gears; the required depth of cut for forming a tooth, and calculations concerning other problems in gearing. In mechanics the boys study subjects relating to the strength of gear teeth, speeds of gears, etc.

In the shop drawing class instruction is given in blueprint reading and the making of such drawings as are necessary to enable the boys to understand clearly the relation of the blueprints to shop practice. Instruction is also given in the making of working sketches such as the up-to-date mechanic is often called upon to make.

The lathe illustrated is a complete product of the boys of the trade school, each department contributing its part in making it a commercial success. The design for the lathe and the necessary tools, jigs and fixtures for its completion, were made in the drafting department. The drafting department was thus enabled to do real drafting and now takes much pride in reviewing the results of its work. Real live problems were furnished as, for example, the design of the proper gear train to cut the desired threads, the change necessary to cut the standard metric threads; the design of the headstock, the power cross-feed, together with the compound rest, and the apron mechanism.

The patterns were built by the boys in the patternmaking department, where the same shop conditions prevailed. The apprentice patternmaker worked from the drawings made by the apprentice draftsman and these furnished the necessary instruction for the patternmaking foreman. As we have no cupola, our castings were made outside. This gave our patterns a severe but very successful test. This fact together with the fact that the completed machine was a success, gave the boys considerable self-confidence and a realization of what was before them in the trade.

In the machine shop the apprentices handled the castings made from the patterns built by the apprentice patternmakers and machined them according to the drawings made by the drafting room apprentices. The work in the machine shop was so arranged that each apprentice was carried through a well organized scheme of machine shop practice, the boys securing a good systematic training. They quickly realized the importance of the job and an active and eager interest was always shown. As in all departments, the standard and accuracy of the work accepted was that of the successful machine shop.

After the apprentices assembled the lathes, they were all tested as to running qualities, feeds, thread cutting, and accuracy of turning—this last test showing a variation of 0.0005 inch on a test bar 20 inches long. The boys in the paint shop put on the final touches and the machines were crated by the carpenters and shipped to the customer. The value of this work in instructing the apprentice in his future trade can hardly be overestimated. He is put under shop conditions at work upon a product that is going to be of use to somebody and he is right "up against it," so to speak. He is able to see what will be expected of him later, and he gets an excellent opportunity to learn his trade under real trade atmosphere.

Since its organization, the policy of the school has been to instruct the apprentice in his trade by giving him real trade work, placing him directly under the care of men who are skilled tradesmen in the particular line he is following. In all departments we have been able to do this successfully. These courses in the trade school at Bridgeport are open to any boy between the ages of fourteen and sixteen, or to any boy who has completed the sixth grade at school. He must attend the shops forty-eight hundred hours and perform his work in an acceptable manner. In connection with his trade practice, he devotes about twelve hundred hours to receiving instruction in blueprint reading, practical shop drawings, shop mathematics and practical shop mechanics.

That the depleting ranks of the tradesmen must be filled is a certainty. That our tradesmen need training in their work can no longer be argued. That the American trades need a better class of skilled intelligent workmen is shown in the products of our European friends. If we as a nation are to be supreme in trade pursuits, we must educate our tradesmen and supply the trades with the best class of tradesmen possible. Our trade school is far-reaching. By means of our continuation school, part time school, and evening school, we are able to reach those who would not receive the benefit of the regular day trade course.

From an educational standpoint we are able to give the boy who would otherwise leave school at fourteen to sixteen, and either enter an occupation with no future for him or hang around and become a nuisance to his friends and himself, a chance to make good and amount to something.

* See "Woods Apprentice Industrial School," December, 1913.

LATTICE BAR SPACING TABLES

BY CHARLES B. GILBERT*

The accompanying tables for finding the pitch of rivet holes for lattice bars will be found useful both in the drafting-room and in the fabrication plant. The tables give spacing for 2 to 21 spaces inclusive, beginning with 6-inch pitch and advancing by eighths to 12-inch pitch.

The use of the tables is simple, of course. For example, what is the over-all distance center to center of 20 rivet holes in a straight line, the pitch being 6⅝ inches? Inasmuch as there are 20 rivets, there are 19 spaces. Referring to the table opposite 19 and underneath 6⅝, we find 10′ 5⅞″, the distance from center to center of the outside rivet holes.

No. of Spaces	Pitch 6″	6⅛″	6¼″	6⅜″	6½″	6⅝″	6¾″	6⅞″	7″	7⅛″	7¼″	7⅜″	7½″	7⅝″	7¾″	7⅞″	No. of Spaces

MAKING HIGH-EFFICIENCY WORM-GEARING*

METHODS EMPLOYED BY THE CLEVELAND WORM & GEAR CO

BY DOUGLAS T. HAMILTON†

In an endeavor to secure quiet running and efficient rear axle drives for automobiles, various types of gearing have been employed, bevel and worm gearing being the two types most generally used. Bevel gearing has been used with considerable success, and when properly made and aligned shows a high efficiency with comparative quietness in action. When bevel gears begin to wear, however, backlash is introduced, tending to produce "clatter" and the familiar humming sound emitted from a transmission case. Dis-alignment of the gearing reduces the efficiency and also produces noise. Within the last few years worm-gearing has been receiving considerable attention on the part of automobile manufacturers for the following reasons: it is possible to produce this type of drive, with the proper equipment, more cheaply than the best bevel

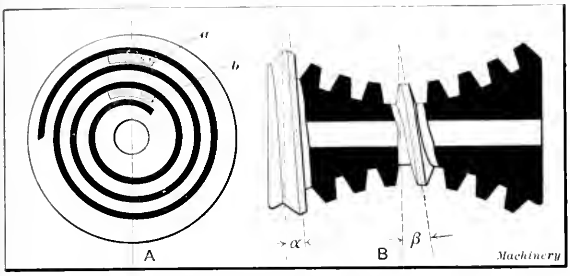

Fig. 1. Diagram illustrating an Objectionable Point in the Contact of the Globoid or Hindley Type of Worm

gearing; it is much more quiet in action; has a longer life; and if properly made, has a higher efficiency and smoother action.

Different Types of Worm-gearing

Generally speaking, there are three distinct types of worm-gearing that have been applied to rear axle drives. The first is the common type of worm drive produced by the ordinary gear hobbing machine method, which generally shows a comparatively low efficiency. The second type is globoid gearing, more commonly called Hindley or hour-glass type of worm-gearing. This shows a very high efficiency, but owing to the refinement necessary in its manufacture and alignment, as will be described later, has not given the satisfactory service that its design would indicate. The third type, and the one on which this article is based, is not so well known as

Fig. 2. Cutting a Straight Worm-wheel by Means of the Tapered Hob Method

the other two, but judging from various experiments and tests that have been made gives a high efficiency and long life combined with quiet running and smooth action. It is known as the "straight worm" type of drive, this name serving to differentiate it from the Hindley type in which the

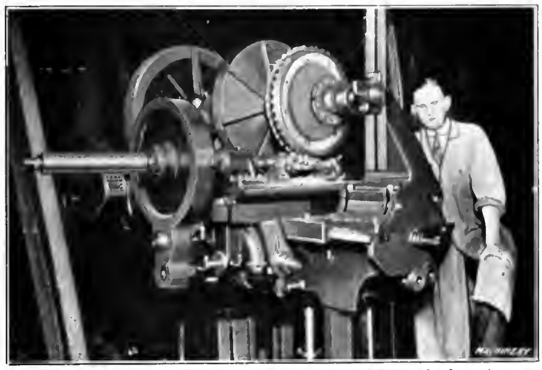

Fig. 3. Machine used for cutting Straight Worm-wheels using Tapered Hobs

worm is curved to conform with the circumference of the worm-wheel.

Globoid or Hindley Worm-gearing

The purpose in designing globoid or Hindley worm-gearing is to enlarge the surfaces in contact so as to reduce wear, and obtain relatively small dimensions—pitch of teeth, etc. While, theoretically speaking, the conditions obtained in this

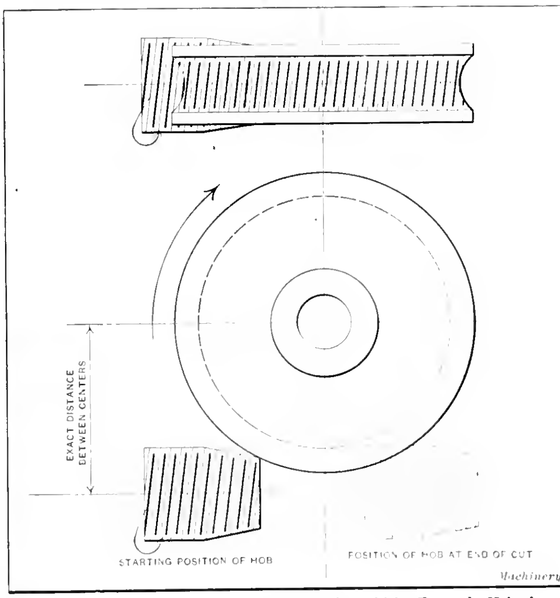

Fig. 4. Diagram illustrating Manner in which Tapered Hob is presented to Worm-wheel Blank

type of gearing would seem almost perfect, there are, in practice, serious objections to its use where dis-alignment of the gearing occurs. To illustrate one weak point in this type of gearing Fig. 1 is presented, in which the ordinary type of scroll used in lathe chucks serves as a means of illustration and comparison. In Position 1 one tooth of the jaw *a* is put into the outer part of the scroll, and in Position 2, the tooth *b* of the jaw is put in the inner part of the scroll. It will be observed that, in theory, the tooth of the jaw has contact only on one vertical line. Now on an ordinary screw the pitch angle depends on the lead and on the pitch diameter, and the angle of inclination of the threads is uniform from end to end. Such is not the case in the Hindley worm where the diameter increases with the length, or in other words, enlarges on each side of a vertical line drawn through the

* For additional information on the making and application of worm-gearing for various purposes, see the following articles previously published in MACHINERY, "Making Hindley Worm Gearing at the Brooklyn Navy Yard," November, 1912; "Efficiency of Worm-Gearing for Automobile Transmissions," September, 1912; "Worm and Helical Gears as Applied to Rear Axle Drives," September, 1912 (engineering edition); "Cutting Hindley Worm-Gearing on the Schuchardt & Schutte Gear-Hobbing Machine," July, 1911; "Table for Calculating the Outside Diameter of Worm-Wheels," April, 1911; "Worm-Gearing Employed for Freight Elevators," December, 1910; "Allowable Load and Efficiency of Worm Gearing," September, 1910; and other articles there referred to.

†Associate Editor of MACHINERY.

axis of the worm-wheel and the center of the worm.

At B in Fig. 1 it will be seen that the angle β of the screw line in the middle portion of the globoid worm is greater than the angle α at the outside. This means that the conditions of contact are similar to those in the lathe scroll as shown at A in Fig. 1. Further, the difference in the theoretical peripheral velocity of the worm would have a tendency to retard the advance of the worm-wheel. From these and other well-known points in gearing, it is evident that the conditions for contact are not so favorable as they are sometimes supposed. In practice, it is not a simple matter in all cases to get the center or hollow of the worm exactly in conformity with the center of the worm-wheel. This, however, is one of the conditions necessary in the alignment of Hindley worm-gearing if good results are to be expected. Hindley worm-gearing shows a very high efficiency when new and when set up in proper alignment, but just as soon as the least wear begins to take place, the efficiency immediately drops. This subject has been admirably treated in an

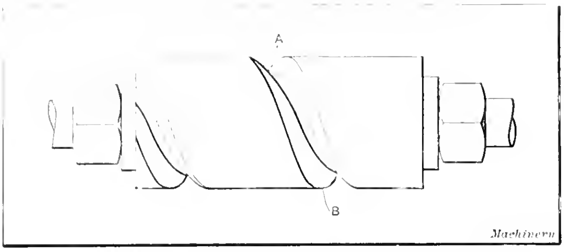

Fig. 5. Diagram illustrating Reverse Curve that is produced on Worm-wheel Teeth by hobbing with a Tapered Hob fed longitudinally and at Right Angles to the Axis of the Worm-wheel Blank

article entitled "The Hindley Worm Gear," by John Edgar, which appeared in the December, 1908, number of MACHINERY, engineering edition.

Straight Worm Type of Worm-gearing

The worm-gearing to be described in the following is known as the "straight worm" type, as previously mentioned. In the straight worm type the difficulties in alignment common to globoid gearing are eliminated, because the center portion of the worm does not have to bear any direct relation to the center of the worm-wheel. The only requirement is that the center distances of the worm and worm-wheel must be exact if perfect action and high efficiency are to result. In the method to be described, this important point is carefully provided for and is comparatively easy of attainment. Fig. 2 shows a close view of the machine used for cutting the straight type of worm-wheel. By this method a taper worm hob *A* held on the arbor *B* is used. The arbor is supported in bearing shoes *C* which are retained in blocks fastened to the table of the machine. The hob is set by means of a

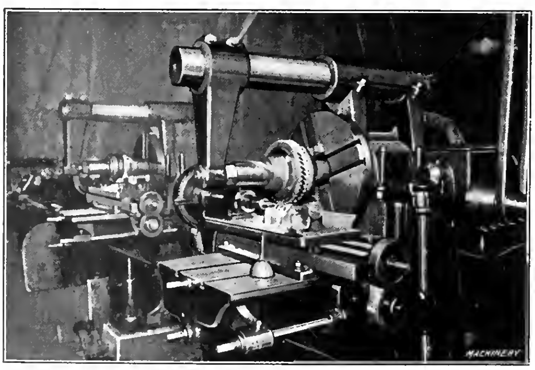

Fig. 6. Two Special Hobbing Machines at work on Worm-wheels for Electric Automobile Rear Axle Drives

vernier and scale at the exact center distance in relation to the worm-wheel blank, and as shown in Fig. 3 is very rigidly supported. The worm hob and work are rotated in the correct relation to each other, and at the same time the hob is fed in a longitudinal direction as indicated in Fig. 4, past the axis of the worm-wheel.

Ordinary and Taper Hob Method of Hobbing Worm-wheels Compared

By applying the hob to the work in the method just described, a theoretically correct and accurate worm-gear is produced, which cannot be excelled where high pitch angles or wide wheel faces—wide in relation to the worm—are concerned. By such a method of production the area of contact between the worm and worm-wheel is as large as possible,

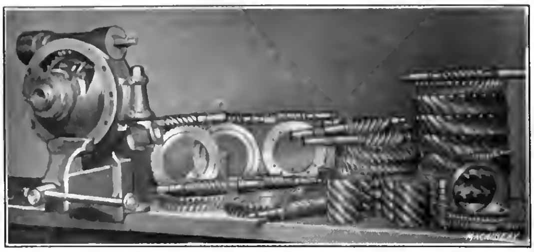

Fig. 7. Group of Straight Worm and Worm-wheels used for Rear Axle Automobile Drives

and provided that a good combination of materials is used, *viz.*, a high grade of phosphor-bronze for the worm-wheel and a good grade of casehardening steel for the worm, this type of gearing shows no appreciable wear under the heaviest loads after having run for a practically unlimited time. In cutting the worm-wheel in this manner, the reversible curve *AB*, Fig. 5, is actually obtained in the worm-wheel tooth. This curve conforms to the path followed by a tooth of the worm in rotating, and in practice is considered to give a surface contact which is impossible to obtain by hobbing worm-wheels in the old way.

The method ordinarily used in hobbing worm-wheels is to gear up the mechanism driving the hob with that actuating

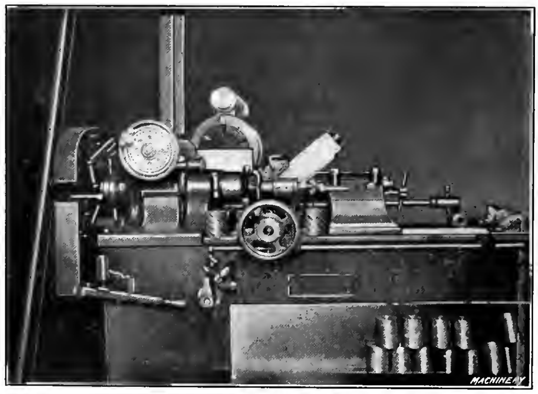

Fig. 8. Thread Milling Machine used for cutting Worms and Tapered Hobs

the dividing wheel which controls the indexing or rotation of the worm-wheel, and to feed the hob axially into the worm-wheel, both hob and blank being rotated at the same time. This action is continued until the hob has been fed in to the correct depth. Now in analyzing this method of cutting the worm-wheel, it will be seen that by presenting the hob in this manner it does not produce a tooth of a theoretically correct shape, for the simple reason that the hob cuts away certain portions of the tooth that are necessary to give a perfect contact with the worm. This is due to the constant changing of the theoretical helix angle of the hob while being fed in axially. Instead, therefore, of producing a worm-wheel tooth that has a reverse curve corresponding with the path through which the face of the worm tooth travels in rotating, this method removes a certain amount of the surface of the worm-wheel tooth that should come in contact with the worm, and in theory the line of contact between a worm-wheel (cut in this manner) and the worm is only on the center. The worm-wheel teeth are relieved toward each end and do not contact at all with the teeth of the worm, these portions of the worm-wheel teeth being removed by the hob in forming them. It will therefore be seen that this method never produces a correct tooth form, and its failings are especially

noticeable as soon as the pitch angle or width of the worm-wheel face becomes somewhat great, resulting in the mutilation of the teeth.

Cutting Straight Worm-wheels

Fig. 3 shows one of the machines employed by the Cleveland Worm & Gear Co., Cleveland, Ohio, for cutting "straight worm-wheels." The hob arbor and the work arbor on this machine both have a positive drive, which is governed by a series of change gears to obtain the required ratio between the worm-wheel and hob. The hob *A*, see Fig. 2, is fed longitudinally and automatically under the blank at the correct speed by means of another series of change gears, located at the left-hand end of the worm-shaft, which drives the work arbor through the dividing wheel. The table of this machine cannot be swiveled one way or the other from a position at right angles to the axis of the work arbor, thus avoiding trouble which has often occurred in the making of worm-gearing by not having the hob cut the worm-wheel at an angle of exactly 90 degrees with the hob axis. When the worm-wheel teeth have not been cut at the correct angle great friction is introduced between the worm and the worm-wheel, especially when the worm is forced to fit in the housing provided for it, which naturally would be machined exactly at an angle of 90 degrees. This machine also has power feeds in all directions and could be used for cutting the Hindley type of worm-gearing if so desired.

In Fig. 6 are shown two smaller type machines at work on worm-wheels for electric pleasure cars, which is one of the

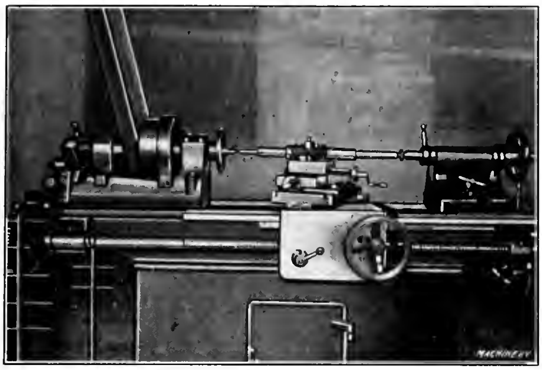

Fig. 9. A Special Type of Lathe used for backing-off or relieving Tapered Hobs

prominent uses being made of this type of worm-wheel. One peculiar feature which is noticeable in cutting a worm-wheel by the tapered hob method illustrated in Fig. 2 is that the hob, in starting to cut on the small end, produces a series of steps on the outside faces of the worm-wheel teeth, and as it feeds in further, the steps are produced on the other side of the teeth. Then as the cutter passes the center all marks are removed, producing a particularly smooth surface and correctly shaped teeth. The two positions of the hob before and after cutting the worm-wheel are indicated in Fig. 4. The hob is fed past the axis of the worm-wheel until the last tooth of the hob passes out of contact with the worm-wheel teeth; this action produces the reverse curve previously referred to. The chief advantages claimed for this worm-wheel is that it has a perfect surface bearing (this, theoretically, would be only a line bearing, but with the aid of the oil film becomes in practice a surface bearing) with the worm teeth for its entire arc of contact. It is also cut theoretically correct, which cannot be said of the ordinary method of worm-wheel hobbing.

A very high degree of accuracy can be obtained by this method of hobbing worm-wheels, owing to the fact that the full size of the hob does not come into play until the finishing cut is reached, so that the teeth of the hob tend to preserve their shape indefinitely. Another point, previously mentioned, that tends to produce accuracy is the fact that the distance between the work arbor and the hob spindle is at all times fixed at exactly the distance between the axis of the worm-wheel and the worm in the finished gearing. This is a refinement of greater importance than is usually realized, and one that is not always looked out for in hobbing operations in which the cutter spindle is fed in toward the work.

Efficiency of Straight Worm-gearing

In order to prove that worm-wheels cut by this method would work out as satisfactorily in practice as theoretical considerations indicated, a number of tests were made by a prominent concern manufacturing pleasure electric cars. In these tests it was found that the efficiency was very high, averaging from 90 to 98 per cent. Continual running ap-

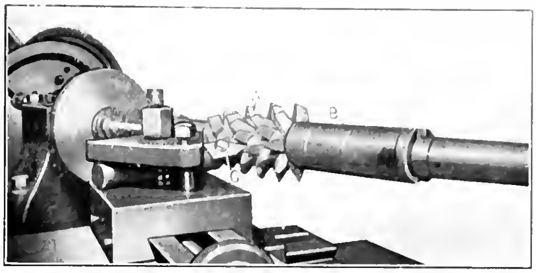

Fig. 10. Close View of Machine shown in Fig. 9 illustrating Method of applying Cutting Tool to Tapered Hob

peared to have but very little effect on the efficiency, and the wear was almost negligible. The way in which the worm and worm-wheels are mounted before being placed in the testing machine is indicated in Fig. 7, where a completed rear axle unit is shown held in an ordinary bench vise. Both worm and worm-wheel shafts run in ball bearings and are held in place so that the center distances of the worm and worm-wheel cannot change due to wear; the only effect that wear has on this type of gearing is to increase the backlash between the worm and worm-wheel teeth. It was also found in these tests that, as far as noise was concerned, the ball bearings did not run anywhere nearly as quietly as the worm and worm-wheel did, which would indicate that from this point of view the conditions met with in this type of gearing are almost ideal. This type of worm-gearing has also proved highly satisfactory for reduction gearing in connection with electric motors. A particularly good example which illustrates the adaptability of this type of gearing to large reductions was a reduction gear having a ratio of 903 to 2 that showed an efficiency of 80 per cent when transmitting 10 horsepower under tests covering a considerable period of time.

Cutting a Straight Worm

The Cleveland Worm & Gear Co. uses a thread milling machine of the type shown in Fig. 8 for cutting straight worms. By means of this machine worm milling becomes quite a sim-

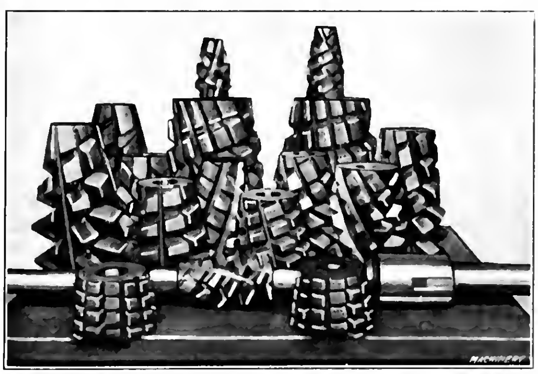

Fig. 11. Group of Tapered Hobs—One necessary for Every Pitch, Pitch Diameter and Variation in Number of Starts on Worm

ple matter, and the machines are so simple in operation that intelligent workmen can easily handle them and turn out good work cheaply and satisfactorily. The cutter head is accurately graduated and can be swiveled either way to the correct angle of the thread. The headstock spindle is hollow, allowing work to pass completely through it, and the cross-slide is provided with an automatic stop. The machine is also stopped automatically, at the end of a thread, thus insuring regularity of length when cutting multiple pitch

worms. There is, of course, as is evident in all milled spiral flutes, a tendency to leave the face of the worm thread cut somewhat concave. In order, therefore, to produce the best results, this company finds it advisable to rough out the worm on the thread milling machine illustrated, and leave a grinding allowance of 0.010 inch on each face of the thread. The worm, after hardening, is then ground by a special machine which corrects this concavity of the worm tooth and also removes any distortion which is likely to occur in hardening.

Making Tapered Hobs

The tapered hobs used for cutting the straight type of worm-wheels are roughed out in the thread milling machine shown in Fig. 8, and are then fluted in the milling machine; before hardening they are backed off in the special backing-off or relieving lathe shown in Fig. 9. This is a patented machine which has been constructed for making gear-cutters of every description as well as side relieved cutters with straight or spiral grooves, right- or left-handed; and if necessary it could be used as an ordinary engine lathe. The longitudinal feed of the carriage is actuated through change gears shown to the left of the machine, and a lead-screw in connection with the usual split nut.

The relieving mechanism works in either direction and can be easily reversed or released; it is actuated by means of a shaft running longitudinally inside of the bed of the machine and by gearing at the right-hand end of the machine. By means of easily interchangeable cams the clearance angles for each special tooth are obtained. The hob *A* to be relieved is held on a special arbor *B*, see Fig. 10, which in actual operation (it is not properly set up in the illustration) is held in the headstock spindle by a screw, and on the other end is supported in a taper bushing held in the tailstock spindle. By means of this method of retaining the arbor, deviation of the work during the relieving operation is impossible as the arbor withstands all pressure from the backing-off tooth *C*. By means of a system of change gears actuated by a lead-screw, a worm-drive and a differential gear, relieving can be obtained to any given length of left- or right-hand spiral. By this arrangement it is also possible to relieve, in addition to the ordinary plain and machine relieved cutters, taps and hobs with any given lead or number of spiral grooves. Provision for relieving spirally fluted hobs is secured by means of the change gears at the right-hand end of the machine. The spacing, of course, is accomplished with cams held on the screw running longitudinally inside of the machine bed. The hob thus relieved is accurate as to shape of tooth, and it is then hardened. In the event of any distortion from hardening, the hob is ground in the special worm-grinding machine previously mentioned.

Fig. 11 shows a group of tapered hobs of various pitches and sizes. For cutting straight worm gearing it is necessary to make a hob for every different pitch, pitch diameter and number of starts on the worm. In making a separate worm hob for each pitch and pitch diameter, the theoretically correctly shaped tooth on the worm-wheel is obtained. The reverse curve previously mentioned is also secured and the action of the worm-wheel teeth with the worm closely approximates ideal conditions. While the making of a hob for each pitch, pitch diameter and number of starts on the worm incurs considerable expense, it is evident that if a perfect working worm and worm-wheel is desired, the expense incident to the making of the hob is of minor consideration.

* * *

The Lackawanna R. R. has recently made tests to determine the practicability of communicating with moving trains by wireless telegraphy. The experiments thus far conducted indicate great possibilities. The Lackawanna has wireless stations at Scranton, Pa., and Binghamton, N. Y. The distance between these two stations is sixty-five miles, and it was found possible to maintain communication with a train running at the rate of fifty-five miles per hour, from one station to the other. The train was equipped with four quadrangular aerials mounted on the roofs of four adjacent cars. The heights of these aerials was limited to eighteen inches to avoid interference with tunnels and bridges. The regular Marconi system is employed except that power is supplied by a special motor-generator set driven from the train lighting dynamo. In the test referred to, when the train had proceeded to a point too far away for the low aerials on the cars to force signals back to the first station direct, the signals were delivered to the station ahead and relayed back to the starting point. At no time during the tests was the train out of communication with both stations.

FIRST INTERNATIONAL EXPOSITION OF SAFETY AND SANITATION

The First International Exposition of Safety and Sanitation was held in the Grand Central Palace, New York City, December 11-20. Among the large American industries exhibiting the advance that has been made in accident prevention and life-saving methods, appliances and devices were the Pennsylvania, New York Central, Southern Pacific, Baltimore & Ohio and Chicago & North Western railroads, the New York Edison Co., the New York Telephone Co., the National Cash Register Co., the Welin Marine Equipment Co., and the United States Steel Corporation.

The Pennsylvania R. R., which was awarded a gold medal by the American Museum of Safety last year for advance in safety, and which has a remarkable safety organization consisting of thirty safety committees, presided over by a central safety committee, had arranged an interesting exhibit based on practical experience. Men from the various shops demonstrated how they revive a comrade who has been shocked by coming in contact with a third rail.

The New York Central R. R. reproduced at the exposition the safety car which travels over all of the New York Central lines and in which lectures and practical demonstrations in safety work are given. This missionary car for safety was a feature of the exhibit. Other railroads showed progress in safety signaling systems, methods of inspection and rules regarding yard practice for employes.

The New York Edison Co. exhibited the many safety devices in use at the Waterside power stations, where half a million horsepower in electrical energy is generated, and in the various sub-stations throughout New York City. By means of these safety devices the Edison Co. has practically eliminated danger in the careful handling of electricity.

The Welin Marine Equipment Co. showed the progress made in saving life at sea. Their exhibit included davits, rafts, life boats and various kinds of life preservers. The New York Telephone Co., which maintains rest rooms, lunch rooms, and roof gardens for its operators, and which is particularly active in caring for the health and comfort of its thousands of employes, had an interesting exhibit. The United States Steel Corporation showed in a graphic manner how the workers in a hazardous industry are being protected.

In connection with the field hospital exhibited by the United States Army, a detail of fifty soldiers was sent to the exposition from Fort Totten on certain days, and these men went through physical drills and exercises which are especially designed a correct certain physical faults and ailments.

Among the exhibitors of safety devices designed for protecting workers in shops and factories were the following:

Allen Mfg. Co., Hartford, Conn. Safety set-screws.

Bass Bros., 82 Walker St., New York City. Safety guards for woodworking machinery.

Benjamin Electric Mfg. Co., 114 Liberty St., New York. Safety guard for punch presses.

Brown & Sharpe Mfg. Co., Providence, R. I. Charts and photographs of safety appliances.

Corbin Cabinet Lock Co., New Britain, Conn. Safety guard for punch presses.

Max H. Fischer, 41 Park Row, New York City. Hollow set-screws. Safety guards for presses.

L. F. Grammes & Sons, Allentown, Pa. Safety guards for woodworking machinery.

Julius King Optical Co., 12 Maiden Lane, New York City. Safety glasses for protecting the eyes of workmen.

Neverslip Safety Clamp Co., 141 Broadway, New York City. "Neverslip" clamps for handling boiler plates.

Norton Co., Worcester, Mass. Safety and sanitary appliances used in connection with grinding wheels.

T. A. Wilson & Co., Inc., Reading, Pa. Eye protectors for foundry, iron and steel workmen, etc.

Zeh & Hahnemann, Newark, N. J. Safety trip for punch presses.

H. & A. Lock Co., Brooklyn, N. Y. Safety guard for power presses.

PROGRESS OF THE SAFETY MOVEMENT*

A REVIEW OF WORK DONE TO PREVENT ACCIDENTS AND TO PROMOTE HEALTH IN THE INDUSTRIES

BY MANCIUS S. HUTTON†

It has been estimated by conservative competent experts that 35,000 workmen are killed and 2,000,000 injured, and that there are 3,000,000 cases of sickness due to occupational diseases among the industrial workers in this country each year. It is known that between 50 and 60 per cent of this economic and social waste is preventable by proper means. It is in those states which have passed workmen's compensation laws that there is the greatest progress in the promotion of safety and sanitation. At the end of the year 1913 the following twenty-two states have passed such laws:

Arizona;	Michigan;	Oregon;
California;	Minnesota;	Rhode Island;
Connecticut;	Nebraska;	Texas;
Illinois;	Nevada;	West Virginia;
Iowa;	New Hampshire;	Washington;
Kansas;	New Jersey;	Wisconsin.
Maryland;	New York;	
Massachusetts;	Ohio;	

The laws in these different states are not alike, some being more drastic than others. Some apply to all workers, others apply only to those working in hazardous enterprises which are specified. All these state laws are elective, as explained later, with the exception of Arizona, California and Ohio, which are compulsory. In the elective states the employer has the choice of voluntarily accepting the provisions of the act or of working under the common law; in the compulsory states he has no such choice. In order to make the law attractive to the employer, all the states which have already passed workmen's compensation laws and some that have not done so as yet, have changed or stricken from the statute books the old common liability law defenses called the "fellow servant" rule and the "assumption of risk" doctrine. By the fellow servant rule is meant "that the injury was caused by the negligence of another employe engaged in the same employment" and by the assumption of risk doctrine is meant "that the employe assumed the hazard of the occupation." In the past the employer has, in 75 per cent of the cases, by using either or both of these defenses, defeated any suit which the injured employe might institute in court to recover damages due to an injury. In addition, the amount of compensation for any injury has been definitely specified. In Maryland, Massachusetts, Ohio, Oregon, Texas, West Virginia and Washington, the employer is required to insure his men against casualty with a state insurance board or in one of the insurance companies which the state allows to receive such insurance. The employer pays the premiums. In ten states "Industrial Accident Boards" or commissions have been created to administer these laws.

The United States government has already passed laws which compensate for injuries and death for about a quarter of its 400,000 civilian employes. There will be presented to congress during this session a compensation bill which will take care of all these civilians. This bill, which will be introduced by Senator Kern of Indiana, provides for compensation for sickness or death due to occupational diseases as well as accidents. During 1914 there will probably be one state, at least, which will pass a compensation law, and two other states which will change their present laws. Besides providing for adequate and prompt compensation for accidents to industrial workers without the necessity of going to court, fifteen states have taken steps to study the question of occupational sickness among wage workers in the different trades, by requiring physicians to report to a state board or department cases of certain occupational diseases which they may be treating. In the near future these and other states will incorporate occupational diseases as well as accidents in their compensation laws. It has been found on investigation that lead-poisoning lurks in 150 different trades.

In the twenty-two states previously mentioned, laws have been passed which have increased and bettered the state inspection department, given the inspectors more power, increased the punishment imposed for violations of the laws besides requiring certain definite protection to be given to the workers in several of the trades. Where the state has an accident board or commission, the law-makers have delegated the prevention end to such board or commission by means of executive orders instead of enacting individual laws.

Active work in the prevention of mine accidents has advanced since the formation of the Bureau of Mines of the Department of the Interior in 1910. There are about three thousand miners killed every year, of which only fifteen per cent are killed in the large mine disasters which get into the daily papers. About seventy-five per cent of the miners in this country are ignorant foreigners. The investigations which the bureau has carried on during the last four years, have been helpful both to the owners and miners. These investigations have been published by the government and can be obtained free upon request. The bureau has taught miners and mine officials how to carry on rescue work in gaseous mines, how to fight mine fires, and how to give first-aid to injured workers. The government has in operation, at the present time, six mine-safety stations and seven mine-safety railway cars, both fully equipped as regards breathing apparatus, fire-fighting apparatus and materials for first-aid to the injured. These are presided over by a mining engineer who has under him a corps of highly trained miners. Up to the present 7734 miners have been instructed in the carrying on of rescue work with the use of breathing apparatus, in the fighting of mine fires, and the giving of first-aid. Safety lectures have been delivered to 71,500 persons by employes of the bureau. Once a year rescue and first-aid teams from various mines compete for different prizes which are offered by several of the mine companies.

For the last twenty-four years the Interstate Commerce Commission has been collecting statistics of accidents from the railroads doing interstate business. These statistics show that during that period 188,037 persons have been killed and 1,395,618 injured. These persons can be divided into three classes: First, the employes of the railroads; second, passengers; third, "other persons," including trespassers on the tracks. The "other persons" are by far the most numerous being about 62 per cent of the whole number of those killed. Of this 62 per cent, about 85 per cent can be classified as trespassers. The reports of the commission show that a large majority of these trespassers were killed and injured at other points on the track than at the highway crossings. The eliminating of grade crossings, the stationing of gate and flag-men at the crossings, has and will in the future, lessen the number of accidents at these points. One of the greatest problems which the railroads and commissions will have to face will be the question of reducing these trespasser accidents. It is the collisions and derailments in which passengers are killed or injured which get into the front pages of the newspapers but it is a fact that the number of injuries and deaths of passengers is small compared to the number of passengers carried. This is said guardedly since there is still fresh in the memory of almost everyone the terrible disasters which have occurred on one of the eastern roads this last year.

The employes of a railroad can be divided into three classes: First, those who work in the shops and roundhouses; second, those who work in connection with the operation of trains, such as yard and switchmen; third, those who operate the trains, which include the engineer, conductor, firemen and brakeman. The men in the first class are like those in any industrial factory and can be protected some-

* For articles on safety activities previously published in MACHINERY, see "American Museum of Safety Award," February, 1913, and "Museums of Safety and Their Activities," September, 1912, and articles there referred to.

† Address: 257 West 86th St., New York City.

what by means of safety devices and can be helped by working in well lighted, well ventilated buildings, which are not overcrowded so that the aisles and passage-ways can be kept clear. There are not many known safeguards which can be used for the second and third classes of employes. These men must run no risks, be quick of action, have a clear vision and brain, and be sure that they are safe before doing anything. In 1910 there was started a "safety-first" movement among the railroads. At the end of this year there will be sixty-seven railroads having a total mileage of over 183,596, which have organized this movement among their employes. Not a week passes but other railroads are taking up this movement, until within a few years, all the railroads will have joined it. This is nothing more than a practical movement to interest and cooperate with the railroad employes so that they will always think and act "safety first." This is accomplished by various means, among which are workmen's safety committees, talks by railroad officials, illustrated lectures on safety and other methods. The men have appreciated what the companies are doing for them, and they are trying to live up to what is required of them, thereby "boosting safety." The railroads which are active in this movement have been able to show a surprisingly large reduction in the number of accidents. Some of these roads have fitted up cars with traveling exhibits of safeguards. They also carry lantern slides of safety devices and methods of protection. Each car is in charge of one of the road's safety engineers, who goes with the car to the different shops, roundhouses and yard terminals of the road, where he lectures to the men and shows them models of the different safety devices which the company uses.

The statistics given in the foregoing only refer to railroads doing interstate business. The street and interurban railroads, besides the intrastate steam railroads, come under the jurisdiction of the state public service or railroad commission, if such has been created by the legislature of the state. The greatest number of accidents which occur on the street railroads are in the getting on and off of moving cars. The prevention of this class of accidents is in the education of the passengers not to be in a hurry, but to wait till the car stops before proceeding to get on or off. The running or stepping in front of moving cars is always a source of great danger. A large number of these latter accidents happen to thoughtless school children. It might be mentioned that the accidents which have happened since the advent of the motor vehicle and motor truck have been increasing instead of decreasing. State and local ordinances have attempted to decrease speeding and reckless driving by chauffeurs. While these are not industrial accidents, everyone is vitally interested in preventing them as far as possible.

Ever since the *Titanic* disaster of April 15, 1912, when 1517 persons were lost at sea, the United States government and the ship-owners have been trying to prevent a repetition of this calamity. As a result, ships which ply on the navigable rivers and lakes and those leaving ports of this country for foreign destinations, which carry more than 50 persons (crew and passengers), must be equipped with a wireless system having a day or night radius of 100 miles at least. This equipment must be so arranged that it can be independent of the engine room supply of electricity. They are also required to have at least two operators so that one will be on duty all the time. The ships must have enough life boats and rafts to accommodate all the passengers and crew. The life boats, rafts and life preservers are regularly inspected to see that they are in sea-worthy condition. Lifeboat and fire-drills by the crew are supposed to take place at regular intervals. Traveling by water to-day is far safer than it was four or five years ago. While it is a fact that some of the worst marine disasters have happened by collisions or by having the vessel tossed against a shore and knocked to pieces by the wind and waves, yet it is also true that the burnings of ships at sea, or in port, have been more numerous. The burning of the S. S. *Volturno* in the summer of 1913 is only one instance in a long line of such disasters. Even with all the latest apparatus for detecting and extinguishing fires, it sometimes happens that the fire gets beyond control. One of the greatest safeguards of the age, as regards protection at sea, has been the use of wireless telegraph in calling for help from other vessels. In December 1913 there was held in London, England, an "International Conference on Safety at Sea," having representatives from twelve different nations. This conference will make a report as regards its findings.

In 1911 the fire in the Triangle Shirt Waist Co.'s loft occurred in New York, and another disastrous fire in Newark, N. J. The next year there was another large fire in a loft building in Binghamton, N. Y. In each of these fires there was a terrible loss of life among the young women workers in the shops. As the result of investigations conducted after these fires, several of the states have changed existing laws and have enacted others to protect the workers in factories and lofts from such disastrous fires. It would take too long to tell what has been done in the line of fire prevention, but mention will be made of the increased number of, and larger fire escapes built of firmer materials, of fire drills conducted in different shops, of more adequate fire fighting apparatus to extinguish a blaze in its incipiency, of buildings constructed of fire-resisting materials and of other methods by which the fire insurance companies and the owners of factories are improving conditions.

All the work of the government commissions, bureaus, state boards, employers and other officials in accident prevention, hygiene, and sanitation, would count for very little if it did not have the active cooperation of the workers themselves. There are several reasons why the safety movement has taken such big steps within the last year or two. One of these has been the awakening of the employers to the fact that they are their "brothers' keepers" and therefore it is their moral and rightful duty to take every means in their power to keep their workers in health and as free as possible from accident. Second, the employe realizes now that it is his duty to become a partner with his employer in carrying out any safety suggestions that will be helpful to both of them. Again both the employer and his workmen know that they owe it to society at large to decrease the number of accidents and cases of sickness.

Among the agencies which are helping the progress of the safety movement are the museums of safety, one of which is now located in New York at 29 West 39th St. Another will be started with the beginning of this year, in San Francisco, Cal., and still a third will be located in Chicago, Ill., in the near future. Other museums are being considered by several of the state boards and by the national government. These museums are stationary and can be seen only by those who are within a traveling distance of these cities or who may be sojourning in them. The lecture work which members of these museums can give need not be confined to these cities. In fact, during the last three years illustrated lectures have been delivered by officials of the American Museum of Safety before audiences of superintendents, foremen and workers of several large industrial plants and railroads. They have also given the same lectures before meetings of chambers of commerce, factory inspectors, organizations of employers, and others of a similar nature. This last year, safety talks have been given by the New York museum to 449,120 children of the schools of Greater New York.

Some of the railroads and large industrial concerns have printed safety talks which they have sent to the school authorities in the cities in which they are located, for distribution among the school children. Lecture work has been given by officials of the National Association of Manufacturers at the different industrial centers during the last few years. This association is proposing to widen its scope of lectures this coming year by fitting up a train which will carry the lecture officials. One car of this train will be arranged so that it can become a moving picture theater, and another car will carry models and samples of various safety devices. One of the railroads already has a train of this nature for its own use and others are considering doing the same thing. Several of the state boards are doing lecture work among the manufacturers of their states. This edu-

cational lecture work has been a great help to all concerned and one of the leading factors that has brought the safety movement to its present state of development.

Another agency which is helping the movement is the cooperation of the technical journals in the publishing of editorials and articles by leaders of the movement, on questions relating to safety, sanitation and hygiene. The *Railroad Record* publishes once a month an issue devoted wholly to safety and safety engineering, and has each month a section given over to questions regarding safety. Several of the insurance companies which carry liability insurance have been actively promoting the safety movement among their insured. It is not unnatural that new organizations whose members consist of those whose interest centers about this movement, should come into existence as the work progresses. Among such organizations might be mentioned the American Mine Safety Association, and the American Railway Safety Association. In Milwaukee, Wis., from September 30 to October 5, 1913, there was held the "First Cooperative Safety Congress" under the auspices of the association of the Iron and Steel Electrical Engineers. At the end of this congress there was formed a National Council of Industrial Safety to serve as a committee for organizing future congresses. In New York there was held, from December 11 to 20, 1913, the "First International Exhibition of Safety and Sanitation" under the auspices of the American Museum of Safety.

It has not been possible in as short an article as this, to give more than a general outline of the progress in the safety movement since its beginning. No mention has been made of other lines of progress in labor which have helped this movement nor has mention been made of what has been done by the legislatures and the employers in hygiene and sanitation. The safety movement has now become a permanent one in this country and it will progress faster here than it did abroad, since America has their experience to draw from.

THE "PAPERED" PRESSES

A story is told of a manufacturer who bought some small presses from a concern that built machinery spasmodically—that is, when it had orders to fill. The presses were delivered, and after a time they were taken down for readjustment. The fitting was found to be hardly satisfactory even to a good-natured man. This man was good natured, but being slightly given to sarcasm, he penned the following letter:

John Blank, Esq.:

I have taken down the presses you sold me and am now ready to put them together. Will you please send me some copies of the *Billtown Bugle?* I don't find any paper around here of the same thickness. Shall need three copies to go around.

Yours truly,
Samuel Dash

TEST GAGES FOR AUTOMOBILE CYLINDERS

BY E. H. PRATT*

In the production of automobile cylinders there is always considerable discussion regarding the cylinder bore being square with the flange, and various devices and gages have been designed to test the squareness, which depends upon several conditions: First, the cylinder boring machine must be of very rigid construction; send, the jig for holding the cylinder must be strong and accurate; third, the boring tools must be kept sharp and have the proper clearance; fourth, the cores that form the cylinder barrels must be set true. The cores are the principal cause of the trouble and it seems almost impossible for the foundry to overcome the difficulty. When the cored hole is considerably out of true, the cutters will have more stock to remove from one side of the hole than the other, and, if the spindle of the boring mill is not perfectly adjusted, there will be a certain amount of play or spring that will allow the cutter to follow the core. The error arising from this cause is likely to be in any direction, and, after the finishing cut is taken, it is necessary to test the bore to determine how much it is out of square.

The test gages shown in the accompanying illustrations represent the ideas of various engineers and inspectors. Some of them have proved to be very accurate but not economical, owing to their excessive first cost, whereas others are accurate, cost little, and therefore are practical. The gage illustrated in Fig. 1 has previously been shown in MACHINERY's columns, but is reproduced to make the set complete. The flange *A* of this gage is placed on the cylinder flange, and the bar *B* which slides in bearings *C* is then moved vertically, thus causing the "anvil points" *D* to pass down the sides of the cylinder wall. Any variation is indicated by the relation of pointer *E* to the graduation marks seen at the upper end of the gage. This gage was very successful, but can only be used on one size cylinder, which is a decided disadvantage in a job-shop where cylinders of several diameters are being made.

The gage shown in Fig. 2 is used to test the variation in thickness between the cylinder bores. It was not very successful, inasmuch as both bores could be out of square with the flange while the thickness between them was uniform. The construction of this gage is clearly shown by the illustration. A gage which proved very satisfactory for testing bores for taper is shown in Fig. 3. Attached to one end of the body *A* there is a movable block *B* normally held out by springs *C*. The indicator arm *D* is pivoted at *E* and is connected with the movable block as shown. The frame is graduated on the upper end and is also formed for a handle with which to operate the gage.

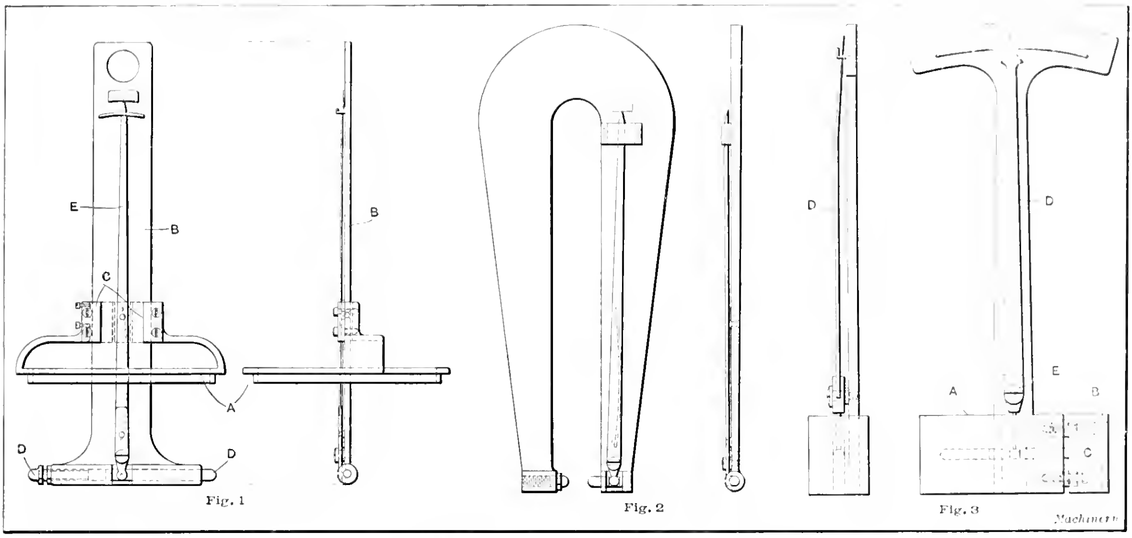

Fig. 1. Gage for testing Squareness between Cylinder Flange and Bore. Fig. 2. Gage for testing Parallelism of Wall between Adjacent Bores. Fig. 3. Gage which shows whether Bore is Cylindrical or Tapering

* Address: 12 Eagle St., Springfield, Mass.

The gage shown in Fig. 4 is very elaborate and is an extensive improvement over the type shown in Fig. 1. It was designed for use on cylinders varying from 4 to 5 inches in diameter, and gave fairly accurate results, but its use under ordinary circumstances would be prohibitive owing to high cost and complicated construction. The body *A* is made in two pieces to allow machining a dovetailed bearing for the gage slide; the latter has a gib for adjustment and a knurled knob at the top (see plan view) by which the slide is operated vertically. When anvil *C* is in contact with the cylinder wall, any variation in the squareness or size of the bore is shown by pointer *D*, which, through the lever *E*, multiplies the variation twenty-five times. The set-screws *G* are used to adjust the gage for different cylinder diameters. The spring *F* keeps anvil *C* in contact with the cylinder bore. The gage is located on the cylinder by means of two stationary pins *H* and the adjustable pin *J*, which is fastened to rod *K*. The latter is controlled by a spring lever *L* as shown in the plan view. To insure the gage being square with the cylinder flange, pins *M* and knife-edge plate *N* are so located that they will give sufficient bearing on the cylinder, but dirt and chips are not likely to get under the gage and throw it out of alignment, because of the small bearing surfaces.

The gage illustrated in Fig. 5 is simple and effective for a given size cylinder. The cylindrical cast-iron body *A* (see also plan view) is made to fit the cylinder bore and is attached to a seamless tube *B* which acts as a pilot for the knife-gage *C*.

The body *A* is placed into the cylinder bore with pilot *B* extending upward, and square *C* is moved down until it comes in contact with the cylinder flange; tissue paper or steel "feelers" are then used to determine the error between the bore and flange. Square *C* is provided with clamp-screws to take up the wear on tube *B*.

The final result of much experimenting is represented by

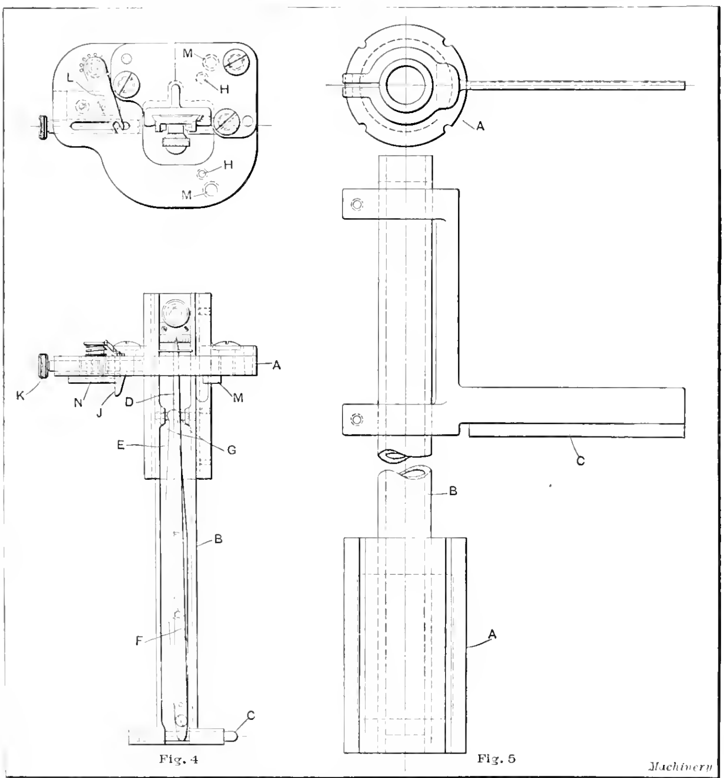

Fig. 4. Expensive and Complicated Type of Gage. Fig. 5. Simple Form of Gage for testing Squareness of Bore

the gage shown in Fig. 6. This gage can be used in various size cylinders, without changes or adjustments, and is simple, cheap and accurate. There are only four principal parts, *viz.*, the base *A*, lever support *B*, and lever pivot *C*, and the indicating lever *D*. The body of this gage is made in two parts to facilitate machining. The indicating lever support is fastened to the body with cap-screws and dowel pins, and extends into the cylinder, so that the center of the lever pivot is somewhat below the face of the flange, as shown. By placing the

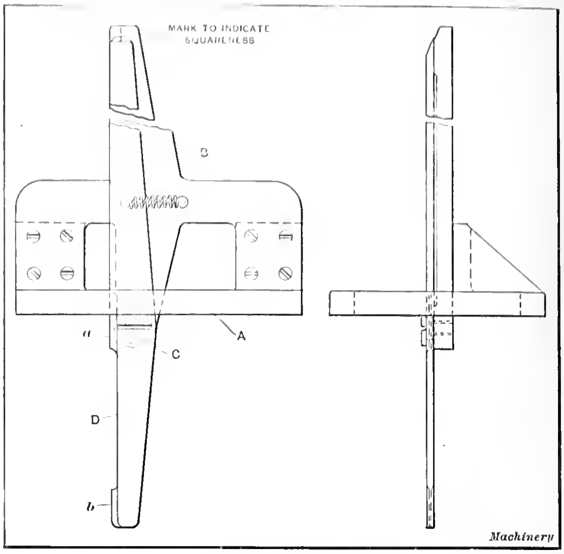

Fig. 6. Simple Design of Gage applicable to Any Size of Cylinder for testing Squareness of Bore

gage on the cylinder flange and bringing the knife-edges *a* and *b* of the lever into contact with the cylinder wall, any variation is shown by the mark at the upper end of the gage. The center of pivot *C* is placed below the face of the cylinder flange, so that when the indicating arm is moved against one side of the cylinder bore, the thrust will be taken directly by this pivot; as the lower end of the lever is held against the cylinder wall by a spring above the pivot, contact is insured at both points. This gage has solved the problem of testing cylinder bores, and it is in daily use in a factory where thousands of cylinders are produced every month.

WATERPROOFING CONCRETE

The College of Engineering of the University of Wisconsin is conducting a series of tests on the permeability of concrete. The object of the tests is to find a simple means of making concrete water-tight. The work shows that there is considerable difference in the imperviousness of concrete when the sand is dry and when the sand is wet before mixing. Good results are obtained if the concrete remains in the mixer from two to three minutes when dry materials are employed, but when the sand and gravel or stone are damp a considerably longer time is required. Therefore the use of wet sand should be avoided if possible. Experiments showed that mixtures consisting of 1 part cement, 1½ part Janesville sand of the "torpedo" grade and 3 parts Janesville gravel, when mixed to a wet consistency, are impervious to water under a pressure of 40 pounds per square inch. Mixtures as lean as 1 part of cement to 6 parts of gravel (graded mixture) have been made impervious by using care in proportioning the amount of water.

* * *

More than 800,000 horsepower has been developed from streams on national forests under government regulation. This is the output under conditions of lowest stream-flow.

MILLING FIXTURE FOR ANGULAR WORK

BY L. J.

The fixture which it is the purpose of this article to describe was designed for milling the sides of the block shown in Fig. 1. Three operations are involved; the parallel sides *A* are milled by means of the straddle cutters and the two sides *B* and *C* are then milled in two subsequent operations. These three operations are all performed without requiring more than one setting of the work. The block is cut off from bar stock, and drilled and counterbored to receive two fillister head screws which hold it in place on the machine of which it forms a part. These holes are also utilized for holding the block in position on the fixture.

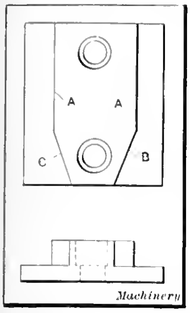

Fig. 1. Piece to have Sides A, B and C milled

Fig. 2 shows plan and sectional views of the milling fixture which consists of an upper plate *A* which is pivoted on the stud *B*. This stud is mounted in the cross-slide *C* which runs on the base *D*. The plate *A* is provided with two tapped steel bushings which are a forced fit in holes drilled and counterbored for the purpose. These bushings receive the two screws which secure the work in position on the fixture, their purpose being to prevent the rapid wear of the threads which would take place if they were tapped directly into the cast iron. Fig. 2 shows the fixture set in position for milling the parallel sides *A* of the work. Referring to the illustration it will be seen that there are two tapered pins *E* and *F* which are used for locating the work in the required position. For milling the parallel sides of the work, the pin *F* is inserted in the hole *N* to locate the cross-slide *C* in the required position. Similarly the pin *E* is located in the central hole to locate the swivel plate *A*. These pins are merely used to locate the fixture, the bolts *G* and *H* being provided to secure it in the required position. Fig. 3 shows an end sectional view of the fixture set in the same position as in Fig. 2, and by referring to this illustration a better idea of the operation of the fixture will be obtained.

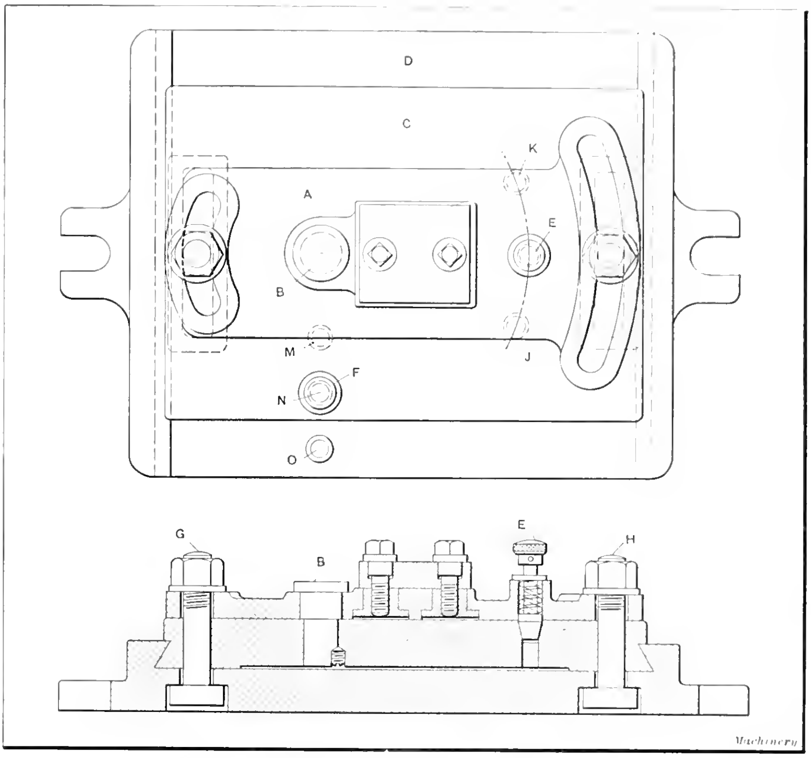

Fig. 2. Plan and Sectional Views of the Milling Attachment

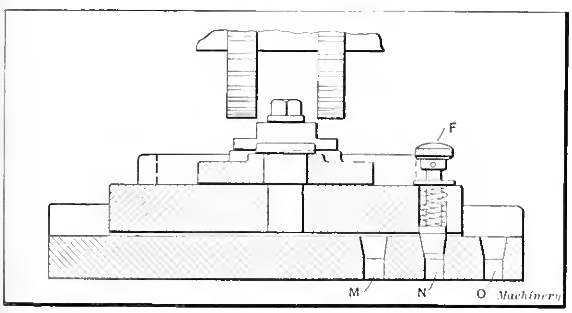

Fig. 3. Attachment set for milling Sides A of the Work

Fig. 4 shows an end sectional view of the fixture set for milling the angular side *C* of the work. For this purpose the pin *E* is inserted in the hole *J* and pin *F* in the hole *O*. This sets the swivel plate *A* at the required angle and also locates the cross-slide *C* at the required distance off center to enable the work to be milled by the outer edge of the cutter, as shown in Fig. 4. After this operation has been completed the swivel plate *A* is swung over to enable the pin *E* to enter the hole *K*. Similarly the cross-slide *C* is moved so that the pin *F* will enter the hole *M*. This brings the work in position to enable the angular side *B* to be milled by the outer edge of the other cutter on the arbor.

LARGE HYDRO-ELECTRIC POWER DEVELOPMENT

The Chattanooga & Tennessee River Power Co.'s hydro-electric development at Hale's Bar on the Tennessee River near Chattanooga was formally opened and dedicated November 13. This is the largest hydro-electric power development in the South and one of the four greatest in this country, ranking with those at Keokuk and Niagara Falls. The power dam and lock were designed and constructed under the supervision of the U. S. Government Engineers at a cost of $9,000,000 and seven years was required to complete them. The length of the dam is 1200 feet and the lock is the highest single lift in the world, the height of the down stream gates being 58 feet. The lock, inside, is 60 by 310 feet and the power house 356 feet long; 65,000 H. P. will be generated.

LETTERS ON PRACTICAL SUBJECTS

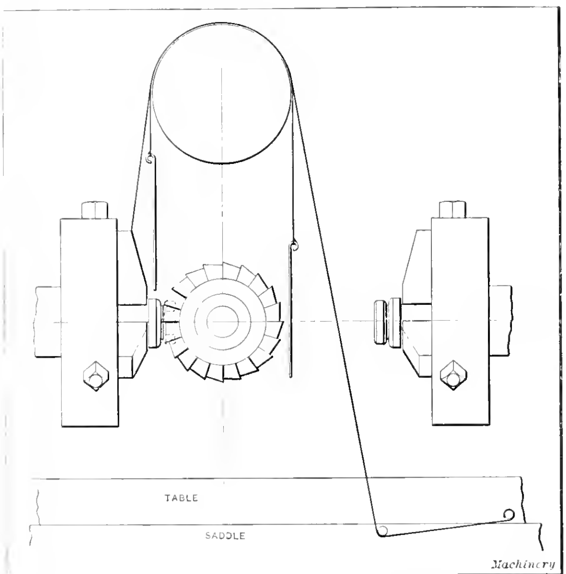
A PROBLEM IN "HEXING"

In the How and Why section of the October number of MACHINERY H. L. B. asked for information concerning a good and cheap method of forming hexagons on machine steel pieces. A multiple jig for milling hexagons on six pieces simultaneously was illustrated and described in MACHINERY some time ago. Aside from the expense of making a jig of this nature, the time required for loading the jig, indexing and removing the finished work is so high, as compared with the actual time required for milling, that the output is not as great as might be expected. The following method requires no special tools or equipment, aside from the guards which protect the operator's hands while setting up the work in the chucks, and if a milling machine is used which has a feed reverse in the table, a close approach to continuous milling is obtained.

The two chucks shown in the illustration are mounted on plain index heads, and a pair of 3½- or 4-inch straddle milling cutters are set up on the arbor of the machine. The guard plates and cords for protecting the operator's hands while setting up work are shown more with the idea of suggesting what is necessary in this way than with the view of presenting a final solution of this part of the problem. Some more rigid device would be desirable, the only essential feature being that the plates should be moved into place and withdrawn alternately, in order to have the plate interposed between the milling cutters and the chuck in which a fresh blank is to be placed. The heads should be set as close together as possible, just sufficient room being allowed to provide for inserting the blanks and removing finished pieces. For the work that H. L. B. refers to, a 2½- or 3-inch movement of the table ought to be ample. It will be evident that the cutters will be working on the piece held in one of the chucks while the other piece is being indexed or while a finished part is being removed and replaced with a fresh blank.

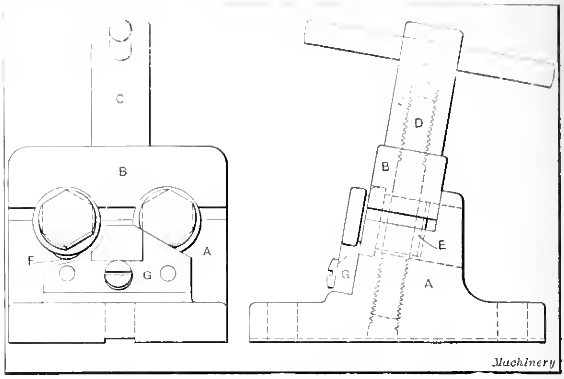


Method of hexing Work where Two Single Chucks are used

Philadelphia, Pa. C. W. PITMAN

The writer believes that H. L. B. would find the use of two milling fixtures of the type shown in the accompanying illustration to constitute a satisfactory solution of his problem in hexing. Referring to the illustration, it will be seen that the fixture consists of a body *A* in which two pieces of work are held by the clamping cap *B*. The method by which this cap is tightened through a nut *C*, that is turned on the stud *D* by means of a handle, will be evident from the illustration. A coiled spring *E* is provided to lift the cap off the work when the nut is released. The holes in which the two pieces of work rest are bored all the way through and counterbored to receive the large diameter of the work; the shoulder at the bottom of the counterbore serves as a stop and the thrust of the cut is carried by it. It will be seen that the two holes are grooved as shown at *F* in order to afford a better grip on the work.

The locating plate *G* is removed while performing the first operation, although it need only be removed from one of the fixtures. As the work comes from this fixture, the pieces are set up in the other fixture to have the second operation performed on them. When a sufficient number of pieces has accumulated, the locating plate *G* is replaced and both fixtures are used for performing the third operation, which finishes the work.



Method of hexing Four Pieces of Work held in Two Opposed Chucks

Two pairs of straddle milling cutters of about 3½ inches diameter by about ⅜ inch face are used. The inner pair of cutters works in the slot in the plate *G* while the outer pair works at either edge of the plate. The cutters are narrow enough to clear the screw which holds the plate *G* in position on the fixture, and their diameter is such that it is just possible to mill the "hex" without interfering with the flange on the work. The object of inclining the fixture is to provide greater convenience of operation which includes ease of cleaning, more room between the clamping handle and the overhanging arm of the milling machine and a better view of the work.

The fixtures are bolted to the table so that they face each other at either side of the spindle. They are located as close to the spindle as it is possible to have them and still provide room to safely remove the machined plugs and insert fresh blanks while the cutters are operating on the work in the opposite fixture. The power feed of the table is tripped by the regular feed-stops which are applied when the cutters have finished their work on the "hex." At this point the cutter will be within about 1/32 inch of the flange on the work, but although there is little room to spare, it is entirely practicable to operate a machine that is in good condition in this way. When one side of the milling cutters becomes dull, they can be reversed on the arbor, thus increasing the length of time that they can be used between grindings.

Watervliet, N. Y. MARTIN H. BALL

In reply to H. L. B.'s problem in hexing presented in the How and Why section of the October number of MACHINERY, I offer the following solution. The method has the distinction of being cheap when the possible output is considered, and may also be of value in suggesting a still better method. The fixture used for this purpose is shown in Fig. 1, where it will

be seen to consist essentially of two plates *A* and *B*. The upper plate is drilled to receive thirty-six studs, upon each of which a piece of work can be mounted. The base is provided with four lugs *C* by which it can be bolted to the table of the milling machine, and the upper plate is held down by means of three bolts *D* fitting in lugs on the upper and lower plates.

Each row of pieces is milled by straddle cutters and after two sides of the hexagon have been finished in this way, the work is indexed through 60 degrees by means of the taper pin *E* which fits into either of six holes in the base of the fixture. Three holes would really suffice for this purpose, but six are used in order to distribute as far as possible any wear which would develop. It will also be noticed from the illustration that there are cored recesses *F* under the holes in the base of the fixture which provide for the use of a drift to force out the index pin. A projection *G* on the plate *A* extends into an opening in the base *B* in order to hold the two plates in alignment while they are being indexed.

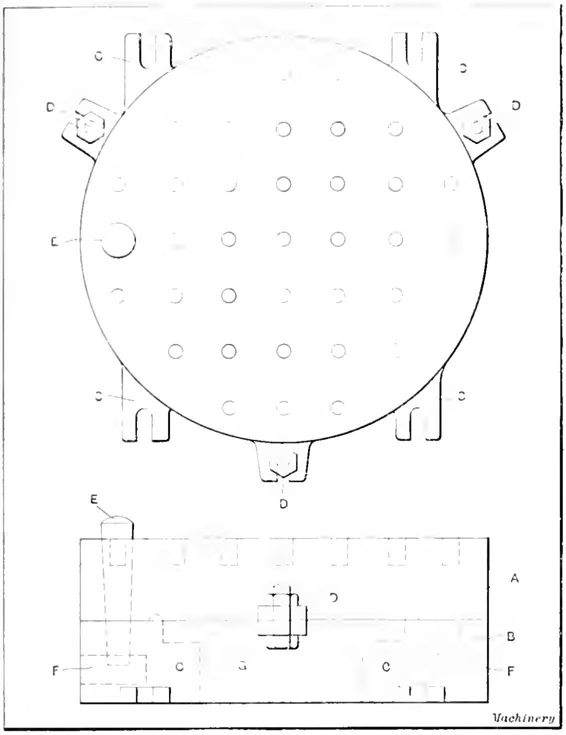


Fig. 1. Design of Multiple Fixture for milling Hexagons

Several methods may be used for holding the work in position on the fixture. One of the simplest devices for this purpose consists of the use of studs over which the work is slipped and held by a nut and washer. A convenient form of stud for this purpose is shown in detail at *B* in Fig. 2. The nut on this stud is made of such a size that the work will slip over it. It will be seen that the washer has a slot milled in it so that it may be slipped into place without requiring the nut to be screwed all the way off the stud. This greatly facilitates the rapidity with which the work may be set up or removed. The studs should be hardened and ground to increase their durability, and it is a good plan to use a bushing in the counterbore of the work, in order to provide for having it held snugly on the stud. Another good method of holding the work in place is by means of split bushings of the form shown at *A* in Fig. 2. These bushings are an accurate fit in the bore of the work and extend into reamed holes in the face of the fixture. When the work has been set up on these bushings, taper pins are driven in, which expand the bushings and hold the work securely in place. If this method is used, the upper plate *A* would be considerably thicker and provided with cored recesses to permit drift pins to be used for ejecting the taper pins.

A similar arrangement of simpler design could be made by mounting five studs in a bar to provide for milling five pieces simultaneously. A bar with the work mounted on it would be placed in the milling machine vise and the work milled by means of straddle cutters. After taking the first cut, the vise—which must have a graduated base—is swung through 60 degrees, after which the second cut is taken. The vise is then swung back through 120 degrees to locate the work ready for taking the third cut, which completes the operation. This method has nothing to recommend it but the reduction in the initial cost of the fixture.

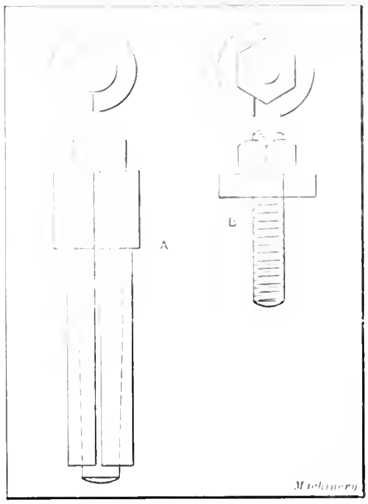

Fig. 2. Details of Two Methods of holding Work

Stillwater, Minn. R. C. MacLachlan

Some time ago the writer saw a hydraulic press rigged up for making semi-steel gears, and it appears that the same idea might be used to advantage in solving H. L. B.'s problem in hexing, which was presented in the October number of Machinery. The writer has not had any experience with this particular class of work, but a wide experience in toolmaking leads him to believe that it would be entirely practicable. The design for a die for handling this operation was taken up in exactly the same way that any other new operation coming into the shop would be handled, the idea being to turn out the work with the least possible expense for tools and labor.

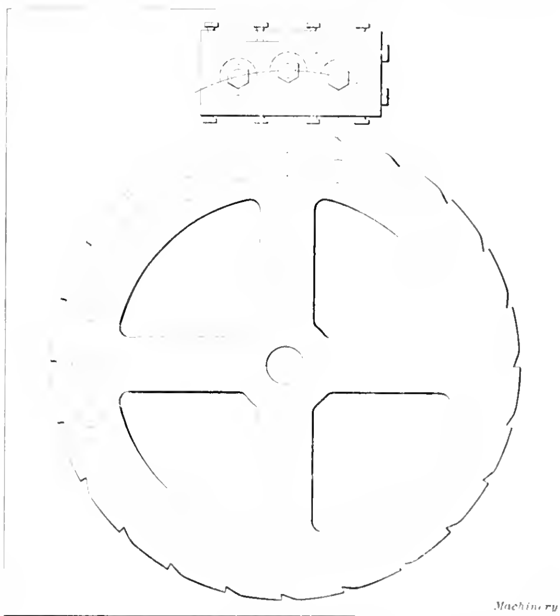

Fig. 1. Method of producing Hexagonal Heads in a Power Press

The preliminary work in producing these pieces would be an ordinary screw machine job, the order of operations being to form the piece, drill the small hole, counterbore and then cut off. After the pieces had been produced in this way, they would be transferred to a punch press equipped with dial feed and a die of the kind shown in Fig. 1. A detailed view of this die is illustrated in Fig. 2, from which its construction will

be better understood. Referring to this illustration, it will be seen that there are three openings in the die laid out on a circle of the same radius as that of the circle on which the work is set up on the dial of the punch press.

From the dimensions given by R. L. B., it appears that there is about 5/64 inch of metal to be removed from the sides of the "hex." To get a good finish, it would be desirable to take this cut in three steps: first roughing cut, 1/32 inch; second roughing cut, 1/32 inch; finishing cut, 1/64 inch. The three dies are graduated in sizes to take these three cuts. The dial is indexed by means of the usual ratchet mechanism so that the work is advanced from die to die between strokes. In this way one piece of work will be finished at each stroke of the press after the first two strokes have been made. It would be entirely practicable to rig up some form of ejecting mechanism which would knock the finished pieces of work out of the dial. With such an arrangement the operator would merely have to sit in front of the press and mount blanks in the holes which had been left vacant by the removal of the finished pieces of work.

Referring to Fig. 2, it will be seen that the three dies are equipped with pilots which assist in holding the die in the desired alignment. It will also be seen that each die is provided with a stripper which is backed up by a stiff spiral spring that ejects the scrap from the die after each stroke. The stripper also serves to hold the work in place in the index wheel. In producing "hexes" in this way, it would doubtless be a good plan to have two dies to fit into the punch-holder. With such an arrangement one die could be sent to the tool-room to be sharpened and the other set up in position so that

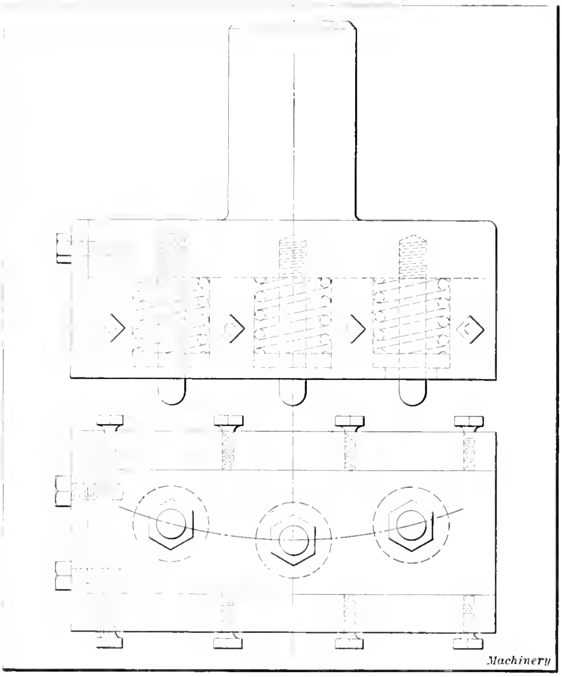

Fig. 2. Design of the Hexing Die

no loss of time would result. The end stop on the holder facilitates bringing the die blank into the desired alignment with the least possible loss of time.

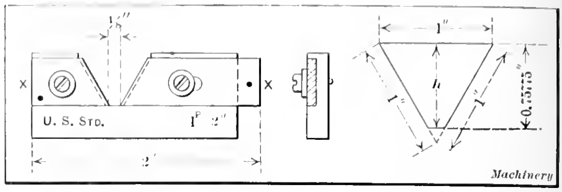
Beloit, Wis. O. F. Philler

[Suggestions for methods of handling this operation were also received from James R. Allan, Chicago, Ill.; Walter Butz, Pearl River, N. Y.; W. J. Kittle, Pearl River, N. Y.; P. S. Souders, Rockford, Ill.; E. Wanamaker, West Haven, Conn., and O. A. Webster, Readville, Mass.—Editor]

U. S. STANDARD THREAD TOOL GAGE

As most mechanics know, the U. S. standard thread has a 60 degree included angle and a flat at the top and bottom equalling 1/8 of the pitch. This means that the depth of a U. S. standard thread of a given pitch is equal to 3/4 the depth of an ordinary V thread of the same pitch. It will be evident from the preceding that a thread of 1-inch pitch has a 1/8-inch flat at the top and bottom, and this is taken as the basis in constructing the present gage.

The decimal equivalent of 1/8 is 0.125. Suppose it is attempted to divide this number by 8 in order to obtain the flat on a U. S. standard thread tool with eight threads to the inch. The length of the flats in this case will be found to be 0.015625 inch, but it would be very difficult to make an accurate gage for a thread tool of this size. This difficulty has been entirely avoided by using a thread of 1 inch pitch for the basis in making the gage. Referring to the illus-



U. S. Standard Thread Tool Gage and Templet used for setting

tration, it will be seen that the gage consists of a body which has one jaw secured to it by a screw and pin. The other jaw is secured by a screw which passes through a slot in the jaw, so that this jaw may be adjusted longitudinally to adapt the gage for different pitches. The jaws run in a slot machined in the body of the gage so that they are kept in the desired alignment, and the end of the tool is brought up against the body. The gage is set for different pitches by measuring the distance between the outside ends of the jaws with a micrometer.

In order to obtain the proper location of the angular sides of the two jaws when they are together for a one-pitch V-thread or open for a U. S. standard thread tool of the same size, a templet was made of the form shown at the right-hand side of the illustration. This templet was first made an accurate equilateral triangle with sides 1 inch long, and one point was then cut off to make the height h exactly 0.75775 inch. The jaws were then adjusted so that they fitted against this templet with one of the sharp points in position, which corresponded to the setting for an ordinary V-thread, and with the cut-off point in position when the setting is that for a U. S. standard one-pitch thread tool. When set for a one-pitch V-thread, the distance between the ends of the jaws, as obtained with the micrometer, is 1.875 inch; and for a one-pitch U. S. standard thread, 2 inches.

A convenient method of setting the gage is to open it a small amount more than is required and then partially tighten the screw which holds the movable jaw. The micrometer is then put over the ends of the gage and screwed up to the required dimension, carrying the movable jaw with it. After the setting has been obtained in this way, the binding screw which holds the movable jaw is tightened up. It will be evident from this description that the gage is easily set by any man who knows how to use a micrometer.

Springfield, Mass. Francis W. Clough

SETTING DIAMONDS

I have read with much interest the short articles which have been published in Machinery relating to methods of setting diamonds. After trying nearly all of these, I decided that setting the diamond in a piece of copper and forging the metal tight around the stone was the most satisfactory for average shop conditions. We use a large number of small diamonds for scoring glass tumblers before they are put into the heat to be cracked off. These diamonds require careful setting as they must make a clean accurate mark.

I would be interested to hear from readers of Machinery what they have found to be the best method of selecting a diamond. This, to my mind, is of more importance than the method of setting. My own practice has been to look at the stones carefully under a magnifying glass and choose those that are the closest grained and of a glossy black appearance.

Some black diamonds are just like pieces of coke—full of small pores. I once set one of these stones that cost $60 and it ground away like graphite. What I would like to know is whether the color has anything to do with the quality of the stone because in all of the different diamonds that I have looked at, the color varied from a deep black down to a dark gray. By way of conclusion, I would say that I have not yet met an agent who would guarantee a diamond.

Bridgewater, Pa. J. TOWLER

ON CLEANING MACHINES

Some time ago I read about a technical school workshop in which the machines were all finished in white enamel. I should like to know if the boys keep these machines clean, or if the cleaning is done by a special attendant. So far as my experience goes, it is about as difficult to teach a boy to clean a machine tool and leave it in passable order at the close of a lesson as it is to teach him anything else.

Finally it began to dawn on me that I was expecting too much from the boys. I saw girls being put through an elaborate course of training, requiring many months, a large part of which consisted in teaching them to keep a house, its furniture and utensils clean. They were drilled in the washing of dishes, pots, pans and tables, day after day, until in place of the gawky little slatterns who entered school a year before, you were dazzled with the trim smart capable young persons who would strike terror into the heart of any ruffian who dared to enter a house without first leaving his boots on the mat outside.

Evidently, the boys needed more elaborate drilling in the cleaning and general order of machines and tools, even though it shortened the time available for their regular work. Such training is most important, however, as a machine which is kept clean and tidy gives less trouble and lasts longer than one which is neglected. A good illustration of this was afforded me a number of years ago, when I was sent to repair a small steam engine which was continually breaking down. I found it located in a dark and dirty shed, smothered in old grease and soot. I gave the attendant a few scrapers and started him on the job of cleaning it while I dismantled the defective parts. After a few hours' work, he announced that it was clean. I directed his attention to parts on which he had not reached the original coat of paint, and he started again. This process was repeated several times during the period the engine was under repair. At last he began to take notice of things himself, and, to my gratification, suggested cleaning and whitewashing the shed and giving the engine a coat of paint. This was done and I left him in charge of an engine which he had cleaned and painted and polished, and of which he was proud. That engine gave no more trouble until it was superseded by a more powerful one some years later.

Christchurch, New Zealand. JOHN PEDDIE

LUBRICANT FOR WORM-GEARS

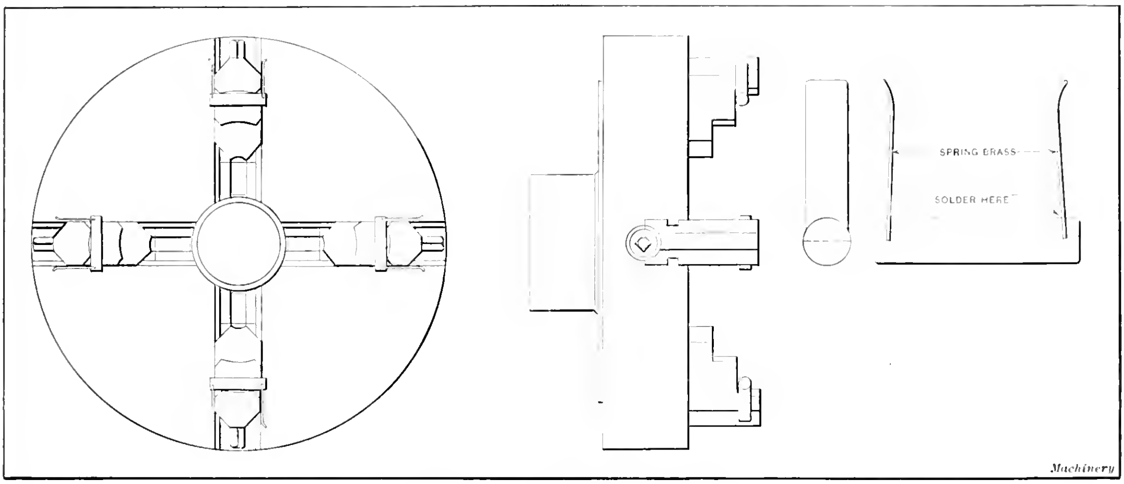
No doubt many readers of MACHINERY have had trouble with worm-gears even in cases where the gears ran in oil. In the majority of installations, the worms are cut from steel while the worm-wheels are of cast iron. The writer has had a lot of experience with worm-geared elevator hoists and gives below a very satisfactory formula for a lubricant which is composed of the following ingredients: Cylinder oil, 2 gallons; common flour, 1 pound; common salt, ½ pound.

It will be found that the flour will make the oil heavy enough to stick while the salt will so glaze the worm and gear that they will run smoothly without any tendency to "score." In extreme cases, where the worm-gear runs hot, owing to continuous and fast running and to friction, it is sometimes advisable to add to the above ½ pound of graphite. The lubricating and cooling properties of graphite are too well known to require discussion. Anyone who has had trouble with worm-gearing will find this lubricant well worth trying.

Decatur, Ind. HARRY FRITZINGER

LATHE JAW DISTANCE PIECES

Machinists, and especially toolmakers, frequently have occasion to set up a job with the work set out from the faces of the lathe jaws. Distance pieces are commonly used for this purpose and various methods are resorted to in order to hold them in place. The accompanying illustration shows the type of distance pieces that I have used for a number of years. They are made from pieces of round drill rod 5/16 inch in diameter and about ¼ inch longer than the width of the chuck jaws. A slot is sawed half way through the drill rod at each end and flat strips of brass are soldered into these slots. The brass pieces are bent to the form shown in the illustration, so that they grip the chuck jaws firmly enough to hold the distance pieces in place.



Convenient Form of Lathe Jaw Distance Pieces

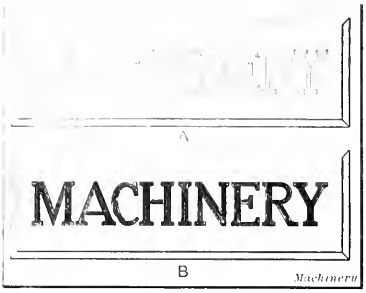
Delphos, Ohio. A. J. BRICKNER

IMPROVED METHOD OF MARKING MACHINE PARTS AND TOOLS

The method of marking machine parts, referred to in this article, is for producing brass letters, numbers, designs, etc., on steel, iron and brass. In addition, this method is very effective for making name-plates, such as are used on front doors of apartment houses and hotels. The desired result may be obtained in various ways, a few of which are given in the following:

The first step is to see that the part to be marked has a true surface, free from rust and dents. The name, or number, is stamped on the work by means of steel letters, or a steel stamp as indicated at *A* in the illustration. The only precaution necessary to take in stamping the letters or num-

bers, is to have them as deep as possible and all of the same depth. A coating of molten brass is next distributed over the entire surface of the work by the common process of brazing, plenty of flux being used. The work is then allowed to cool, after which it is ground on a grinding machine, or by other means, in order to remove the surplus brass from the surface. This operation leaves the brass only in the letters or numbers that have been previously stamped on the work. After the surface is polished in the usual manner, the letters present a very pleasing appearance. The view *B* illustrates the plate after grinding. If it is desirable to give the letters a bronze appearance, the work, after polishing, should be immersed for a few seconds in a solution of equal parts of nitric and hydrochloric acids.



(A) Stamped Name-plate
(B) Stamped Name-plate with Brazed Brass Letters

Another method is to first outline with a pencil, the name or design, on the surface of the steel or iron to be marked. The outline is then gone over carefully with a center punch, the punch marks being made as close together as possible without touching, and about one-sixteenth inch deep. After the work is brazed and polished, as previously explained, the letters have the appearance of being formed of inserted brass plugs.

Still another method is to etch the name or design on the steel, by means of a suitable acid, after which the foregoing procedure is followed. It is necessary with this method, to boil the work for a few minutes, in soda water, before brazing, to remove any trace of the acid from the letters or design.

To stamp brass with "steel" letters, the same method may be employed, with the exception that solder is used to fill up the letters. Any common soldering acid or paste may be used as a flux for this purpose.

The methods given in this article, may, of course, be changed somewhat to suit requirements, and many new methods substituted; the work will be found very attractive, and *"out of the ordinary."*

East Orange, N. J. GEORGE GARRISON

AUTOMOBILE REAR AXLE DESIGN

I have just finished reading the article entitled "Automobile Rear Axle Design" that appeared in the September number of MACHINERY and have several criticisms to offer. The equations that appear immediately above Fig. 4 should read:

$$TI = Q\,r\,\mu$$

and for one wheel

$$\frac{TI}{2} = \frac{Q\,r\,\mu}{2}$$

Some designers make a great mistake in assuming that if one wheel is locked by the greater frictional resistance of the road or by getting wedged in a narrow rut, the other wheel takes the full torque TI. Such is not the case. When one wheel is completely locked, the differential mechanism causes the other wheel to rotate at twice its ordinary speed, and hence the torque drops to $\frac{TI}{2}$.

In the equation below Fig. 5, the coefficient ½ should be inside the parentheses, as it does not refer to the tension of the driving chain. But the quantities $\frac{Q\,r\,\mu}{2}$ and the tension of the driving chain cannot be added together, as they are different quantities, the first being a moment expressed in inch-pounds and the second a force expressed in pounds. If anything, this expression should be:

$$M_2 = A_2\left(\frac{Q\,\mu}{2} + \text{tension of driving chain.}\right)$$

The $\frac{Q\,\mu\,A_2}{2}$ is all right but the tension of the driving chain should be multiplied by a lever arm A_3, which is the distance from the center line of the chain to the center line of the radius rod, as shown in Fig. 2. Then

$$M_2 = \frac{Q\,r\,\mu\,A_2}{2}$$

$$M_3 = \text{tension of driving chain} \times A_3$$

The resultant bending moment M of the axle is then given by the following:

$$M = \sqrt{(M_2 + M_3)^2 + M_1^2}$$

Further on in the article the expression occurs:

$$\text{Torque of ball} = \frac{43{,}200}{60} = 720 \text{ pounds.}$$

The term "pressure" should be used in place of "torque." If the quantity was a torque, the result would be expressed in inch-pounds.

I do not agree with the way in which the force F on the housing pin is figured. As shown in Fig. 5, the torque rod, the housing torque boss, and the torque rod pin form the familiar type of hinge construction. As such, the pin is subject to a shearing stress in the planes of the joint, which are found to be 7.5 inches apart by scaling the drawing. Regarded in this light, the magnitude of the shearing force will be:

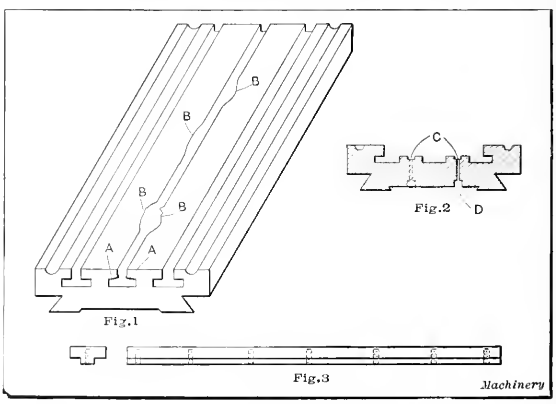
$$F = \frac{720 \times 56\tfrac{3}{8}}{7.5} = 5400 \text{ pounds.}$$

Mr. Najder does not state whether he regards the stress as a bending or a shearing stress, but as he uses the distance of 10.75 inches between the centers of the bearings supporting the pin, it appears that he is figuring for bending. As a matter of fact, there can be no bending action on the housing pin, as it invariably forms a press fit in the torque rod and a nice sliding fit in the housing torque boss, which is generally lined with an accurately reamed bronze bushing. If Mr. Najder had a shearing force in mind, the illustration is wrong; and if the illustration is right, he must have based his analysis upon the assumption that the pin was subjected to a bending stress.

Flint, Mich. M. TERRY

REPAIRING A MILLING MACHINE TABLE

The milling machine table shown in Fig. 1 has been broken at *A* and *B* through the use of common bolts for clamping the work in position. Tables are frequently damaged in this



Figs. 1 to 3. Method of repairing a Broken Milling Machine Table

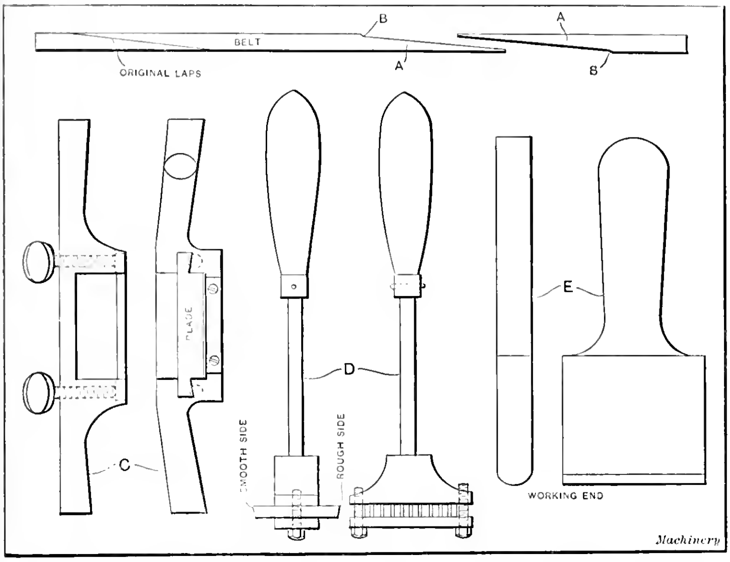
way when the remainder of the machine is in good condition; hence a method of making a satisfactory repair is of considerable value. The method which I developed for this purpose may be briefly described as follows: The two bars which form the T-slots were planed off, after which two

grooves were planed as shown at *C* in the sectional view, Fig. 2. Two bars shown in Fig. 3 were next planed up with extensions to fit into the grooves *C* in the table. When this work had been done, the table was turned over and the bars put in place under it, after which seven holes *D* were drilled and tapped in each bar to provide for holding the bars in place by countersunk screws. Hexagon cap-screws were used for this purpose. With the bars secured to the table in this way, a very satisfactory repair was made

New York City. MAX HIMOFF

PREPARING AND CEMENTING BELTS

The cementing of endless belts—either new ones or old ones that have parted in service—is not as well understood as it might be by the average mechanic. With the view of explaining the method of procedure in cementing belts for the benefit of men employed in shops where there is no regular repair man, the following article has been written. In order to prepare an old belt that is greasy, the first step is to clean is thoroughly by soaking in benzine for about fifteen minutes. The belt is then laid out flat on a board or bench to allow it to dry. The ends that are to be joined should be further cleaned by placing blotting paper over and under them and then applying a hot iron to soften the grease so that it will be absorbed by the blotting paper. It is, of course, understood that a clean new belt does not require this treatment.



Method of forming Belt Laps and Tools used for the Forming and Cementing Operations

In the case of a new belt, the belt should be fastened to a board or bench and the ends beveled as shown at *A*, the tools *C* and *D* being used for this purpose. The tool *C* is employed to rough down the ends to shape and the smooth side of *D* is used to scrape the end of the lap to produce the shoulder *B*. The rough side of the tool is then brought into action to rough the surfaces to be joined so that they will take the cement. In beveling the ends of the belt, care should be taken to see that the finished lap will run in the same direction as the original lap in the belt, the length of the lap being determined from the length of the original lap of the old belt.

A good cement for joining the ends of a belt is cheapest, as a cheap cement is dear at any price. A good cement can be made from the following formula: Peter Cooper's white glue, 1 pound; powdered white lead, 1 ounce.

This glue is heated in a double boiler and thoroughly stirred until it forms a thick paste. Before using, the paste is thinned down the required amount with grain alcohol until a thin paste is formed. This paste is applied hot. After joining the ends of the belt, the joint is rubbed with the end of the wooden spatula *E*, taking care to apply pressure over the entire lap. Two small pieces of board can be clamped or nailed over the joint, after which the belt is placed in a warm, dry corner away from drafts. The joint should be allowed twenty-four hours to set before it is used.

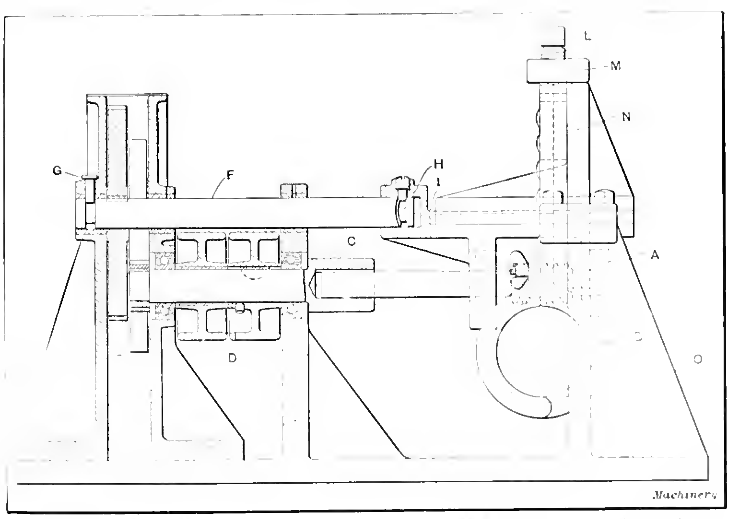
New Britain, Conn. W. C. BETZ

WORM AND WORM-WHEEL LAPPING FIXTURE

There is no part of an automobile that requires more careful attention than the steering gears. It is essential for these gears to be designed to meet the requirements of the particular car on which they are to be used, and to keep the cost of production within certain limits. There are several types of steering gears that may be used, among which may be mentioned the worm and segment, the bevel gear and bevel segment and bevel gears. The most universally used type is the worm and worm-wheel.

In manufacturing these gears the best grade of high-carbon machine steel, nickel steel, chrome-nickel or chrome-vanadium steel is used. These steels all forge well and are easily machined. They are always carbonized and hardened to give the greatest strength and wearing qualities. It is during this hardening process that strains are set up which cause the steel to warp. No matter how accurately the parts may have been machined, they will be distorted by the heat-treatment to such an extent that many cannot be used. It was to overcome this distortion that the fixture shown in the accompanying illustration was designed. By grinding or lapping the worm and worm-wheel together, it was found that the uneven spots which caused the steering wheel to turn harder in one position than another were removed, and the wheel would then turn smoothly and easily.

After a worm and worm-wheel have been used on a car for some time, it is necessary to adjust the worm and wheel to take up end motion. Therefore it is essential for more than one thread on the worm to be lapped to the wheel. It is for performing this lapping operation that the present fixture was designed. For this purpose the worm is placed



Fixture for lapping a Worm and Worm-wheel to insure having them run smoothly together

in the fixture at A and the wheel at B. The end of the worm-shaft is fitted to the driving shaft C; this driving shaft carries tight and loose pulleys D and a small gear which engages the train of gears E that operate the shaft F. The gears E run in an oil bath formed by means of the upright members of the fixture. The pin G fits in a groove at the left-hand end of the shaft F and prevents it from moving in an endwise direction, while a cam H is cut at the opposite end of the shaft F; this cam operates the slide I in which the worm is mounted. By means of this cam the worm receives an oscillating motion which laps enough of the thread to allow adjustment between the worm and wheel.

The worm-wheel is also clamped in an adjustable slide which is provided to allow various sized worm-wheels to be lapped in the fixture. Gibs provide an ample bearing for this slide, which is operated by the screw L which runs in the plate M. The casting N supports the gibs and forms the dovetailed bearing for the slide I. The base casting of the fixture is shown at O.

In using this fixture the worm is driven at about fifty revolutions per minute, and the gear reduction is such that the worm is removed longitudinally at about one-quarter the rate at which it revolves. This ratio allows the thread of the worm to engage each tooth of the worm-wheel, and the use of emery and oil for lapping gives a very smooth surface that insures even running between the worm and wheel.

Springfield, Mass. E. H. Pratt

REPAIRING AN AUTOMOBILE CYLINDER

The shop in which the writer is employed recently made rather an unusual repair on an automobile cylinder, and a description of this repair will, perhaps, interest readers of Machinery. The reason trouble was taken to repair the cylinder was because considerable time would have elapsed before a new one could have been obtained from the manufacturer; also, to make a new cylinder in a local shop would have meant a large expense in the preparation of patterns.

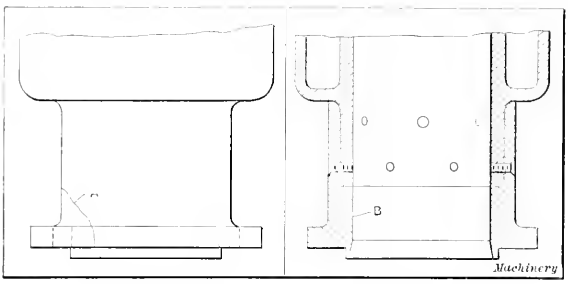


Fig. 1. The Broken Cylinder Fig. 2. Repaired Cylinder

The cylinder was broken through the bottom flange as the result of being bolted down unevenly to the crank-case. The position of the break may be seen at A in Fig. 1. In making the repair, the cylinder was first placed in a lathe, and the flange parted off at the break, as shown in Fig. 2. The outside diameter of the cylinder was next turned right up to the water-jacket, a light cut being taken to leave the wall as thick as possible. The casting B was then made and machined to go over the outside of the cylinder, and to fit up underneath the water-jacket. This casting was secured in place by means of eight manganese-bronze set-screws staggered around it. The reason the set-screws were made of manganese-bronze was because this material expands at practically the same rate as cast iron when it becomes heated, and so, although the set-screws penetrate to the inside of the cylinder, they will not score the piston. The holes for the set-screws were drilled and tapped into both the casting and the cylinder, and then countersunk. The set-screws were screwed home and the ends riveted over.

Before the original cylinder was touched the necessary dimensions were taken to make sure of the repaired cylinder having the same compression as the original. Up to the present time, the cylinder has not given any trouble.

Christchurch, New Zealand. J. H. Clarke

A GROOVING TOOL

If one stops to study the problem that was presented when it was desired to machine the casting shown in Fig. 1 on an automatic turret lathe, it will be seen that a grooving tool will be needed which must not only be strong but very compact and accurate. Fig. 2 shows the design finally adopted, which has proved very satisfactory, both as to automatic action, strength and accuracy. Although rigid enough as it is, a pilot, of course, would add to its rigidity.

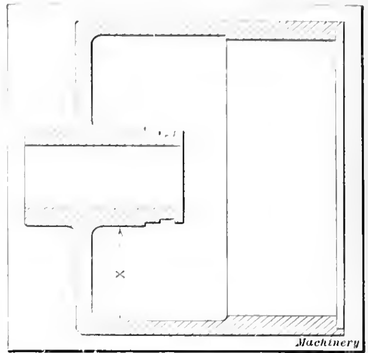

Fig. 1. Work for which Grooving Tool was made

The bar A is offset as shown at B, point C being the center of the lathe chuck and point D the fulcrum point of the tool-holder E, which is a steel casting bored to hold the tool F. This tool is set and held in the proper relation as regards its cutting edge by clamps G and nut H. It will be noticed that the tool F is so shaped that it will allow of much and inexpensive grinding, forestalling any possible objection to such an expensive cutting tool. The tool-holder E is free to move on the bar A up to a certain limit, and when this limit is reached, pin J will come into contact with screw K. It is necessary to adjust this screw very accurately, for upon it, more than upon the travel of the lathe carriage, depends the accuracy of this tool; it takes the backlash out of the cam, so to speak.

The lathe carriage, of course, also has an adjusting screw L which engages the surface of the plate M as the carriage moves inward and brings the tool-holder around, thus feeding the cutting tool into the work the required amount. The pull-back arrangement consists of a spring N, pin O, bracket P and adjusting screw Q. When we consider that this tool, from which so much is expected as regards rigidity and automatic performance, needs but 1½ inch working space at X, as shown in Fig. 1, it will be apparent that it is of excellent design.

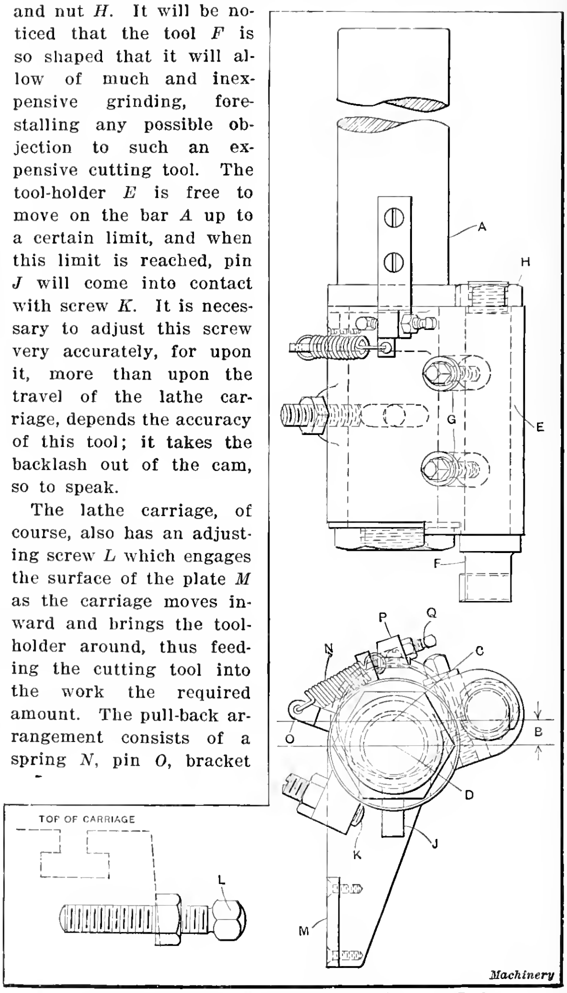

Fig. 2. Grooving Tool for use on Automatic Turret Lathe

Richard Russell

"RELIEF OF TAPS"

In the December number of MACHINERY on page 263 (engineering edition) in the article, "Relief of Taps," is a misstatement of fact which we believe you should correct.

The form of relief shown in Fig. 13 is not new. We began making taps with that form of relief in March, 1885,

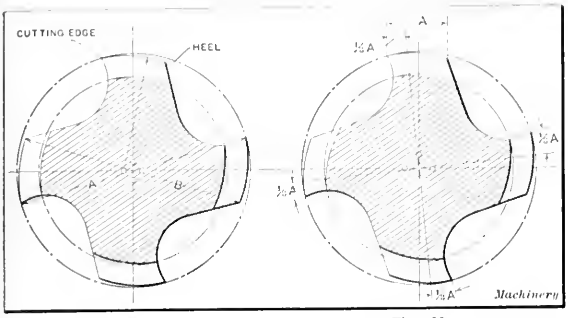

Fig. 1 Fig. 13

and have continued the practice ever since, calling the tap "machine relieved." One-third of the width of the land is concentric, that is, the top, angle and bottom of the thread follow the curve of the hole. The remaining two-thirds of the land is relieved on the top, angle and bottom of the threads.

Thousands of users of "Lightning machine relieved" taps will recognize the error into which your editorial department has fallen.

Greenfield, Mass. WILEY & RUSSELL MFG. CO.

[We are glad to publish this letter from the Wiley & Russell Mfg. Co., which is something of a revelation. The letter will remove the impression existing, we believe, not only among tap users but among tap makers that "Lightning" machine relieved taps are made with full eccentric relief, the relief beginning at the cutting edges of the teeth as shown in Fig. 1. We think that many users of "Lightning" taps are not aware of the fact that one-third the land is concentric and the remaining two-thirds eccentric, as shown in Fig. 13. The editorial department was never taken into the confidence of the company as regards the exact shape of thread relief used and was as much in the dark as to the details as the average tap user.—EDITOR.]

"RELIEF OF TAPS"

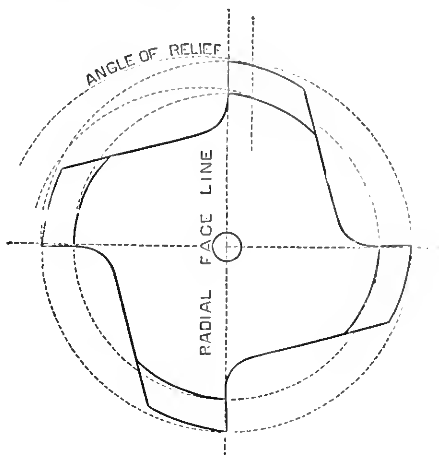
I have read with great interest the article in December MACHINERY entitled "Relief of Taps," and wish to endorse heartily the conclusion reached therein that the type of relief shown in Fig. 13 is the most practical and satisfactory form discussed. The article contains one error, however. The Pratt & Whitney Co. is wrong in its belief that it is the originator of this particular type of relief, when adopting it five or six years ago. I can testify, from personal knowledge, that this identical type of relief was used on the tap product of the Wiley & Russell Mfg. Co. during the whole time I was connected with them—a period of about eighteen years—prior to the retirement of the Russells from that company upon its reorganization about two years ago. I believe they still use it.

The accompanying cut and text are from a catalogue of the Wiley & Russell Mfg. Co. published about eight years ago, and will be found to describe accurately the same type of relief as shown in Fig. 13 of MACHINERY's article. This catalogue clipping, while not giving the exact width of the concentric land, shows in the cut that the full diameter of the tap is maintained for approximately one-third of the land, and this, indeed, was our practice.

In that catalogue of eight years ago was first printed the description of our tap relief, but I have in my possession a Wiley & Russell catalogue of thirty years ago, which contains this phrase: "Our taps are all machine relieved on the most correct principle." This refers to the same type of relief as that we are now discussing, and was printed at about the time we began applying this relief by machinery during the process of threading. Even earlier than that, probably for a period of about five years, we had been applying this same relief to our taps by hand with a "three-square" file. While I cannot get from the records the exact date when this type of relief was first used upon the Wiley & Russell tap product, it is safe to assume from the above that it was at least thirty-five years ago.

The long experience of the management of our new organization, the Russell Mfg. Co., has so strongly convinced us

Lightning Machine Relieved Taps



The above diagram shows our Machine Relief, exaggerated to show the principle.

Every tooth, both top and bottom of thread, is relieved like a milling cutter This reduces friction and binding to a minimum, and produces a free, clean cut.

In this form of relief, the true size of the tap is maintained the full length of the flute; ample stock being left behind the cutting edge, so that it may be reground for sharpening many times without destroying the size.

This relief might also be termed a "parallel" relief, as the full threads are of the same diameter throughout and absolutely parallel from end to end.

The life of these taps is much longer than that of taps relieved by the common method, which have the true size only in the first few teeth at the point, the relief being gained by gradually reducing the size toward the shank. It will readily be seen that the size of taps, relieved in this way, is lost as soon as the teeth at the point wear down; and these teeth wear the fastest, because they do all the cutting.

Our relief is applied in process by special machinery, which insures absolute uniformity.

☞Index on pages 4 to 6

of the superiority of this type of tap relief over all others that we will use it upon our product as soon as it is ready for the market.

Greenfield, Mass. CHARLES C. RUSSELL

RECHARGING PERMANENT MAGNETS

In the How and Why department of MACHINERY for December I note that A. B. has trouble in retaining magnetism in permanent magnets of magnetos. In the first place, the steel should be very hard, as this is an important feature of permanent magnets. As the magnetic flux is strong when the current is on, the current evidently flows in the proper direction; the trouble is elsewhere. I have magnetized permanent magnets with success by tapping them with a hammer while in the magnetic field. The sharp hammer blows seem to help the magnets take up the flux. The hammer should be of brass or other non-magnetic metal to prevent it from sticking to the magnetized steel. After the magnets are energized, they should be subjected to as few shocks or blows as possible, as this tends to weaken them.

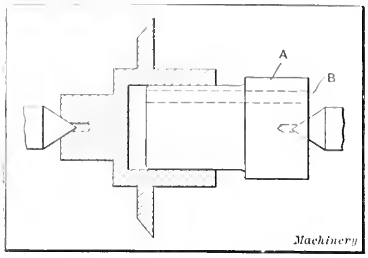
SHOP AND DRAFTING-ROOM KINKS

INGENIOUS MEANS AND SHORT CUTS FOR SAVING LABOR AND MATERIALS

REMOVING A PLUG FROM A FINISHED PIECE

It sometimes happens that a finished piece with a regular center at one end and a central bore at the other must be held between centers on a lathe. Such a piece is shown in the accompanying illustration, where it will be seen that an auxiliary plug A has been driven into the bore to provide a bearing for one of the lathe centers. If it is necessary for this auxiliary plug to be a tight fit in the bore, it may be difficult to get the plug out again without spoiling the finish on the work. An easy way of doing this is to drill a small hole *B* of such a size that a piece of drill rod will be a slip fit in it. After filling the bore with oil, the piece of drill rod is inserted in the hole and then struck on the end with a hammer. This action is equivalent to that of a hydraulic ram and causes the plug to slip out of the bore in the work.

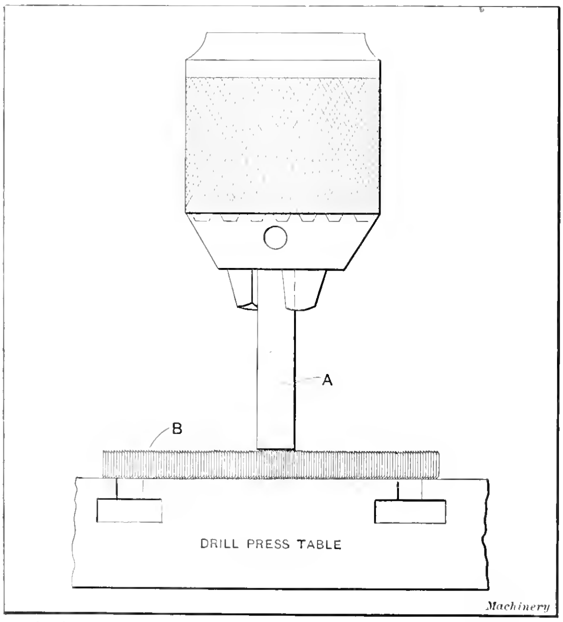


Method of removing a Plug from a Finished Piece

Detroit, Mich. HERMANN MUELLER

FACING STOCK IN A DRILL PRESS

The accompanying illustration shows a useful "kink" for facing off and finding the center of stock that can be chucked in a drill press. The stock to be faced is shown at *A*, which illustrates a piece of round stock held in the drill chuck and being fed against a flat file *B*. A few revolutions will be sufficient to locate the center of the stock. In facing pieces by this method, a bastard file can be used for roughing, after which the finish is produced with a smooth file.

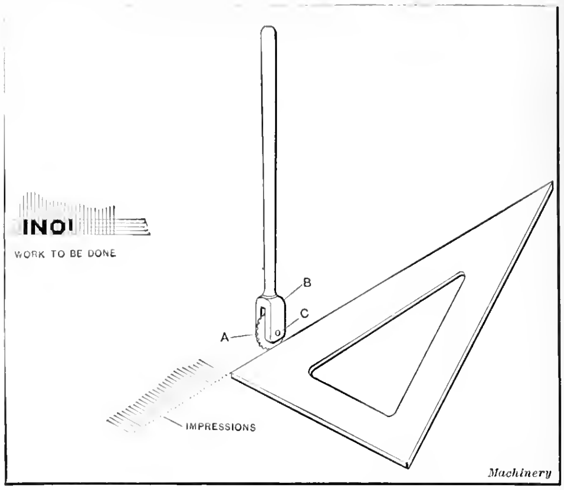


Rapid Method of facing and centering Stock held in a Drill Chuck

Corbin, Ky. J. A. JESSON

A HANDY DRAFTSMAN'S INSTRUMENT

It was necessary for a lot of neat block lettering to be made for titles of standardization sheets, etc. To do this well, accurate spacing is required. Such spacing, if done by the ordinary method of pricking it off from a scale, is very tedious as well as expensive, and it would pay any draftsman to make the simple little tool here shown. To do so, sharpen the teeth of a wheel from an old clockwork to the desired point and mount it in a handle *B* with a pin *C*. The wheel *A*, if run along a triangle, will impress dots with speed and accuracy. It will also be of aid in cross-sectioning.

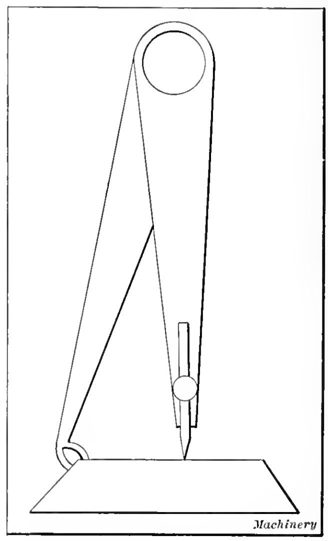


Instrument for laying off Spaces for Block Letters or Section Lines

East Lynn, Mass. R. F. POHLE

SPECIAL HERMAPHRODITE CALIPERS

The writer recently had to lay out some pieces with beveled sides and found that he could not use an ordinary pair of hermaphrodite calipers with only one hook on the leg. For this job, a special pair of hermaphrodite calipers, illustrated herewith, was designed. The illustration will be self-explanatory to any mechanic, but it may be mentioned that the size of the double hook is exaggerated in order to show it more clearly. There are probably many mechanics who have felt the need of such a tool from time to time. For the particular job for which these calipers were made, it would have been difficult to scribe a straight line for even a short distance with a tool of the ordinary design, as it would require a very steady hand to keep the calipers running on the beveled side of the work. The double hook did away with this difficulty entirely so that the laying out was a very simple matter.



Special Hermaphrodite Calipers for use on Beveled Work

Philadelphia, Pa. FRED HENKE

* * *

Don't forget that a drill with a short shank can be removed from the spindle, if a short piece of drill rod is dropped on the end of the shank through the spindle broach so the drift can strike it.

HOW AND WHY

QUESTIONS ON PRACTICAL SUBJECTS OF GENERAL INTEREST

MAKING TEMPLETS AND TOOLS FOR INVOLUTE GEAR CUTTERS

A. J. T.—I would like to see an article published in MACHINERY describing the process of generating or forming a templet and the tools for planing and backing off a one diameter pitch B. & S. involute gear tooth cutter. What I would like to know is how the templet is made so that it will be exactly alike on both sides and theoretically correct as to the radii of the curves and over-all dimensions; the kind of steel used and the process of making the tools and fly-cutters if any are used.

A.—The data on tooth shapes are regarded as a private matter by the manufacturers of so-called involute gear cutters. The method of making templet and formed cutters, however, is more or less common knowledge among first-class toolmakers. An article on the subject would be welcomed by the editorial department.

DRAW-BAR PULL OF TRACTORS—DRAFT OF PLOWS

B. E. M.—1. What percentage of the power of an internal combustion motor tractor is available at the draw-bar when working on soft soil? 2. What is the draft per unit of a gang plow?

A.—1. The draw-bar pull of tractors varies widely. The design of the driving wheels and the efficiency of the driving gear as well as the character of the ground on which the tractor is working must be taken into account. An average of the draw-bar pull of farm tractors working on soft soils probably would lie somewhere between 15 and 35 per cent of the power developed by the engine according to the experience of one tractor builder. Conditions may be so adverse, however, that the tractor is barely able to pull itself, when the pulling power, of course, will be practically nil. The design of the tractor wheels is an important consideration. The following data were furnished by C. H. Melvin of Deere & Co., Moline, Ill.: One tractor weighing 8000 pounds, with driving wheels $5\frac{1}{2}$ feet diameter by 14 inches face, driven by a 40 horsepower, four-cylinder engine, developed 3000 pounds draw-bar pull under normal favorable traction conditions. Another tractor weighing 12,000 pounds and having four driving wheels 5 feet diameter by 12 inches face developed a draw-bar pull of 2950 pounds under exactly the same conditions. Apparently there is no rational basis as yet for fixing standard draw-bar pulls of different types of tractors.

2. The draft of plows varies greatly in different soils, as is indicated in the following table compiled from tests made of the draft of a single unit, 14-inch plow.

Corn stubble, 7 inches deep	300 to 350 pounds
Wheat stubble, 7 inches deep	350 to 400 "
Clover sod, 7 inches deep	350 to 450 "
Blue grass, 7 inches deep	500 to 600 "
June grass, 7 inches deep	500 to 600 "
Breaking prairie sod $3\frac{1}{2}$ to $4\frac{1}{2}$	700 to 800 "

A turf and stubble plow working under normal conditions to an average depth of 6 inches will require a draw-bar pull of 425 pounds, and the same plow will vary in draft in various conditions of soil from 250 pounds in light soils to 650 pounds under hard plowing conditions, and even more. In fact, 1050 to 1250 pounds pull is required in the black waxy Texas lands. M. Rumely Co., La Porte, Ind., states that under ordinary conditions the draft of a plow per square inch of cross-section in old ground is from 4 to 6 pounds; $2\frac{1}{2}$ to 3 pounds in sandy ground and as high as 15 to 20 pounds in virgin gumbo sod. This company states that the draw-bar horsepower of a tractor ranges from 25 to 65 per cent of the indicated horsepower. Further information on the subject can be obtained from a book entitled "Power and the Plow."

TAPER TURNING WITH COMBINED FEEDS

A. S.—When taper turning is done with a vertical boring mill, by using the horizontal and vertical feeds in combination, how is the angular position of the tool-head determined? Suppose the surface is to be turned to an angle of 84 degrees (as shown in the illustration Fig. 1) and the tool feeds 8 inches in a horizontal direction while it feeds 5 inches vertically. How much should the tool bar incline from the vertical?

A.—The method of determining the vertical position of a boring mill tool-head when turning tapers by using both feeds in combination, is as follows: If the horizontal feeding move-

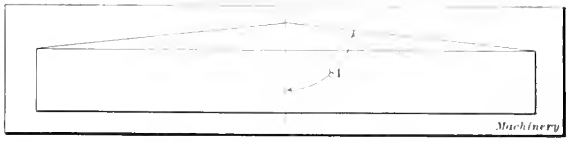


Fig. 1. Conical Shape to be turned

ment H (Fig. 2) is 8 inches and the vertical feeding movement V is 5 inches, obviously the surface will be turned to angle c, provided the head is vertical, but if inclined to some angle x, angle c will be diminished, and if the tool-bar is set over the right amount, the conical surface can be turned to an angle a equal to 6 degrees, thus giving an 84-degree angle as measured from the axis.

The first step in determining the angle x is to find angle b. The sine of angle $b = \frac{\sin a \times H}{V}$ in which H represents the rate of horizontal feed and V the vertical feed.

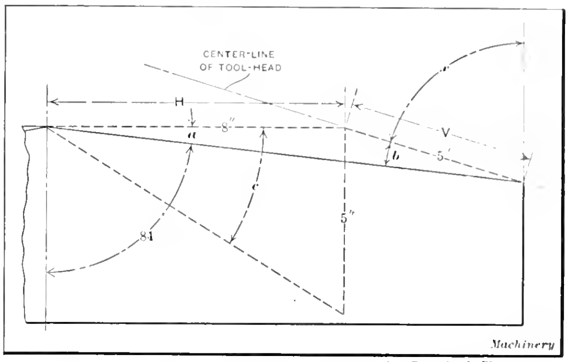

Fig. 2. Combination of Feeds that generate the Required Shape

The value of angle b is next found by referring to a table of sines. We now have angles b and a and by subtracting the sum of these angles from 90 degrees, the required angle x is obtained. To illustrate, the sine of 6 degrees or angle a, is 0.1045; hence $\sin b = \frac{0.1045 \times 8}{5} = 0.1672$.

By referring to a table of sines, we find that the angle corresponding to 0.1672 is 9 degrees 38 minutes, approximately; then angle $x = 90° - (6° + 9° 38') = 74° 22'$.

If the required angle a is greater than angle c, which is obtained when the tool-bar is in a vertical position, it would then be necessary to swing the lower end of the bar to the left, rather than to the right of a vertical plane.

* * *

The Ronay process for briquetting brass, bronze, aluminum and other metal chips, without the use of a binding material, was developed in Germany and is now protected in this country by U. S. patents. The process subjects every part of the material to heavy hydraulic pressure, so great that a comparatively solid briquette is produced. In order to produce the greatest possible solidity, it is necessary that the air be thoroughly expelled. The air cannot be expelled if the pressure is exerted in the mold from one direction only. It is necessary to exert pressure on the briquettes from the sides also. Briquettes produced by this process, in which all air is expelled, melt in the furnace with little or no more waste than pigs of new metal. The pressure employed approximates 30,000 pounds per square inch.

ANNUAL MEETING OF THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS

The annual meeting of the American Society of Mechanical Engineers was held in New York City, December 2-5, the Engineering Bldg. being the headquarters. The papers presented covered a wide range of subjects, giving the program a scope and interest hardly before exceeded. They comprised boilers and their operation, cement, enameling, fire protection, gas measurement, gas power engineering, lineshaft bearings, machine tools, management, properties of steam, rope drive, steel railway cars, textiles with reference to mill engineering, and vacuum cleaning.

The president, Dr. W. F. M. Goss, read his presidential address, "Efficiency in Technical Education a Factor in the Development of Professional Ideals," Tuesday evening, after which a reception was given to the members and their friends. On Wednesday evening the Grashof medal, presented by the Verein deutscher Ingenieure to George Westinghouse, was conferred. Mr. Westinghouse was unable to be present because of illness, and the medal was transferred to the keeping of James Hartness the new president. An address illustrated by lantern views on Leonardo da Vinci, engineer and artist, was made Wednesday evening by John W. Lieb, Jr. The customary reunion took the form of a German dinner given Thursday evening. This dinner reproduced one of the menus served to the visiting engineers in Germany last summer. The dinner was held at the Hotel Astor and a brief account of the trip illustrated by lantern views was given by Worcester R. Warner, which was followed by dancing. The technical program comprised the following papers:

"Notes on the Further Operation of Large Boilers of the Detroit Edison Co.," by J. W. Parker.

"Task Setting for Firemen and Maintaining High Efficiency in Boiler Plants," by Walter N. Polakov.

"Properties of Steam," by R. C. H. Heck.

"Hoisting and Conveying," sub-committee report.

"Dynamic Braking for Coal and Ore-Handling Machinery," by Clark T. Henderson.

"Steel Under Frame Box Cars," by G. W. Rink.

"Steel Upper Frame Box Cars," by R. W. Burnett.

"Cotton Conveying Systems; their Safeguards against Fire," by H. A. Burnham.

"Specifications for Factory Timbers," by F. J. Hoxie.

"Textile Cost Accounting," by C. B. Annett and C. F. Cunningham.

"Efficiency of Rope Driving as a Means of Power Transmission," by E. H. Ahara.

"Comparative Tests of Three Types of Lineshaft Bearings," by Carl C. Thomas, E. R. Maurer and L. E. Kelso.

"Pitot Tubes for Gas Measurement," by W. C. Rowse.

"Tests of Vacuum Cleaning Systems," by J. R. McColl.

"Tests Upon the Transmission of Heat in Vacuum Evaporators," by E. W. Kerr.

"The Art of Enameling, or the Coating of Steel and Iron with Glass," by Raymond F. Nailler.

"Gears for Machine Tool Drives," by John Parker.

"Cast Iron for Machine Tool Parts," by Henry M. Wood.

"Standardizing Machinery," by Fred H. Colvin.

"A Record of Pressed Fits," by C. F. MacGill.

"A New Process for Cleaning Producer Gas," by H. F. Smith.

"The Present Status of Large Gas Engines in Europe," by Prof. P. Langer.

"Extinguishing Fires in Oils and Volatile Liquids," by Edward A. Barrier.

"The Fire Hazard in Turbo-Generators," by G. S. Lawler.

"Control of Automatic Sprinkler Valves," by Fred J. Miller.

"The Need of More Care in the Design and Construction of Elevated Tanks," by W. O. Teague.

"Fire Pumps," by Ezra E. Clark.

The entertainment included excursions to a number of power stations and manufacturing plants, among which were the tunnel construction plants of the Catskill Aqueduct, Waterside Station, P. R. R. and N. Y. C. Stations, Henry R. Worthington, Brooklyn Navy Yard, E. W. Bliss Co., Davis-Bournonville Co., etc.

The following officers were elected for the coming year: James Hartness, president; H. L. Gantt, E. B. Katte, E. E. Keller, H. G. Reist, vice-presidents; A. M. Dean, John Hunter, E. H. Whitlock, managers; W. H. Wiley, treasurer.

JAMES HARTNESS

James Hartness, the newly elected president of the American Society of Mechanical Engineers, is a son of John Williams Hartness and Ursilla Jackson Hartness; he was born in Schenectady, N. Y., 1861. The first twenty years of Mr. Hartness' life were spent in Cleveland, Ohio, where after passing through the public schools he entered practical work in machinery building plants. Following this early mechanical experience, three years were spent as foreman of a manufacturing plant in Winsted, Conn., and the next four years as foreman and inventor in a hardware manufacturing plant in Torrington, Conn.

James Hartness

In the fall of 1888 Mr. Hartness designed machinery for the Jones & Lamson Machine Co., in Springfield, Vt., and shortly afterward took an active part in the management of the company. He served successively as superintendent, manager and for the last dozen years as president. He is known in the machinery building industries as the inventor and manufacturer of various machines for metal turning, designed to take the place of the engine lathe. One of his first inventions in this line was the flat turret lathe which has been very successful, both from a mechanical and financial point of view. Another of Mr. Hartness' designs is the "Lo-swing" lathe built by the Fitchburg Machine Works, Fitchburg, Mass. Numerous patents have been taken out on other inventions, the total number of patents granted to Mr. Hartness being over eighty.

Mr. Hartness has been a consistent believer in the policy of specialization in manufacturing. When he went with the Jones & Lamson Machine Co., a large variety of machines was made, many of them being built to order. This practice was found to be unprofitable, and a change was effected in the direction of making fewer machines and manufacturing rather than building them. When the flat turret lathe was developed and put on the market, the time was ripe for specialization, and it was made the exclusive product of the company with very gratifying financial success. Mr. Hartness early recognized many of the basic principles of so-called scientific management and applied them in the design, manufacture and selling of machine tools.

A number of years ago Mr. Hartness became much interested in astronomy, and in 1910 he invented the turret equatorial telescope which had for its object the protection of the astronomer from the rigors of cold weather observation. This interesting astronomical apparatus was illustrated and described in a paper presented by Mr. Hartness before the American Society of Mechanical Engineers at the December, 1911, meeting. His accomplishment in this line is notable in that the object for which the design was made was attained without incurring the serious optical losses that had resulted from previous designs made for the same purpose.

Mr. Hartness has been a member of the American Society of Mechanical Engineers since 1891. He served as one of the

managers of the society from 1901 to 1912 and then as vice-president. He is a Fellow of the American Association for the Advancement of Science and a member of the British Institution of Mechanical Engineers, Verein deutscher Ingenieure, Astronomical and Astrophysical Society of America, London Astronomical Society, Royal Arts Society, Boston Chamber of Commerce and vice-president of the Western New England Chamber of Commerce, and an honorary degree of mechanical engineering was granted him by the University of Vermont in 1910. He is the author of "Machine Building for Profit" and "The Human Factor in Works Management." In both these books the author has shown his grasp of the psychological problems of industrialism. He is an advocate of specialization as a necessary means of making the best use of man's energies and adapting him to the world of today.

In addition to his interests in the Jones & Lamson Machine Co., Mr. Hartness is also interested in four other machinery building companies. He married Miss Lean Sanford Pond in 1885 and has two daughters: Mrs. Beardsley, wife of William H. Beardsley, M.D., of Springfield, Mass., and Mrs. Flanders, wife of Ralph E. Flanders of Springfield, Vt.

AWARD OF MEDALS BY THE AMERICAN MUSEUM OF SAFETY

An award of medals was made at the first annual dinner of the American Museum given to about four hundred guests at the Waldorf-Astoria Friday evening, December 12. These medals comprise the *Scientific American* medal, which is given for some safety or life-saving devices, invented within a recency of three years and exhibited in the museum's collections; the Dr. Louis Livingston Seaman medal, which is given for progress and achievement in hygiene and sanitation and the mitigation of occupational disease; the Rathenau medal, which is placed at the disposal of the Museum of Safety by Dr. Emil Rathenau, president of the Allgemeine Elecctricitaets Gesellschaft of Berlin; the Travelers Insurance Company medal, which is given to the American employer who has done the most for the protection of his work-people in limb and life; and the E. H. Harriman memorial medal which is given to the American railroad that has been most successful in protecting the lives and health of its employes and of the public.

The *Scientific American* medal, received by George M. Schroeder, secretary of the Welin Marine Equipment Co., was awarded his company for boat davits, lifeboats, rafts and life preservers. The Travelers Insurance medal, awarded the New York Telephone Co., was received by President U. N. Bethel and a special Travelers Insurance medal, awarded the Allgemeine Electricitaets Gesellschaft, by T. C. Martin. The Louis Livingston Seaman medal was received by President James A. Farrell for the U. S. Steel Corporation and the Rathenau medal by President G. E. Emmons for the General Electric Co. The E. H. Harriman memorial medal was awarded to the Southern Pacific Co., and received by Julius Kruttschmitt, chairman of the board of directors. Prof F. R. Hutton made the presentations.

Following the presentations, Dr. William H. Tolman briefly reviewed some of the safety and welfare work being done in the United States and in Europe, especially Germany.

* * *

The Pennsylvania Railroad has introduced an innovation in dining car service. A new steel lunch counter car was put into service between New York and Philadelphia, December 1. The new car is eighty feet long and the exterior appearance is the same as a Pennsylvania R. R. all-steel passenger car. The interior is quite different from the ordinary dining car; instead of tables, there is one long table extending over half the length of the car. Facing this counter are revolving chairs fastened to the floor, and twenty-one people can be seated at once. The pantry and kitchen are at one end of the counter. The convenience of a lunch counter car to travelers between New York and Philadelphia should make it popular with the traveling public.

EXHIBITION OF AUTOGENOUS CUTTING AND WELDING

On the afternoon of December 4, about one hundred and fifty members and guests in attendance at the annual meeting of the American Society of Mechanical Engineers, made an inspection visit to the plant of the Davis-Bournonville Co., Jersey City, N. J., where arrangements had been made to give a demonstration of autogenous cutting and welding equipments. The Davis-Bournonville plant is divided into two general sections, one of which is devoted to building cutting and welding equipments and the other to job work in welding. The exhibits in the factory consisted of mechanically-guided cutting and welding torches, all of which were shown in operation. In the welding shop, various classes of welding—both repair work and applications of the oxy-acetylene process of welding in building new equipment—were shown. In addition, the practice followed in the generation of acetylene was demonstrated, and in the yard outside the factory several exhibitions of cutting heavy metal with both the oxy-acetylene and oxy-hydrogen flames were demonstrated. All of the different exhibits were numbered and placards were provided showing what class of work was being handled in each case. This enabled the visitors to see at a glance what work they were most interested in and to study the demonstration of the work in its details.

In the exhibition of mechanically-operated welding and cutting torches, the following machines were shown: The No. 1 and No. 2 "oxygraphs" were shown cutting out various shaped pieces. The "railagraph" and the "holograph" were shown cutting off rails and cutting the holes in the webs of rails for bolting the joints together. An interesting application of the "radiagraph" consisted of cutting rings from one-inch plate to form flanges for power plant piping. Where this method is used, the flanges are cut out to fit the ends of plain pipe and are then welded in place. The automatic barrel welding machine was also shown in operation for the first time.

In the welding shop, various classes of welding work were being done. As examples of repair work, it may be mentioned that metal was added to gear-wheels at points where teeth had been broken off, in order to provide for cutting new teeth. A cracked engine cylinder and broken flue-bridges in a boiler were also welded. An interesting demonstration of the application of the oxy-actylene torch in the case of welding products in course of manufacture consisted in the production of expansion bends for use in power plants. The steel plates from which these bends are made are blanked and formed so that they fit together with a reasonable degree of accuracy. Consecutive plates are put in place so that the edges come fairly close together; the welding torch is then used to melt the metal so that it fuses together forming a tight joint. Demonstrations of the practice followed in welding aluminum, brass, iron, steel and other metals were conducted.

Among the more spectacular exhibitions of heavy cutting that were made in the yard outside the factory, the following may be mentioned: The oxy-hydrogen flame was used in cutting a slab of armor plate 16 inches thick. This slab was 12 inches wide, and a cut was made through the piece in three minutes and thirty seconds. Another interesting example of cutting was shown in connection with the emergency equipment which has been developed for use by municipal fire departments in cutting away steel bars that may impede their progress. The oxy-acetylene cutting torch for this purpose enabled three one-inch steel bars to be cut from a grillwork in a few seconds, making a space large enough for a man to pass through. Each bar had to be cut twice, making six cuts in all.

Particular credit is due to the Davis-Bournonville Co. for the efficient way in which the exhibition was handled. By having the general exhibits separated and each one continually in operation, the visiting engineers were able to see each exhibit and get a good idea of the work that was being shown. This would have been impossible if a large crowd had been gathered around each individual machine at one time when it was in operation.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW DESIGNS AND IMPROVEMENTS IN AMERICAN METAL-WORKING MACHINERY AND TOOLS

LODGE & SHIPLEY UNIVERSAL TOOL-ROOM LATHE

The new model universal tool-room lathe built by the Lodge & Shipley Machine Tool Co., Cincinnati, Ohio, which is illustrated in Fig. 1, is made in a 16-inch nominal size but actually swings 18½ inches. To meet the requirements of various users, different types of headstocks can be furnished, *viz.*, 4-step and 5-step cone, single back-geared, 3-step cone, double back-geared and "selective head" for single-pulley belt or motor drive. As the universal tool-room lathe is designed especially for tool-room work, it has certain refinements and attachments not required in lathes for manufacturing purposes. The unit system of construction is employed throughout, so that the application or omission of various attachments which can be furnished, will in no way affect the other parts. All parts are made interchangeable so that attachments ordered subsequently can readily be applied by the customer.

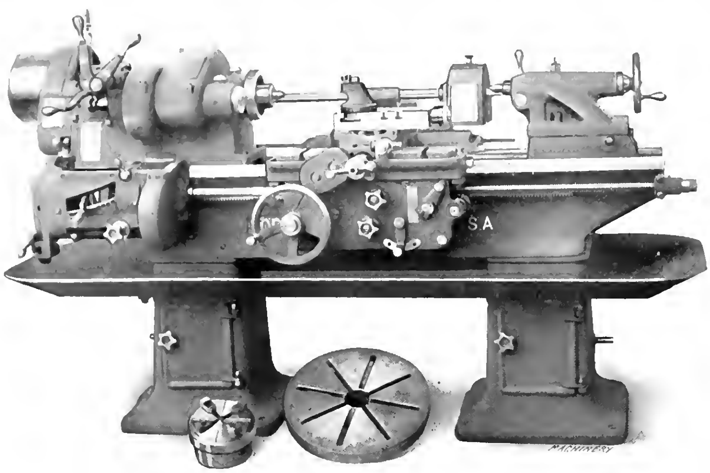

Fig. 1. Lodge & Shipley Universal Tool-room Lathe with "Selective Head"

The 16-inch by 6-foot "selective head" type is shown in Fig. 1. This lathe has full equipment comprising a pan, universal taper attachment, universal relieving attachment, translating gears for cutting metric threads in addition to English threads, draw-in chuck with collets, and step chuck with closer. Fig. 2 shows a 16-inch by 6-foot, 4-step cone-head- universal tool-room lathe without additional appliances.

Headstock and Tailstock Construction

As the selective head was described in the July, 1913, number of MACHINERY, it is sufficient merely to mention that when driven by a constant-speed belt or motor, the selective head gives twelve changes of spindle speeds obtainable through conveniently located shifting levers, and that this head derives its name from the selective type transmission used in the gear box where there are chrome-nickel steel heat-treated gears mounted on chrome-nickel steel shafts running in ball bearings. The double nose for the spindle (as formerly described in conjunction with the selective head) is used in both the selective and the cone-head lathes. It provides a pilot for centering the chuck or faceplate and a large diameter of shoulder against which the plate is screwed.

As illustrated in Fig. 2, the main housing of the cone head is carried up slightly above the center line of the spindle. This makes a very rigid construction and ties the front and rear spindle bearings securely to each other and to the head. In each of the different styles of heads, the back-gearing is designed to give uniform progression over the entire range of speeds. On the 3-step cone head the double back-gear is moved lengthwise by means of a lever conveniently located at the top of the headstock cover. In the selective head, the back-gearing is located at the front of the head and the face gear pinion may be withdrawn from mesh. The back-gear sleeve and pinion are both cut from a single steel forging.

The spindle bearings are of special white metal, interchangeable and replaceable, fitted and held into the headstock by screws. These bearings are faced and turned in halves to exact standard size, and the screw holes are drilled to jig. The end thrust of the spindle is taken against the rear housing by alternate hardened steel and bronze washers. Oil wells are provided over the spindle and back-gear bearings, and a wick oiling system delivers the proper quantity of oil by capillary attraction. All bearings in the quick change gear mechanism and apron are reached by suitable oil tubes.

The tailstock has a long bearing on the bed and is designed to allow the compound rest to be set at 90 degrees when using the tool on small diameters. Set-over screws are provided, and a hardened scale is secured to the lower side. Plug clamps lock the spindle without throwing it out of line. The spindle is made of tool steel, graduated lengthwise on top for quick reference, and has a long traverse.

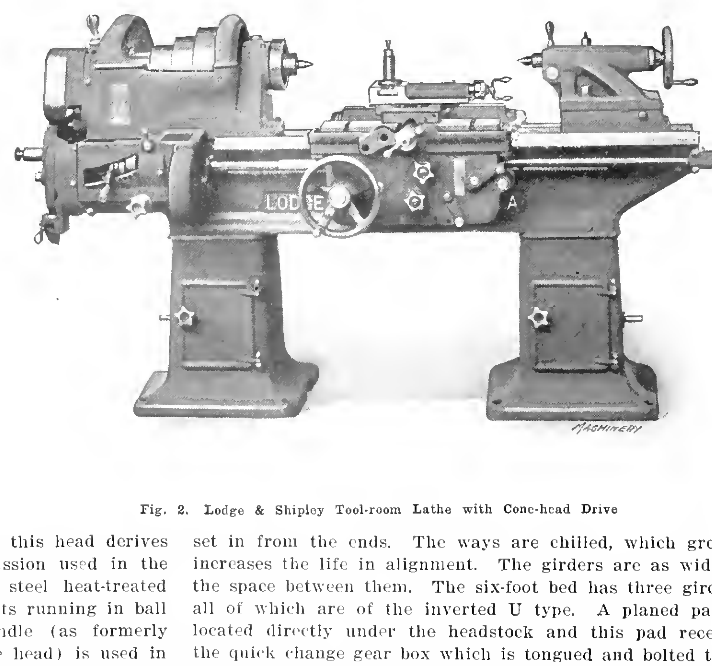

Fig. 2. Lodge & Shipley Tool-room Lathe with Cone-head Drive

The bed is of box section, wide and deep, and the legs are set in from the ends. The ways are chilled, which greatly increases the life in alignment. The girders are as wide as the space between them. The six-foot bed has three girders, all of which are of the inverted U type. A planed pad is located directly under the headstock and this pad receives the quick change gear box which is tongued and bolted to it. A coarse-pitch steel rack is bolted to the bed directly back of the lead-screw.

Carriage and Quick-return Mechanism

The carriage, a top view of which is shown in Fig. 3, has an unusually long bearing on the outside shears. It is gibbed at the front, back, and inside. The bridge has a supplementary bearing on the inside front shear of the bed, for resisting the pressure of the cut and absorbing the vibration from the cutting tool. An oil trough is cast entirely around the carriage, and shear wipers are provided for the bearing surfaces. The cross-feed screw has a large self-locking micrometer dial graduated to thousandths of an inch. All carriages are planed and drilled to receive either style of taper attachment, and also to receive the relieving attachment, and no additional fitting is required when applying these parts.

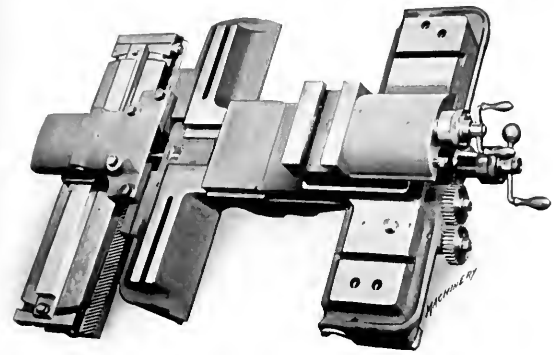

Fig. 3. Top View of Carriage with Universal Taper Attachment

The compound-rest top slide is provided with a large self-locking micrometer dial, graduated to thousandths. It is designed so that the extreme width of the swivel rests directly upon the lower slide, thus avoiding overhang of the top slide. The apron is of the double-plate type and is provided with all steel feed gearing throughout. The handwheel for imparting hand motion to the apron can be disengaged from the stem while chasing. All shafts have unusually long bearings and oil receptacles are provided to properly distribute the oil to all bearings. The half-nuts interlock with the friction feed mechanism. The apron is tongued and bolted to the carriage and the pinion engaging the rack on the bed is made of high-carbon steel and hardened. The lead-screw is set well up under the front carriage V to avoid overhang.

An entirely new quick return of the carriage for screw cutting is incorporated in the apron. The reverse is by friction and is controlled by the movement of the same lever which opens the half-nuts. By raising the half-nut lever, thus disengaging the half-nuts, the carriage stops. If the lever is raised slightly higher, the quick return mechanism is engaged, and the carriage returns four times as fast as the speed at which the thread is being chased.

Chasing Dial—Chasing Stop

A new design of chasing dial is provided which has a hardened notched disk mounted upon the shaft which is secured to a worm-wheel engaging the lead-screw threads. This notched disk has longitudinal movement and any selected index may be engaged with the stop dog which prevents the half-nuts from becoming engaged, until the proper notch in the disk is presented to the dog. This preserves the accuracy of the lead-screw on account of preventing the half-nuts from clamping on the tops of the threads, and it is also valuable in that the operator need not watch a dial.

Fig. 4 illustrates the automatic chasing stop which is attached to the dovetail of the carriage by a clamping screw and is directly connected to the lower slide of the compound rest. Its function is to form a dead stop for succeeding cuts over the thread. The rate of advancement or depth of cut can be adjusted to thousandths of an inch by knurled screws, and this cut may be varied from 0.002 inch to 0.010 inch of depth. The setting for the depth of cut is accomplished by withdrawing the cutting tool from the work. In using this device the operator need not watch the micrometer dial, but can chase the thread to the proper depth, the rest at all times coming directly against the dead stop. This chasing stop prevents breaking the point of the tool and with the quick return reduces chasing to a very simple operation.

Quick-change Gears

The quick change screw cutting and feeding attachment is bolted to a pad on the front of the bed. This attachment has two shaft centers, one for the lead-screw, and another for the cone of steel gears. The sliding tumbler is supported in a slide independent of the shaft bearings, and this slide is arranged close to the handle which moves the sliding tumbler within the slot, thus avoiding overhang of the handle and preventing binding and cramping when setting. Both shafts of the gear box extend through the left end of the box, and the change gear may be applied to either of these shafts. Power is transmitted from the feed gear on the end of the spindle, through a reverse plate to the stud in the headstock, then through a quadrant mounted on the end of the gear box which quadrant gives three changes. The gear box itself gives thirty changes, so with the quadrant, ninety changes are provided in the regular quick change gear mechanism. The housing carrying the sliding tumbler is locked into position before the intermediate gear can be meshed with the selected gear of the cone. All the shafts are short and the drive is direct. The index is simple and is attached to the top of the box where it can be seen readily by the operator. The machine may be ordered with the plain English threading index, and the metric attachment can be subsequently supplied without any additional fitting.

Equipment for Metric Threads

With the metric index it is necessary to make the cone of gears the driver, whereas in the English index the cone of gears is the driven member. When supplying the machine with the metric attachment, it is only necessary to add a gear cover, into which is mounted the translating gears. This gear cover is machined and made a duplicate of a plate which is secured to the gear box when the metric compounding gears are not supplied. When the gear box is arranged for metric pitches it is possible to cut either metric or English threads by simply turning a knob attached to the bottom of the box. By turning this knob to the left the metric pitches are obtained, and to the right, the English. It is also necessary to place the driving gear at the end of the gear box on the proper shaft; the upper shaft for the English and the lower for the metric.

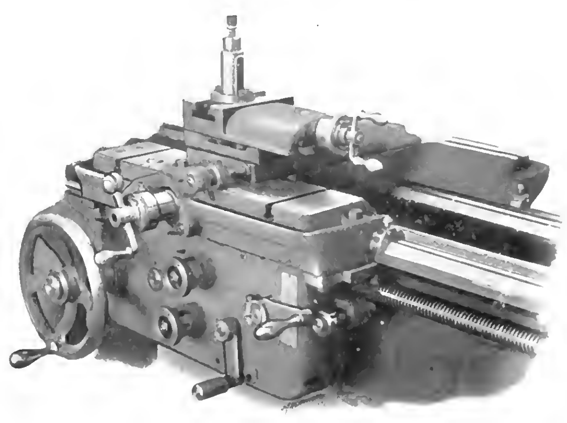

Fig. 4. Detail View of Carriage showing Chasing Dial and Stop

Plain and Universal Taper Attachments

The taper attachment requires no planed strip on the back of the bed, and therefore a special bed is not required, and the taper attachment can readily be applied to the machine at any time. All carriages are drilled to receive it. The bracket carrying the swivel bar is bolted to travel with the carriage so that at whatever part of the carriage the taper attachment may be, it can be engaged instantly. The taper attachment slide is provided with an extension which may be connected on either side, and this extension engages the

arm which clamps it to the bed and holds it stationary when the carriage is feeding. The taper attachment swivel is a steel straightedge. A gibbed shoe slides upon it, and this is secured to a slide which confines the cross-feed screw to it. The cross-feed screw telescopes through the cross-feed pinion on the front side of the carriage; thus the taper attachment may be used with a plain rest or with a relieving attachment, and the depth of cut set by the cross-feed screw. The hardened steel straightedge can be set to graduations in inches per foot, and a micrometer adjustment is provided to give extreme accuracy in setting. A nicely graduated steel scale with a compensating pointer gives accurate reading to the swivel bar.

In addition to the parts just described for a plain taper attachment, the universal taper attachment has a power traversing mechanism which provides various rates of travel.

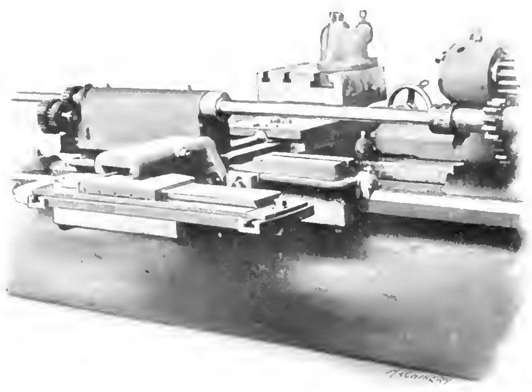

Fig. 5. Universal Relieving Attachment

Fig. 3 shows the universal taper attachment fitted to carriage. A cover plate which protects the taper attachment rack, and a cover for the gears on the front of the apron, are purposely omitted to give a clearer idea of the construction. The mechanism for giving power traverse to the swivel bar of the universal taper attachment is controlled by a shaft extending through the bridge of the carriage and operated by change gears at the front, driven direct from the apron feed train. Thus, when the universal traversing mechanism is employed, the forces necessary to produce the taper are all contained within the carriage, and all side pull is eliminated.

The plain taper attachment is satisfactory for tapers not exceeding 4½ inches per foot, but on very abrupt tapers it is impossible to feed the tool against such steep angles, and to accommodate work of this character the independent driving mechanism for the taper attachment slide has been provided. Since the slide can be fed at various speeds, it is capable of turning much longer tapers than with the plain taper attachment; in other words, if the slide feeds one-third as fast as the carriage, the carriage will travel three feet while the slide is traveling one foot, and *vice versa*. The complete range of the universal taper attachment covers tapers from 1½ inch per foot and 54 inches long, up to 13½ inches per foot and 6 inches long.

Universal Relieving Attachment

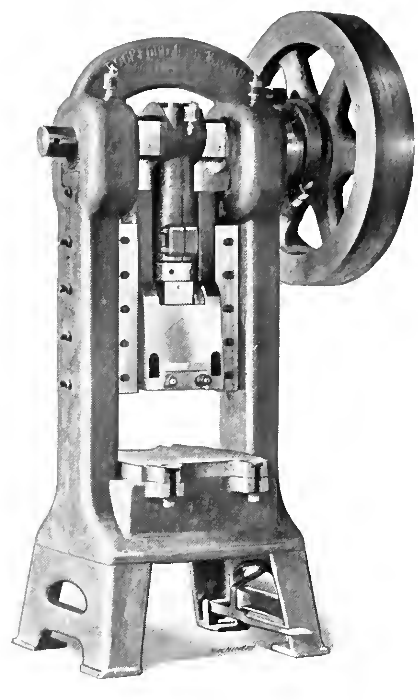
The relieving attachment illustrated in Fig. 5 is designed to produce radial, angular, end, or inside reliefs. It is never necessary to go behind the machine to make adjustment. Power is transmitted from the splined shaft at the back of the bed, through a sleeve and change gears, to a shaft below and parallel with the driving shaft. This lower shaft in the housing transmits its power through hardened spiral gears to the cam-shaft which takes its bearing in the cross-slide. This cam-shaft engages a roller mounted in a plunger. The plunger engages a bell-crank which is mounted in the top slide of the relieving attachment. The abutting portion of this bell-crank is made adjustable by an adjusting screw, and by removing the top cover this screw can be adjusted for various depths of relief from zero to ¼ inch movement of the slide. Since the power for operating the relieving slide is supplied directly through the swivel center, the swivel itself may be set at any angle without affecting the movement of the slide; thus it is possible to relieve at any angle, inside or outside, or on the face of a piece of work. The cam-shaft is placed below the surface of the bridge so that the full swing over the bridge is obtained for relieving.

Chucks and Collets

The draw-in chuck is mounted directly on the nose of the spindle. No draw tube passes through the spindle, which makes it possible for the draw-in collet to receive stock as large in diameter as the size of the hole through the spindle. Collets may be furnished for diameters from ⅛ inch to 1 5/16 inch inclusive. The collets are tightened and released by a small key wrench, which makes it unnecessary to hold the driving belt when tightening and releasing the chuck. A step chuck with adjustable jaws and closer is made to apply to the regular draw-in chuck body and is very desirable when a finished piece must be true; it is also useful for facing thin pieces of large diameter.

ROCKFORD STRAIGHT-SIDE POWER PRESSES

The No. 8 size of a line of straight-side power presses which has been placed on the market by the Rockford Iron Works, Rockford, Ill., is shown in the accompanying illustration. Like the inclinable type of presses built by this company, the



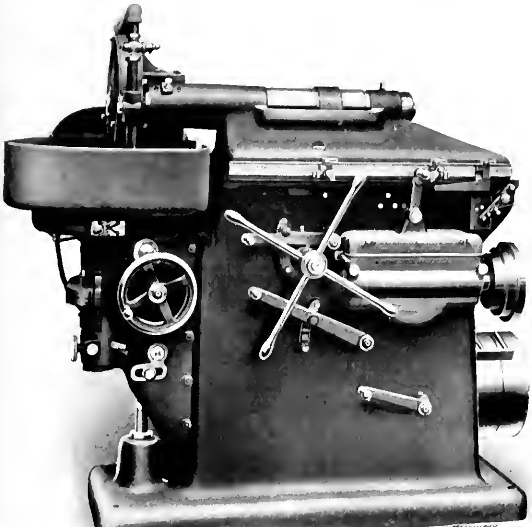
No. 8 Size of Rockford Straight-side Power Press

straight-side machines are built to meet the requirements of modern manufacturing work. The frames are of massive construction, the shafts of ample proportion, and the slides are of exceptional length and width and supported in gibs for nearly their entire length. A special feature is the construction of the main bearings which are so designed that they can be adjusted by means of a sliding wedge.

The straight-sided presses are especially adapted for such work as trimming drop-forgings and for heavy punching, piercing, stamping or forming operations. They are made in three standard sizes which weigh 5000, 7000 and 10,000 pounds, respectively. The 10,000-pound machine is shown in the illustration; this machine has a capacity for pressures up to 100 tons. The weight of the flywheel is 2000 pounds, the diameter of the shaft 4¾ inches, and the width of the main bearings 9 inches.

HEALD ROTARY SURFACE GRINDER

The 16-inch rotary type of surface grinding machine illustrated herewith is a recent product of the Heald Machine Co., 20 New Bond St., Worcester, Mass. This machine is intended for grinding flat surfaces on a great variety of work that can be rotated within its capacity, and combines accuracy with a high rate of production. The frame is of massive construc-



Heald 16-inch Rotary Surface Grinder

tion with the metal distributed in a way that insures great rigidity. The bearings are of ample proportions; all shafts are carefully ground to accurate dimensions, and the ways of the machine have broad wearing surfaces to maintain correct alignment. The grinder is driven by a single belt direct from the lineshaft, no countershaft being required.

The grinding is done by the periphery of a wheel 14 inches in diameter by $1\frac{1}{4}$ inch face. This method of using the wheel is claimed to be the most satisfactory where a high degree of accuracy and perfection of finish is necessary. When this practice is followed, feed lines and radial scratches on the work are practically eliminated. The wheel spindle is hardened and ground and runs in phosphor-bronze bearings that are provided with efficient means of lubrication and adjustment for wear. The belt pull is downward and acts in conjunction with the weight of the wheel slide to prevent the wheel from lifting under heavy cuts. This is an important factor in the high rate of production and accuracy of finish attained on this machine.

Either a 12- or a 16-inch magnetic chuck constitutes part of the standard equipment of this grinder, but other types of chucks or work-holding fixtures can be used when so desired. The 12-inch chuck has a capacity for rings up to 11 inches in diameter and disks up to 12 inches in diameter; the 16-inch chuck has a capacity for rings up to 15 inches in diameter and disks up to 16 inches in diameter. The vertical adjustment of the chuck on the grinder is 7 inches. Angular adjustment for the chuck and work spindle are also provided for use in grinding concave or convex surfaces. This adjustment is also useful in correcting slight errors of alignment which may develop after the machine has been placed in service.

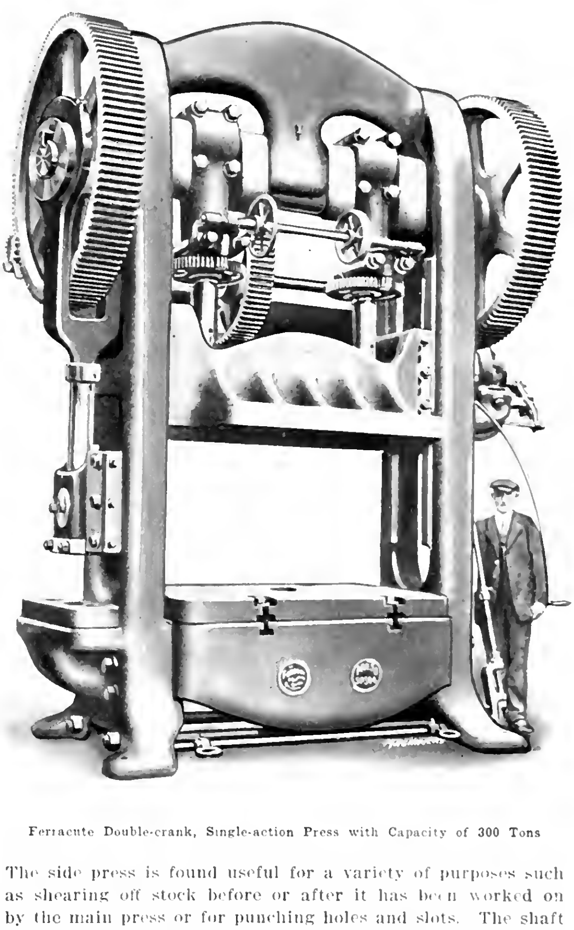
Six changes of chuck speed are available, either of which may be instantly obtained without stopping the rotation of the chuck. The work is fed to the wheel by elevating the chuck. This is accomplished by means of a screw and handwheel which is provided with a graduated dial reading to 0.001 inch. The machine may also be provided with vertical power feed as a special equipment. The wheel is fed across the work by either hand or power, the hand feed being especially satisfactory for use on small work. Three power feeds are available in connection with each work speed and each power feed is automatically reversed.

The grinder is equipped with a pump, tank and water guards for use in wet grinding. The pump furnishes a liberal supply of water which is under absolute control of the operator. The guards are designed in such a way that they prevent water from being splashed onto the operator or thrown on the floor, and also protect the bearings from being damaged by water. Centralized control is a strong feature of this machine, every lever and wheel being located within easy reach of the operator without requiring him to move from his position at the front of the machine. The maximum diameter of the surface that can be ground on this machine is 16 inches, but the machine will swing 22 inches so that it is possible to handle parts that have projecting members extending out beyond the actual surface that is to be finished. The thickness of the work that can be handled is $4\frac{1}{2}$ inches with the size of wheel that is ordinarily used; by using a smaller wheel, however, work as thick as 7 inches can be ground.

FERRACUTE SINGLE-ACTION PRESS

The Ferracute Machine Co., Bridgeton, N. J., is now building a new line of double-crank, single-action presses. These machines are made in various widths between the columns, but all of them exert the same pressure—300 tons. One of this line of presses is shown in the accompanying illustration, this particular machine having a distance of 76 inches between the columns.

These presses are equipped with side punches which make them virtually two presses combined in a single machine.



Ferracute Double-crank, Single-action Press with Capacity of 300 Tons

The side press is found useful for a variety of purposes such as shearing off stock before or after it has been worked on by the main press or for punching holes and slots. The shaft is a high-carbon steel forging with a diameter of $8\frac{1}{2}$ inches at the journals and 10 inches at the cranks. The standard stroke of these machines is 3 inches, but the presses are de-

signed for any stroke up to 24 inches; the illustration shows a press which has the maximum stroke. The adjustment of the ram is 4 inches and the height from the bed to the ram, with the ram at the top of its stroke and adjustment, is 24 inches. The ram is adjusted by means of a worm-shaft connected by gearing to the pitmans, the action on which is simultaneous. The worm-shaft may be revolved by hand, but a pulley is also provided to enable the adjustment to be made by the motor.

These presses are equipped with a combination friction clutch and brake by means of which the machines may be started or stopped at any point of the stroke. The flywheel has a diameter of 40 inches, a face width of 12 inches, and weighs 1800 pounds. The twin gears are 76 2/3 inches in diameter by 11 inches face width, the ratio of the gearing being 40 to 1. The depth of the bed from front to back is 50 inches, and there is an oblong hole in the bed 58 by 36 inches in size. The bolster is $5\frac{1}{2}$ inches thick. The press shown in the illustration weighs about 72,000 pounds.

GARVIN VERTICAL SPINDLE MILLING MACHINE

The vertical milling machine which the Garvin Machine Co., Spring and Varick Sts., New York City, has recently added to its line possesses a number of features that increase its productive capacity. Both the table and cross-slide are provided with fast feed in either direction, which is controlled by automatic trips in the same way as the regular feeds. The

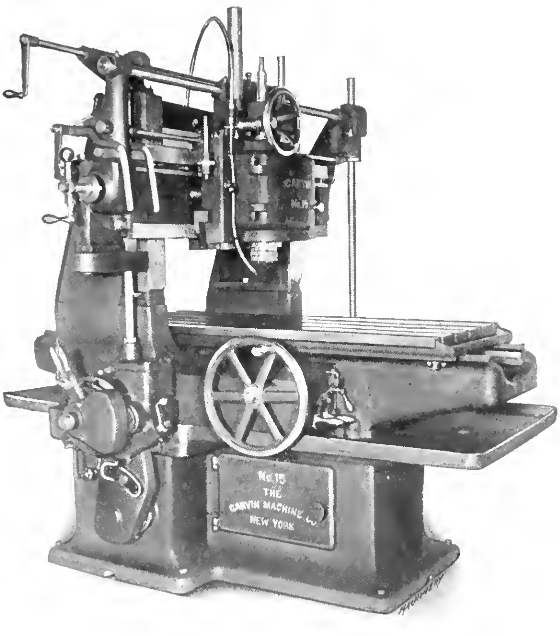


Fig. 1. Garvin No. 15 Vertical Spindle Milling Machine

drive is self-contained, power being transmitted through a cone pulley supported on a bracket secured to the base of the machine. This design lends itself readily to the application of individual electric motor drive, a silent chain being used to connect the motor to the cone pulley shaft, as shown in Fig. 2. Power is taken from the cone pulley shaft through bevel and spur gears connecting with the upper ends of the spindle and back shaft. By shifting one gear, the spindle may be driven direct at high speed or through the back-gears at slow speeds, and in each case the direction of rotation is the same. The spindle has a threaded nose $3\frac{1}{4}$ inches in diameter to take a No. 24 B. & S. cutter; and sufficient power is provided by the machine to drive a cutter 12 inches in diameter.

The table movement is obtained through a Sellers drive which is controlled by a pilot wheel. Both the table and cross-slide are equipped with double feed boxes, giving either the regular or the fast feed at the will of the operator. These feeds are thrown in by separate handles and controlled by dogs on the table and cross-slide in the ordinary way. Two styles of dogs are provided on both the table and the cross-slide. One set of these dogs provides for tripping and coming up against a solid stop, while the other set are buttons that trip the feed but permit of passing over. The fast and the regular feeds are in the same direction, so that the arrangement permits of making quick jumps over intervening spaces be-

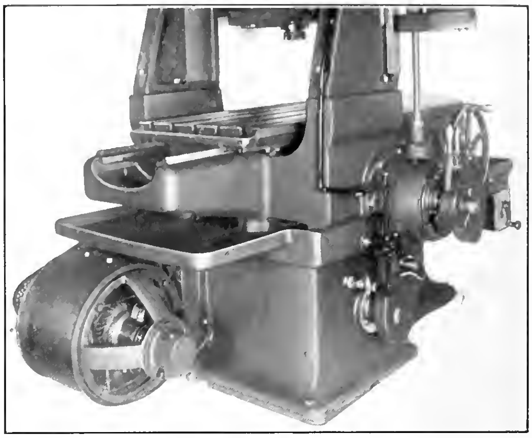

Fig. 2. Motor Drive through Silent Chain applied to Garvin Milling Machine

tween cuts. An interlocking mechanism prevents throwing in both the fast and the regular feed at the same time. One turn of the change feed handle throws the gearing in the feed box out of action, and when this is done another handle on the box may be operated to traverse the table and cross-slide rapidly back or forth by power. The second handle is interlocked with the feed-box to prevent the possibility of accidents.

STOW PORTABLE ELECTRIC TOOLS

The accompanying illustrations show a toolpost grinder and a breast drill which constitute recent additions to the line of portable electric tools made by the Stow Mfg. Co., of Binghamton, N. Y. The toolpost grinder is particularly adapted for grinding lathe centers, dies, cutters and a variety of other classes of work, and it handles both internal and surface grinding. It will be seen from Fig. 1 that a flexible cord and

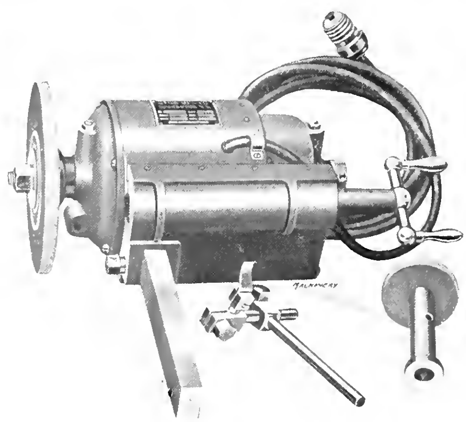

Fig. 1. Stow Electric-driven Toolpost Grinder

plug are used to supply current to the motor, the plug being connected to an ordinary lamp socket. The motor for this grinder is made for 110- or 220-volt, 60-cycle alternating current; or for 110- or 220-volt direct current. The wheel used for external work is 6 inches in diameter by $\frac{3}{8}$ inch face and the attachment for internal grinding is shown beside the motor.

Fig. 2 shows this company's new breast drill which has a capacity for drills up to $\frac{1}{2}$ inch. This tool is equipped with

either a Jacobs or Pratt chuck for straight shank drills. Like the toolpost grinder, the drill motor is provided with a flexible cord for connection with a lamp socket. There is a switch in the handle for controlling the motor. The motor is for use on 110- or 220-volt, 60-cycle alternating current circuits; or for 110- or 220-volt direct-current circuits. Particular attention has been paid to having all parts of the drill carefully balanced so that it is convenient to handle.

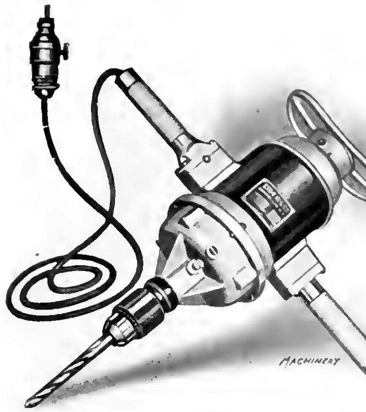

Fig. 2. Stow Portable Electric Breast Drill

CINCINNATI EIGHTY-FOUR INCH PLANER

The accompanying illustrations show an 84-inch planer which has been added to the line of the Cincinnati Planer Co., Cincinnati, Ohio. In designing this machine particular attention has been paid to the means for obtaining rapid manipulation of the heads; all of the control levers are also conveniently placed for the operator, so that this planer is just as handy to run as a smaller machine. Rapid power traverse in both directions is provided for all the heads, and all movements are independent of each other and can be operated whether the table is moving or not. The motor at the top of the machine is used for driving the rapid power traverse and feed to the heads, and for elevating or lowering the cross-rail. The motor pinion engages a large gear on the horizontal rapid traverse shaft from which the pinion that drives the feed clutch receives its power; the latter is shown at the right-hand end of the shaft. Near the center of the horizontal shaft there is a gear that meshes with a pinion on the gear-case of the elevating mechanism, through which power is transmitted for moving the cross rail. A lever from this gear-case passes to the left hand side of the machine and operates the clutches for raising or lowering the cross rail.

The power feed to the heads receives its power from the driving clutch which has a bell-crank and link motion to the bevel gear on the horizontal shaft. This bevel gear meshes with a gear on the vertical shaft which drives the trigger gears on the end of the rail and side heads through spur gears. The driving clutch is tripped by a rod that receives its motion from the tumbler and dogs on the side of the table and bed. The feed is varied by graduated heads which indicate the exact amount of feed at all times, thereby eliminating guesswork. The rapid power traverse receives its power from a second vertical shaft on the side of the housing, the arrangement being similar to that employed for the feed. The small handles seen at the end of the rail and side heads operate the rapid power traverse and feed. Turning these handles to the left engages the rapid power traverse, and turning them to the right engages the regular feed. It is impossible to engage both movements at the same time. The handle at the bottom of the rail is used for reversing the direction of the rapid power traverse. The gearing is contained in the case at the end of the rail, and the operator can make any desired change without moving from his position.

All the heads are taper gibbed and the clapper box is held by a heavy clamp and three screws. The housings are of massive box construction, tongued and doweled to the sides of the bed and fastened at the top by an arch. The cross-rail is secured to the housings by inside and outside clamps which give great rigidity. The table is also of box form and is heavily ribbed to give the required stiffness. The ways are oiled by forced lubrication provided by a pump at the back of the housing. The bed is of the four-wall type and exceptional care has been taken with the bracing. It is bored to receive the driving shaft boxes, which are of large diameter and provided with oil chambers of ample size. All driving gears are of steel and the pinions and table racks are cut from steel forgings. Fig. 1 shows one of these planers with a 34-foot table; and Fig. 2 shows the arrangement of the reversible motor drive, in which the motor is connected direct to

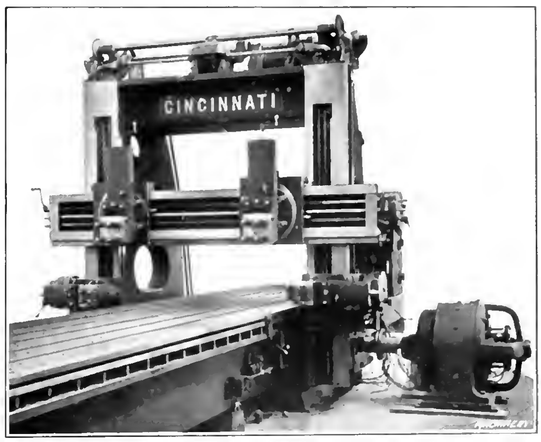

Fig. 2. Arrangement of the Reversible Electric Motor Drive

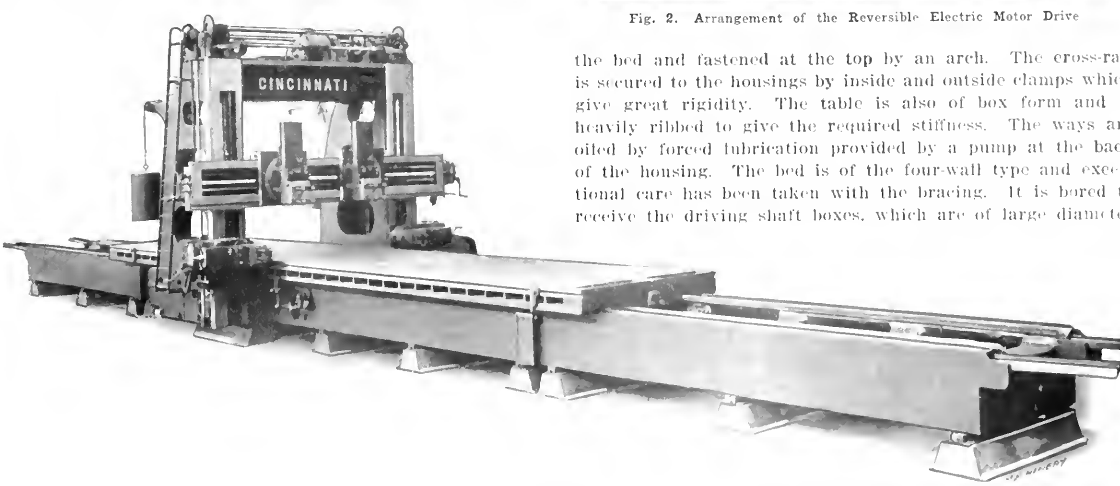

Fig. 1. Cincinnati 84-inch Planer equipped with Reversible Motor Drive and a 34-foot Table

the driving shaft through a flexible coupling. The motor controller is mounted on the housing. Planers of this type are being built in different sizes and lengths.

LANGELIER SWAGING MACHINE WITH SEMI-AUTOMATIC HOLDER

The swaging machine illustrated in Figs. 1 and 2 is a recent addition to the line of swaging machines built by the Langelier Mfg. Co., Providence, R. I. The functions of the machine and holder, taken as a unit, are to feed, reduce or size and automatically withdraw from the machine dies, solid stock, round, hexagonal, square or other sections requiring one plain unreduced butt or end and a reduced shank or blade. This machine handles such work as valve push-rods, nut tapper taps, single-butt automobile spokes, gun cleaning rods and similar parts ranging up to ½ inch diameter and from 8 to 14 inches long. The operator's duties consist only in loading, starting the machine, and unloading the holder; the swaging, feeding and withdrawing of the work from the dies is done automatically.

The reductions of stock are effected without waste of material or removing the surface. An idea of the economy of the swaging process both as to the saving of material and time of production may be obtained from Fig. 3, which shows the lengths of several blanks and also the lengths of the swaged samples. In addition, the saving in grinding expense may be considerable, as the parts are swaged very close to the finished size so that very little grinding is necessary. In many cases the parts are swaged so close to size that grinding is eliminated.

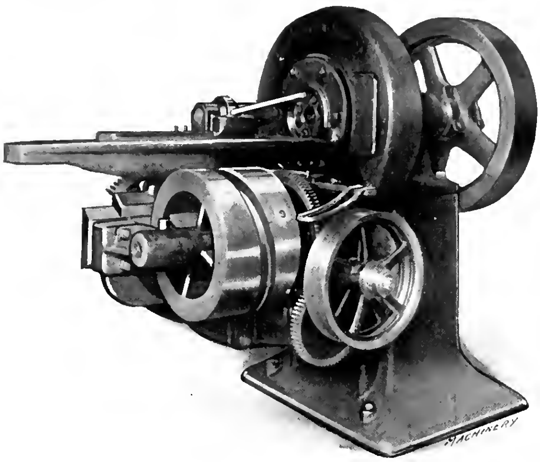

Fig. 1. Langelier No. 4 Swaging Machine with Semi-automatic Holder

The particular machine illustrated is so built that the size to be swaged can be controlled very closely. The machine is heavily constructed throughout to secure a rigid unit so that an unskilled operator can maintain steadily a high degree of accuracy and a large output without injury to the machine. The spindle, which is a vital part, is made unusually large and heavy. It is of hammered steel, turned and ground, and is bored the entire length so that long pieces can pass through and beyond the dies. The spindle is slotted across the enlarged end to receive a pair of hammer-blocks and dies. All sides of the slot are lined with hardened and ground steel plates securely riveted in place, thus practically enclosing the dies and hammer-blocks in a hardened steel box. This construction keeps the dies in true alignment and insures long life to the surfaces in contact.

The hammer-blocks carry on their outer ends two hardened and ground steel rolls which come into contact, during every revolution of the spindle, with a number of hardened steel rolls located in the machine head of the spindle. As the head rolls are in fixed seats, the hammer-blocks and dies are caused

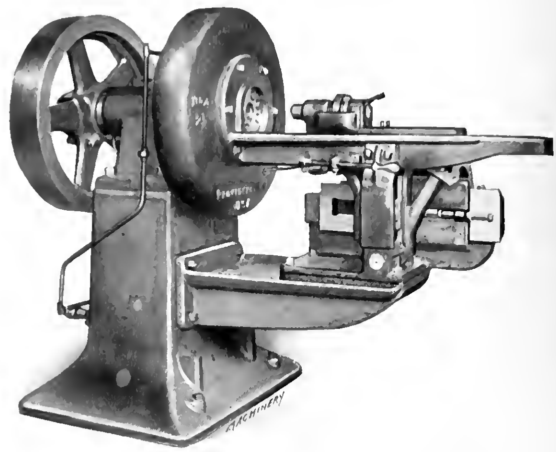

Fig. 2. Opposite Side of Langelier Swaging Machine illustrated in Fig. 1

to strike many sharp, quick blows in rapid succession for each revolution, thus producing a permanent set in the metal being swaged and imparting a high surface finish. The dies are made of high-speed steel and maintain their size for a long time. These dies can be quickly removed if desired. To control the proper die opening and maintain the reduced size required for the stock, two conical pointed screws are let into the front plate in the slotted end of the spindle and project into corresponding holes in the end of the hammer-blocks. Washers of the proper thickness are used under the heads of these screws to retain the distance which the conical screw points enter the hammer-blocks. By adjusting these screws in or out, different amounts of opening between the dies are obtained.

The spindle has an extra long bearing and is provided with loose floating sectional cast-iron bushings which serve to greatly decrease the surface velocity and increase the wearing surface. These bushings are perforated all over and the oil holes act as small reservoirs and serve to distribute the oil over the bearing as the bushings gradually revolve with the spindle. The flywheel is heavy and the hub is bolted and keyed to the spindle. At the rear end of the spindle a clamp nut is provided that serves both for taking up end play which

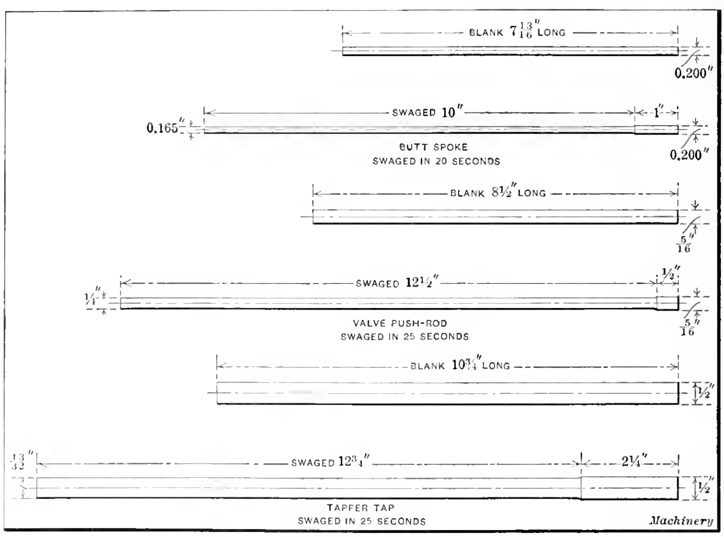

Fig. 3. Comparative Lengths of Blanks and Swaged Samples and Rate of Production

might occur as a result of long service, and for holding the flywheel in position endwise. An automatic oil pump driven from the main spindle, circulates oil through the running parts of the machine and is connected to the large oil reservoir in the machine base. The ample capacity of this reservoir permits running the machine a long time with only periodical attention to the oiling.

The holder consists of a rigid projecting rail bolted to the front of the machine, which provides long bearings on which a crosshead and saddle reciprocate. This crosshead carries an interchangeable and self-centering spring chuck with a hand lever tightener for holding the stock firmly, even when the grip is very short. The crosshead feeds the stock to be swaged, then it pauses slightly to allow the stock to be swaged neatly against the shoulder, joining the unswaged and swaged portions, after which it starts on the return stroke. The crosshead recedes at twice the feeding speed and the stock is automatically withdrawn from the dies; when near the end of the return stroke, the driving belt shifting device for the holder mechanism operates, thus shifting the belt to a loose pulley. This causes the holder to stop in the "loading" position. As the next blank is gripped by the chuck, the operator shifts the driving belt to the tight pulley, thus starting the crosshead again on the feeding or forward stroke. This cycle of motions is repeated for every blank.

The crosshead can be set at any desired position on the holder rail, and the forward or backward travel of the crosshead can be varied according to the length of the blank before and after swaging. The length of the feeding and return strokes of the crosshead are determined by the arc which a segment gear (partly shown in Fig. 1) which meshes with a rack on the under side of the crosshead saddle, describes as it is actuated by a straight-line movement of an adjustable stud on the lower crosshead. By setting this stud at different positions the length of the arc is varied. On the rear of this lower crosshead another stud is provided, carrying a roller which engages the large cylinder cam seen in Fig. 2. This cam is rotated by a wormwheel and worm driven through reducing gears and tight and loose pulleys, from the overhead countershaft.

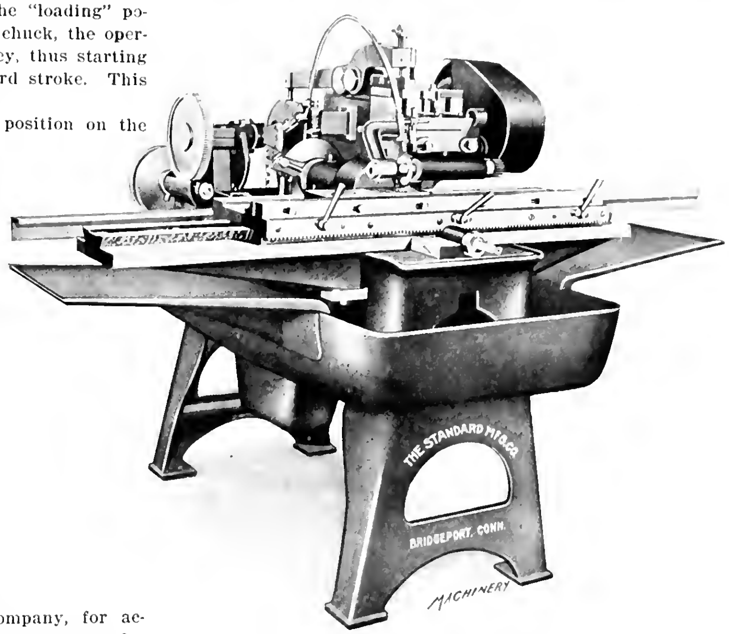
This same type of feeding and withdrawing mechanism can be applied to other types of swaging machines built by this company, for accommodating longer lengths and larger diameters or for reducing tubing. When equipped with high-speed steel dies 2½ inches long, the machine illustrated herewith reduces cold-rolled steel stock 0.311 inch in diameter down to 0.250 inch, in two operations. The feed is at the rate of 30 inches per minutes, and the piece is withdrawn at the rate of 60 inches per minute. Faster feed and return speeds can be used if the size and nature of the stock will permit.

STANDARD RACK CUTTING MACHINE

The Standard Mfg. Co., Bridgeport, Conn., has recently placed on the market an automatic rack cutting machine which has a capacity for work up to 30 inches in length. It will be seen from the illustration that this machine is provided with a deep oil pan equipped with detachable wings. This pan, in combination with an efficient oil pump, insures an adequate supply of oil being delivered to the cutter without the oil being splashed or wasted. The low substantial legs of the machine are a factor in providing for increased stability.

The cross-rail is keyed to the table, clamped by set-screws and fastened underneath. The vise is provided with long bearings and a gib on the inside to enable any wear which may develop to be compensated for. An adjustable steel jaw runs the entire length of the vise. The vise is equipped with a rack with which a pinion meshes that is operated by a crank; this rack and pinion provide for returning the vise to the starting position after the work has been completed. There is an adjustable trip for disengaging the feed when the work has been finished.

To insure accuracy and eliminate vibration, the cutter spindle bearing has been made of ample proportions, and an overhanging support is also provided to hold the arbor at its outer end. The slide which carries the cutter spindle is provided with both vertical and horizontal adjustment by means of screws, and a micrometer adjustment is provided for accurately gaging the depth of the cut. Four-stroke cams are regularly furnished for ordinary work and special stroke cams for special work. This machine has all the regular features of the Standard gear-cutting machines, such as quick return for the cutter; means for raising the cutter free of the work on the return stroke, thus obviating the necessity of again passing through the rack; and allowing the indexing to be done during the return stroke. The locking of the index plate, means of quickly changing the amount to be indexed and similar features of the gear-cutting machines have been retained on this rack cutter. If desired, the rack cutter may be converted into a gear-cutting machine. The rack cutter is made in sizes corresponding to the Nos. 1, 2 and 3 gear-cutting machines made by the Standard Mfg. Co.



Standard Rack Cutting Machine for Work up to 30 Inches in Length

MONITOR A. C. MOTOR CONTROLLER

The Monitor Controller Co., Baltimore, Md., has recently perfected a controller for use on either single, two- or three-phase alternating-current motors. This controller is similar to the pre-set speed type of direct-current equipment manufactured by this company. With alternating-current motors, the dynamic brake for stopping cannot be used; consequently it is necessary to employ a foot-brake on the machine or a magnetic brake on the motor. Where the magnetic brake is used it can be operated from the new Monitor controller.

The accessories used with this new type of controller are identical with those used on the corresponding type of Monitor direct-current apparatus, *i. e.*, provision is made for starting, stopping and reversing the motor and for making slight movements of the machine. Every movement is controlled by either a push button or a safety lever, as shown in the illustrations. The distinctive feature of this controller is that, in starting the motor, a proper amount of resistance is automatically inserted in each phase which gives absolutely correct starting characteristics and is the same under all running conditions. The starting effort required of the motor is

the same, regardless of the position of the regulating handle. After the rotor has attained the proper speed, the starting resistance is automatically cut out by the controller, and the regulating resistance, which has been previously determined by setting the handle, is automatically thrown in, thus bringing the motor to the desired speed, which may be anything

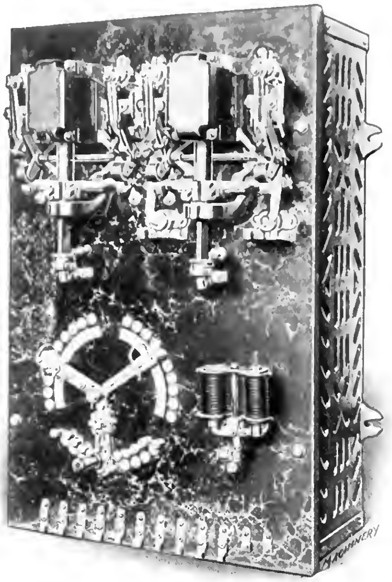


Fig. 1. Monitor Alternating-current Motor Controller

between normal and the lowest specified speed. A no-voltage release is provided with the controller so that in the event of a failure of the line voltage and the consequent stopping of the motor, the entire system is automatically cut out of the circuit and will not start again with the return of the voltage until the operator has moved the starting lever or button.

Fig. 2. Control Station

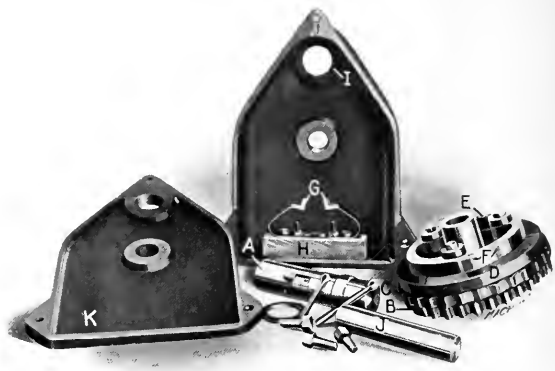
When this is done the starting cycle is again gone through, to place the motor in operation. These controllers are built for one or two motor drive, depending upon the amount of speed variation required, and will eventually be built in all sizes. At present they are made for motors whose rotor current does not exceed 150 amperes.

The control station shown in Fig. 2 is mounted on the machine, and in the case of large machines more than one of these stations will be used. The lever is shown in the "start" position at *A*, the "ready" position at *B* and the "stop and safety" position at *C*.

CLEVELAND CRANE LIMIT SWITCH

In order to perform its essential function of protection in the face of careless operation, a crane limit switch must be designed in such a way that it will always be in operating condition when required. It is impossible to design any mechanical device that will not sooner or later get out of order, and in the case of a limit switch the essential feature is to have an arrangement which will give warning if there is anything wrong. In the closed circuit type of limit switch made by the Cleveland Crane & Engineering Co., Wickliffe, Cleveland, Ohio, this idea has been applied by connecting the switch into the hoist motor circuit in such a way that the electrical operating parts are always charged with current when the hoist is in operation. Should any defect—such as a broken wire or loose connection—develop, it at once throws the motor out of commission the same as though the hoist had been run up to the limiting point. In this way, positive assurance is obtained that the switch mechanism is unfailing in its action when the hoist is running. A feature of the design is the simplicity and accessibility of all parts and the facility with which the switch may be installed.

The parts of this limit switch are shown in the accompanying illustration, from which the method of operation will be readily understood in connection with the following description: The tripper *A* is connected to one end of the hoisting drum shaft by two pins driven into the end of the



Cleveland Closed Circuit Type of Crane Limit Switch

drum shaft. Four holes drilled in the end of the tripper allow for one-quarter turn positive adjustment. A tooth at the end of the tripper engages one tooth of the tripper sprocket *B* at each revolution of the drum. An oval recess cut at the side of the tooth in the tripper permits the check sprocket *C* to rotate while the tripper tooth is engaged in the tripper sprocket. The conformation of the teeth on the outside of the check sprocket to the contour of the tripper prevents the sprocket wheel from turning while the tripper is completing the revolution. Attached to the sprockets by small insulated through bolts is a fiber insulating ring *D* and a brass contact ring *E*. Two fiber contact blocks *F* are inserted in the brass contact ring at a distance apart which depends upon the number of revolutions of the drum required to raise the hoist block between the two extreme positions. Mounted on a fiber block *H* are two contact springs *G* which form electrical connection with the brass contact ring *E*. The circuit leads are attached to terminal posts on the contact springs and are connected to the coil of a magnetic switch which controls the hoist motor current, the switch being located in the cage within easy reach of the operator. When the block reaches the limit of its travel, the switch is opened by the breaking of the circuit in the switch coil, due to the contacts *G* resting on the fiber blocks *F*. The cast-iron box *I* encloses the entire mechanism and is attached to the frame of the trolley by through bolts. One end of the pin *J* which carries the

contact ring and sprockets is held by a bearing in the box, and the other end by a bearing in the cover *K*. The tripper pin is supported in the same way. When the cover is removed from the box every part is instantly accessible and may be readily removed. The small size of this switch makes it particularly convenient to install.

BROWN & SHARPE GEAR CUTTING MACHINES

In developing the Nos. 3-H and 13-H automatic gear cutting machines (Figs. 1 to 4), the intention of the Brown & Sharpe Mfg. Co., Providence, R. I., has been to produce machines that are adapted for taking heavy cuts on coarse pitch gearing and at the same time produce work of a high degree of accuracy. With this idea in view, particular care has been taken in the distribution of the metal to secure the greatest possible rigidity and consequent freedom from vibration. The wheels and levers for controlling all of the movements, as will be seen in the illustrations, have been placed at the front where they are within easy reach of the operator. This is obviously a great convenience in setting up work and in the subsequent operation of the machine. Referring to the illustrations, it will be evident that the No. 3-H machine shown in Figs. 1 and 2 is simply adapted for cutting spur gears, while the No. 13-H machine is intended for cutting both spur and bevel gears. The design and construction of the two machines is essentially the same with the exception of the cutter slides. The No. 3-H machine is described first and the same descriptive matter will apply to the No. 13-H machine with the exception of the cutter slide and one or two other details which will be referred to.

The No. 3-H Spur Gear Cutting Machine

Referring to the rear view of the No. 3-H machine illustrated in Fig. 2, it will be seen that the drive is through a single pulley. In the line-cut Fig. 5 *A* is the shaft on which the driving pulley is mounted. The feed of the cutter slide is taken from this shaft by means of spur gears which transmit through the shaft *B* to the change gear box shown at the right-hand end of the machine in Fig. 1. From the change gear box the drive is back through the shaft *C* which carries a worm meshing with the feed worm-wheel *D* mounted

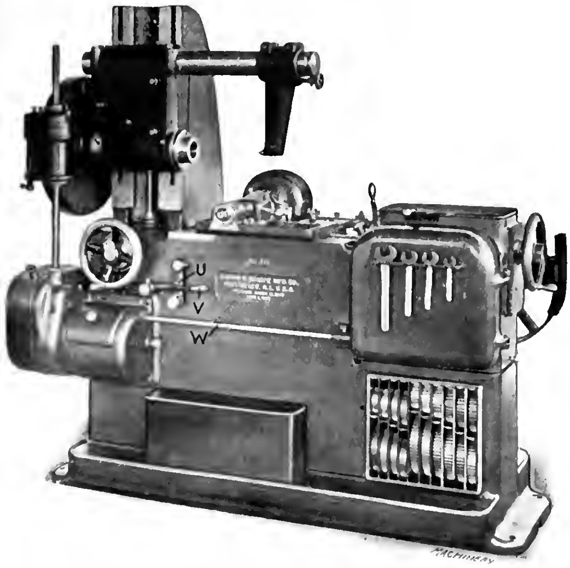


Fig. 1. Front View of Brown & Sharpe No. 3-H Gear Cutting Machine

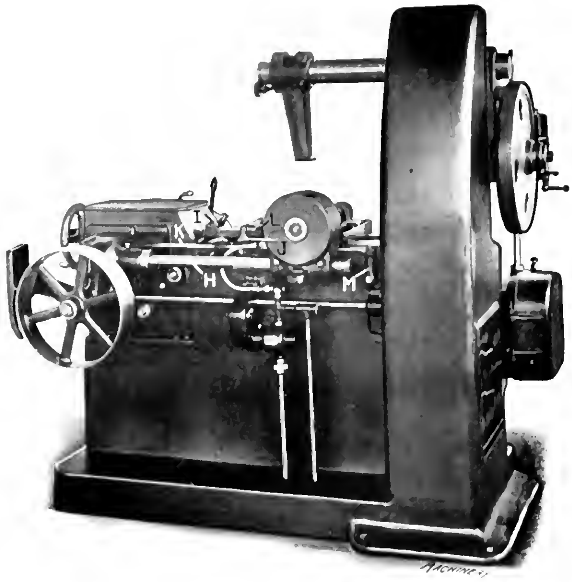

Fig. 2. Rear View of No. 3-H Gear Cutting Machine

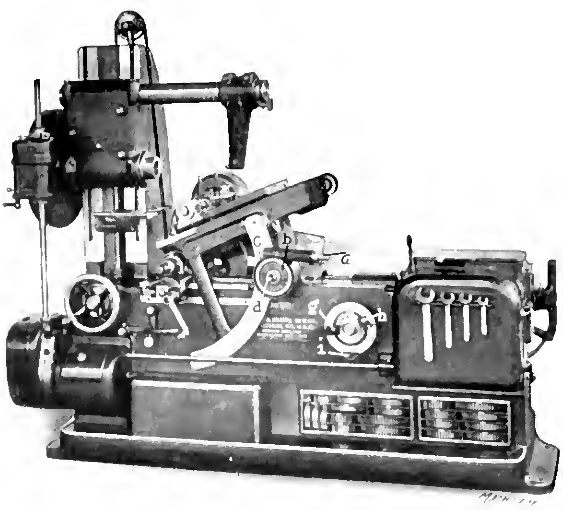

Fig. 3. Front View of Brown & Sharpe No. 13 H Gear Cutting Machine

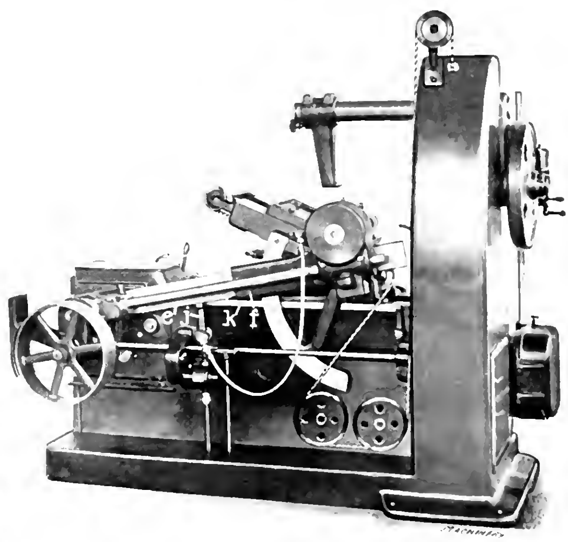

Fig. 4. Rear View of No. 13-H Gear Cutting Machine

on the feed shaft E. The cutter slide is moved by this threaded feed shaft. Sixteen changes of feed are provided by the change gears; these feeds are in geometrical progression and cover a range of from 13/16 to 15 3/4 inches per minute.

The speed changes for the rotation of the cutter are obtained by change gears in the same box in which the feed gears are mounted. The drive to the cutter is carried back through the shaft F, Fig. 5, which drives the shaft H, Fig. 2, by means of bevel gears. There are twelve speed changes provided which are in geometrical progression and cover a range of from 30 to 156 revolutions per minute. An outer bearing has been provided for the cutter spindle which gives additional support to adapt the machine for heavy classes of manufacturing work. Another distinctive feature is the application of a heavy balance wheel on the cutter spindle. This balance wheel is employed to carry the cutter through hard spots in the work or to compensate for any other inequalities that would have a tendency to cause the speed of rotation to vary.

When the cutter has been fed across the face of the work, the movement of the cutter slide is reversed by the action of the dog I which engages the stop J mounted on the horizontal shaft K, Fig. 2. The operation of the mechanism may be briefly explained as follows: When the dog I engages stop J it continues to move forward and carries the stop with it. This, in turn, carries the shaft K forward and operates the clutch mechanism shown in the line-cut, Fig. 6. This illustration shows the feed worm-wheel D and the quick return worm-wheel G which are mounted on the cutter-slide feed rod. Either of these worm-wheels may be secured to the feed rod by means of an intermediate clutch which is operated by the arrangement of the dogs shown in Fig. 2. When the dog I engages the stop J and pulls the shaft K forward, a stop on the end of the shaft K engages with the end of the lever N, Fig. 6. Further movement of the shaft K causes the lever N to swing on its pivot; and the roller carried at the lower end of the lever N runs over the pointed plunger O and pushes this plunger down against a compression spring. This movement continues until the roller has passed the top point of the plunger, when the action of the spring causes the lever N to be thrown over with great rapidity.

A pin carried by the lever N works in a slot in lever P. At the time when the roller has reached the top of plunger O, this pin is engaged with the end of the slot and further movement of lever N causes a corresponding movement of lever P. The cam surface at the lower end of lever N engages with the projection Q on the locking plunger R and causes this plunger to be pushed down against the tension of a spring. The depression of the plunger releases the clutch from the feed worm-wheel D and allows it to be thrown over by the action of lever P so that it engages with the quick return worm-wheel G. When the clutch engages with the worm-wheel, it is locked in engagement by means of the locking plunger R' and remains locked until the carriage has been returned to the starting point. The clutch is then released from the return worm-wheel and thrown back into engagement with the feed worm-wheel. Referring back to Fig. 5 it will be seen that the quick return worm-wheel G is geared direct to the main driving shaft A by means of a pair of spur gears. This drive allows the cutter slide to be returned at fifteen feet per minute.

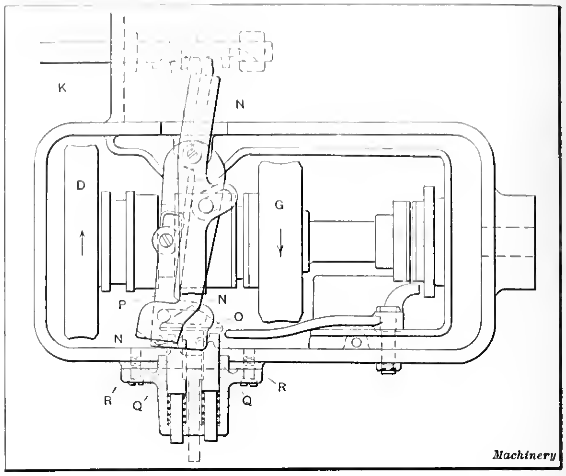

Fig. 6. Mechanism for engaging Feed and Quick-return Worm-wheels

A handwheel is provided at the end of the feed shaft for feeding the cutter slide by hand. This wheel is secured to the shaft by sliding it into engagement with a clutch. It is evident that when the feed of the cutter slide is reversed so that the quick return comes into action, the handwheel would be rotated in the opposite direction at a high speed. Were such a condition allowed to take place, there would be a risk of injuring the operator. To avoid this danger, a lever is provided which acts automatically to throw the handwheel out of engagement with the clutch before the quick return is engaged. This lever is operated by the lever N, Fig. 6, from which the arrangement will be readily understood.

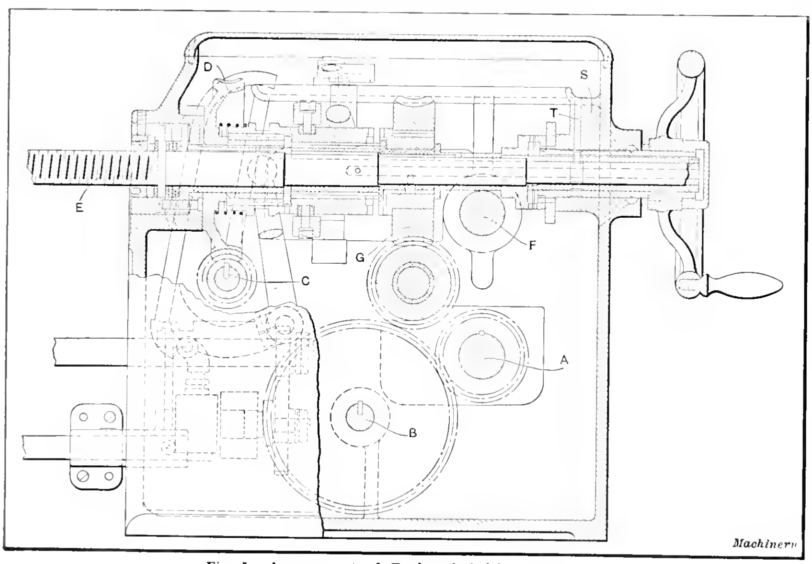

Fig. 5. Arrangement of Feed and Quick-return Drives

It will be remembered that the maximum feed employed on this machine is 15¾ inches per minute while the cutter slide is always returned at the rate of 15 feet per minute. Evidently this change of speed in connection with the reversal of the cutter slide would result in subjecting the gearing to a serious shock. To overcome this difficulty, the arrangement shown in Fig. 7 has been employed. In this illustration G is the worm which meshes with the quick return worm-wheel on the feed shaft. At the moment when the clutch engages with the quick return worm-wheel, the worm is allowed to move over on its shaft against the tension of a stiff spring, and in this way the shock of reversal is taken up by the spring instead of being borne by the gearing. This eliminates damage to the gearing and also does away with the shock and consequent vibration which would result if such a method were not employed. This method of

taking up the shock is a new device which has been recently adopted.

When the cutter slide is being returned to the starting point the dog L, Fig. 2, engages with the stop J carried on the shaft K. This causes the lever N, Fig. 6, to be thrown in the reverse direction. The roller on lever N acts over the spring plunger O as previously described and causes the cam on lever N to disengage the locking plunger R'. In this way, the clutch is released from the quick return worm-wheel G and comes into engagement with the feed worm-wheel D. The cutter slide is then ready for the next cut. The dogs I and L are adjustable so that the traverse of the carriage may be regulated as desired.

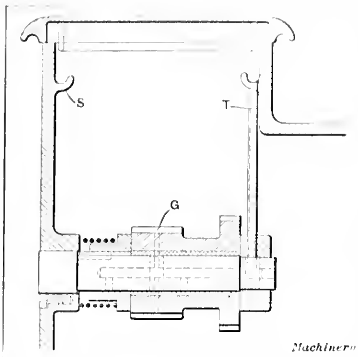

Fig. 7. Spring for absorbing Shock of Reversal and Oil Trough

The gear pump which is provided for supplying lubricant to the cutter is shown in the rear view of the machine illustrated in Fig. 2. This pump delivers lubricant from a large tank which extends all of the way under the machine. This tank is of ample size to insure having an abundance of cool lubricant available at all times ready to be supplied to the cutter. The chips and oil drop down into a pan located under the work. This pan is perforated at the bottom to allow the oil to drain back into the reservoir while the chips are retained so that they may be easily removed.

The gear-box which provides the feed and speed changes is now built as a unit ready to be mounted on the machine, instead of having the different parts of the change gear mechanism assembled in the machine as separate pieces. An improved method of lubrication has also been applied on these machines. This consists of a geared oil pump which delivers lubricant to a trough S shown in the sectional views, Figs. 5 and 7. Small brass taps T are let into the bottom of this trough which deliver oil to all of the bearings. The oil from the bearings runs back to the reservoir from which it is pumped back to the trough S. In this way there is a continual flow of oil being delivered to all of the bearings.

The index mechanism is driven by the lower of the three horizontal shafts shown at the back of the machine in Fig. 2, and the index mechanism is contained in the case shown at the left-hand end of the machine in Fig. 1. Provision is made for cutting all numbers of teeth from 4 to 50 and all numbers from 50 to 100 except prime numbers and their multiples. The placing of the indexing mechanism at the front of the machine is one of the changes referred to in placing all control levers within reach of the operating position. Another change was that of placing the change gears for the index mechanism as shown in Fig. 2, where they are particularly convenient for the operator. The operation of the index mechanism is entirely independent of the speed of the cutter and the rate of feed that is being employed, the indexing taking place during the period that the cutter slide is being returned. Indexing occurs when the cutter slide has reached the end of its reverse stroke.

The way in which the indexing is effected is as follows: When the dog L engages the stop J and pulls the shaft K backward, Fig. 2, it swings the lever M to the left. This lever is carried on a shaft which extends through to the front of the machine and has the small lever U mounted on it. The movement of the lever M rocks the lever U and throws up the lever V. The movement of the lever V engages the index mechanism and at the same time disengages the feed through the action of horizontal shaft W which extends from the index mechanism to the feed change gear-box. This shaft W trips an arrangement of levers which positively disconnects the clutch from the feed worm-wheel. The arrangement of the index mechanism is essentially the same as that employed on the standard No. 3 machine. One slight change may be mentioned in connection with the method of disengaging the worm from the index worm-wheel in order to enable the work to be rotated by hand. This is done by releasing the binder lever X. It will be seen that the upper and lower sections of the case in which the worm is mounted are secured to the case over the worm-wheel. The central section can be swung back when the binder lever is released, and in this way the worm is disconnected from the worm-wheel so that the work may be rotated. This device is found to be a decided convenience in setting up work and making adjustments.

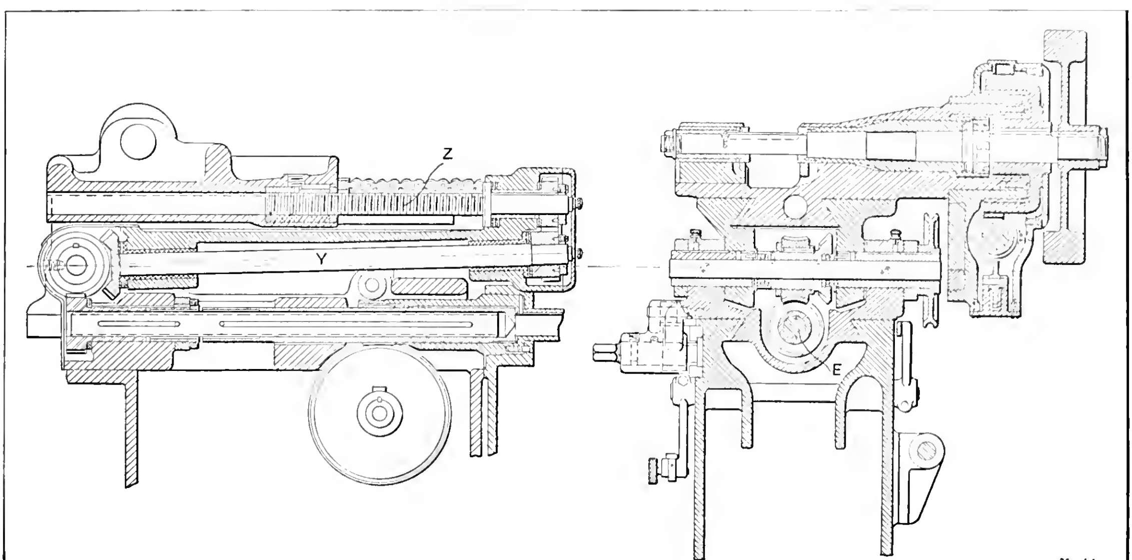

Fig. 8. Longitudinal and Cross-sectional Views of Cutter-slide

The arrangement of the work-spindle slide is evident from the illustrations. In this connection it may be mentioned that a departure from preceding designs of Brown & Sharpe gear cutting machines has been made in the introduction of T-slots in the face of the upright to which the work-spindle slide is clamped by three bolts. The slide is adjusted by means of a screw and handwheel equipped with a dial graduated to 0.001 inch, which facilitates making accurate settings of the depth to which the teeth are to be cut. The thrust on the

screw is taken by a ball bearing. The work-spindle has a No. 11 taper hole and is fitted to receive a faceplate or fixture. There is a hole through the spindle 1 13/16 inch in diameter which provides for the use of a bolt to clamp the mandrel upon which the work is carried in place in the spindle. The over-arm construction employed on this machine is particularly heavy, and as shown in the illustrations, the outboard support is fitted with an adjustable center to engage the mandrel. When so desired, a bushing may be used instead of this center.

The capacity of the No. 3-H gear cutting machine is for spur gears up to 24 inches in diameter and up to 8 inch face width. Gears as large as 3 diametral pitch may be cut from cast iron and 4 diametral pitch in steel. The machine occupies a floor space 85 inches in length—measured at right angles to the cutter spindle—by 45 inches in width. The net weight of the machine is about 4400 pounds.

No. 13-H Combination Spur and Bevel Gear Cutting Machine

Front and rear views of the No. 13-H combination spur and bevel gear cutting machine are illustrated in Figs. 3 and 4. The arrangement of the drive, the change gears for the feed and speed of the cutter, the method of indexing and the design of the work-spindle slide are essentially the same as on the No. 3-H machine. The difference in the design of the No. 13-H machine lies in the provision for making angular settings of the cutter slide for handling bevel gears. First among the improvements in this machine may be mentioned the provision of two segment gears for elevating the cutter slide instead of a single gear. It will be seen that the two segment gears are located at either side of the machine and in connection with the two trunnions which support the cutter slide provide four points of support. This effectually does away with any tendency for the cutter slide to tilt out of alignment.

Fig. 8 shows cross and longitudinal sectional views through the cutter slide. In this illustration E is the feed rod which remains in a horizontal position in the base of the machine. This rod drives the feed-screw in the cutter slide by means of a worm and worm-wheel, a pair of bevel gears and an intermediate shaft Y which transmits the motion to the feed-screw Z through a pair of spur gears. It will be evident that the use of the worm and wheel and the pair of bevel gears allows the cutter slide to be set at any required angle. The angular settings of the slide are made by means of a crank fitting onto the squared shaft a, Fig. 3. This shaft carries a worm meshing with the worm-wheel b and the worm-wheel drives a pinion which meshes with the segment gear. Any angle up to 90 degrees may be obtained by means of a scale graduated on the inner edge of the segment gear. This scale runs under the indicator c which acts as the reference point in making angular settings. After the desired setting has been obtained, the slide is clamped in place by means of a wrench fitting over the end of the squared shaft d.

When the slide is set to angles greater than 30 degrees, a counterweight is employed to relieve the pressure that would come on the feed-screw. This weight is supported by a cable running over pulleys, the arrangement of which is clearly shown in Fig. 4. The counterweight runs down inside the upright of the machine, which represents another improvement in design. This arrangement eliminates the possibility of the weight falling and injuring a workman. To protect the shaft which drives the cutter from strain, a supporting member e has been provided, as shown in Fig. 4. This support is trunnioned at the left-hand end of the machine and runs in a bearing f which is pivoted to the cutter slide.

The method by which the feed and quick return of the cutter slide are obtained is slightly different from that employed on the No. 3-H machine. On the No. 13-H machine the dogs g and h, Fig. 3, rotate and engage with the stop i. This stop is at the end of a crank carried by a shaft which extends through to the back of the machine, Fig. 4. This shaft carries a crank j which moves the horizontal link k. This link corresponds with the horizontal shaft K on the No. 3-H machine. The operation of the clutches and indexing mechanism from the link k is then exactly the same as described for the No. 3-H machine.

The capacity of this machine is for spur or bevel gears up to 24 inches in diameter by 6 inches face width. Cast iron gears up to 3 diametral pitch may be cut and steel gears up to 4 diametral pitch. The floor space occupied is 103 inches long—measured at right angles to the cutter spindle—by 16¾ inches in width. The net weight of the machine is about 5300 pounds.

"STANDCO" HOLLOW SET-SCREW

The "Standco" hollow set-screw is a recent product of the Standard Pressed Steel Co., Philadelphia, Pa., for use in connection with the "Hallowell" cold-rolled steel safety set-collar of this company's manufacture. These hollow set-screws are made from steel bar stock of a special analysis which has been found exceptionally well suited to this purpose.

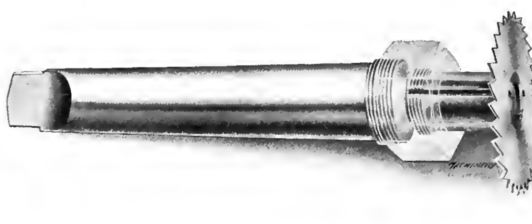
The "Standco" Hollow Set-screw

The heat-treatment and hardening process to which these set-screws are subjected have been given particularly careful attention with the result that they are uniform in hardness and toughness and able to stand up under the most severe service. "Standco" safety set-screws are made with either a hexagonal or a square hole, and in almost any diameter and length. They are furnished with different forms of threads and points to suit the requirements of a variety of classes of service for which they are adapted in addition to their application on the "Hallowell" set-collars.

GRANT INTERNAL GRIP ARBOR

There are many milling operations where the nut or the end of the arbor extending out beyond the cutter interferes with the work or clamps, and in such cases end or face mills have to be used. The effective radius of cutters and saws used on an ordinary arbor is also reduced by an amount equal to the thickness of the wall of the clamping collars. To overcome these difficulties the Grant Mfg. & Machine Co., 80 Silliman Ave., Bridgeport, Conn., has brought out an internal-grip arbor which is shown in the accompanying illustration. No nut is used on this arbor that would interfere with the work and, for any given operation, the size of the cutter or saw that is required is materially reduced.

This arbor has the usual form of taper shank, and at the opposite end there is a tapered extension over which fits a



Grant Internal-grip Arbor for Milling Cutters and Saws

split sleeve. The end of this sleeve is threaded left-hand, while the end of the arbor is threaded right-hand. The sleeve is first screwed into the clamping nut, after which the nut is screwed onto the arbor. This causes the split sleeve to be drawn up on the tapered end of the arbor and expanded sufficiently to secure a firm grip on the inside of the cutter. To release the cutter from the arbor it is merely necessary to loosen the nut.

Many shops are not well equipped with face milling cutters and the arbors for holding them. The use of this internal-grip arbor enables ordinary side-tooth cutters to be employed for face milling operations, thus adding materially to their

field of usefulness. The sleeves provided for use on these arbors are made in different lengths to suit all cutters of ordinary width. An arbor of this type is also made, which is adapted for use in the vertical attachment for the milling machine. This allows the entire equipment of standard cutters in a shop to be used in the vertical attachment, where formerly only end-mills or special cutters provided with taper shanks could be employed. The standard arbors of this type are made with either No. 9 or No. 10 B. & S. taper shanks, and they are equipped with sleeves for cutters having holes 7/8 or 1 inch in diameter.

THE BRIGHT BALL-BEARING HANGER

The Hess-Bright Mfg. Co., Front St. and Erie Ave., Philadelphia, has introduced a new ball-bearing hanger which is the result of a careful study of hanger requirements. Before referring to this hanger it may be well to call attention

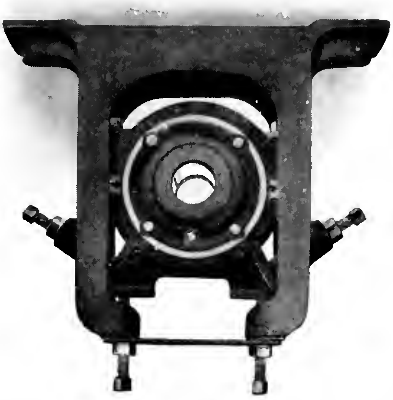


Fig. 1. Bright Ball Bearing Hanger of Universal Swiveling Type

to some of the reasons for its construction and arrangement. As is quite generally known, the ball-bearing hanger formerly manufactured by this company consists principally of a box frame carrying a heavy yoke which is free to swivel about a vertical axis and contains the box and bearing. The box is held within the yoke upon horizontal set-screws, thus providing a universal swiveling movement for the bearing and box. This hanger, which was developed from the four-point screw suspension type, has given satisfactory results,

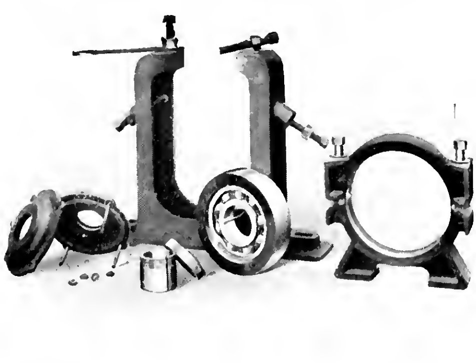

Fig. 2. Component Parts of the Bright Ball Bearing Hanger

although in some instances trouble was experienced because of careless erection. If a millwright when installing the hanger tightened the two horizontal set-screws (which hold the bearing and box within the yoke) excessively, the box body and hence the bearing might be distorted, and even if this distortion were very slight it would subject the close-fitting balls to enormous pressure as they passed the narrow places thus formed between the races. To make it impossible to distort the bearing in this manner and, at the same time, retain the universal swiveling movement the new hanger shown in the accompanying illustrations was designed.

This hanger was originated by Mr. Fred E. Bright, President of the Hess-Bright Mfg. Co. It has a rigid box frame, the jaws of which are flanged on the inside to retain a yoke which holds the bearing box and bearings. This yoke is divided on the horizontal center line, and it is securely held in position by four set-screws which come against the base. Two of these set-screws bear against the bottom of the base and provide vertical adjustment, whereas the other two set-screws are inserted through the sides, near the base, at an angle of 45 degrees and bear against a surface on the base which is at right angles to them. With this arrangement the yoke is held securely, but the clamping screws cannot possibly cause distortion of the box as the result of excessive tightening. The yoke is provided with a machined spherical seat for the box which contains the ball bearing. This feature enables the bearing and box to swivel in any direction. The bearing is enclosed within the box, and as both move together in case there is any deflection of the shaft only a very slight clearance is required between the shaft and the box covers at the ends, thus excluding dust and protecting the races and balls. This improved form of swiveling box and bearing will be applied to the post type of hanger and also to floor stands and pillow blocks.

GARDNER PATTERNMAKERS' ROLL SANDER

The roll sanding machine shown in the accompanying illustration is made by the Gardner Machine Co., Beloit, Wis., and is used in making wood patterns. A typical application

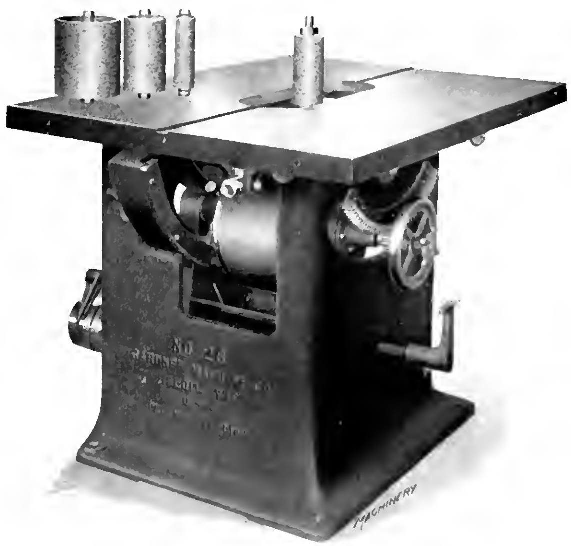

Fig. 1. Gardner Patternmakers' Roll Sander

of the machine is for finishing core boxes. The cutting member consists of a metal roll covered with a strip of "netbac" garnet paper. This strip of paper is joined on an oblique line in order to avoid the "chug" which would take place at each revolution if the ends were butted on a perpendicular line. The roll, which oscillates slightly up and down, is driven by a friction pulley, and its speed can be increased or diminished according to the size of the roll which is being used. This speed adjustment is made by a regulator screw located on the under side of the housing; and a speed variation of from 2000 to 6000 revolutions per minute can be obtained. The equipment includes four rolls, which are 7 inches long by 2, 3, 4 and 6 inches in diameter, respectively. The smaller the roll, the higher the speed required in order to obtain an efficient cutting speed.

Helical hardened steel gears are used to produce the oscillating motion of the roll spindle. Instead of tilting the table for sanding work at an angle, simple means are provided for tilting the roll spindle and locking it in any required position,

as shown in Fig. 2. This allows the operator always to work with the table flat, which is said to be an advantage. The angle to which the roll is tilted is accurately indicated by graduations located on the rim of the segment gear directly behind the handwheel. The opening in the table through which the roll passes is elongated to provide for moving the table laterally. This lateral motion, which is governed by a screw equipped with a micrometer dial, is utilized when fix-

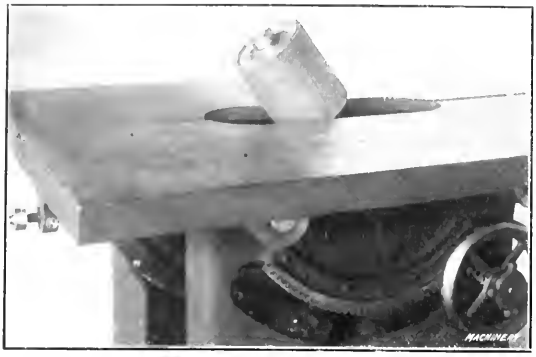

Fig. 2. Method of tilting Roll on Sander

ture are employed in sanding a large number of duplicate pieces. If small pieces of work are to be sanded, the opening in the table around the roll is closed by dropping a removable plate into place, this plate usually being made of hard wood. One of these plates is shown in use in Fig. 3. The table is 36 inches wide by 48 inches long and the height from the floor is 36 inches.

It will be evident from the preceding description and illustrations that this machine is adapted for sanding both in-

Fig. 3. Finishing an Internal Angular Curve on Gardner Sander

ternal and external work with either perpendicular or inclined faces. Fig. 3 shows the method of finishing an internal, inclined curve. This is typical of a class of work which is frequently met with in almost every pattern shop, the piece shown being the head of a core box for an ordinary straight core. For handling this work, the roll is tilted to an angle of 20 degrees and the operator simply follows the line which has been laid out on the work. The convenience of having the table flat is particularly marked on work of this kind. A feature of this sanding machine is that knots, nails, or the grain of the wood do not interfere with its operation in any way. The complete equipment includes four rolls, cement and an assortment of "netbac" garnet strips. No countershaft is required. A dust hood can be suspended from above to keep the top of the table clear. The floor space occupied is 6 by 8 feet and the complete weight of the machine 1700 pounds.

MC CROSKY VARIABLE SPEED AND REVERSING ATTACHMENT

The "Wizard" variable speed and reversing attachment for drill presses shown in Figs. 1 and 2 is a recent product of the McCrosky Reamer Co., Meadville, Pa. This attachment combines the functions of a drill speeder and tapping attachment, with an addition of two speed changes. By operating the small knurled handle at the front of the attachment either of three forward speeds may be obtained; the rotation of the tool is also reversed by this handle. As an example of the work for which this attachment is intended, consider a case in which it is necessary to drill a small and a large hole and tap one of the holes. The variable speed feature provides for driving the small drill at a high speed and the large drill at a low speed, while the reverse enables the tap

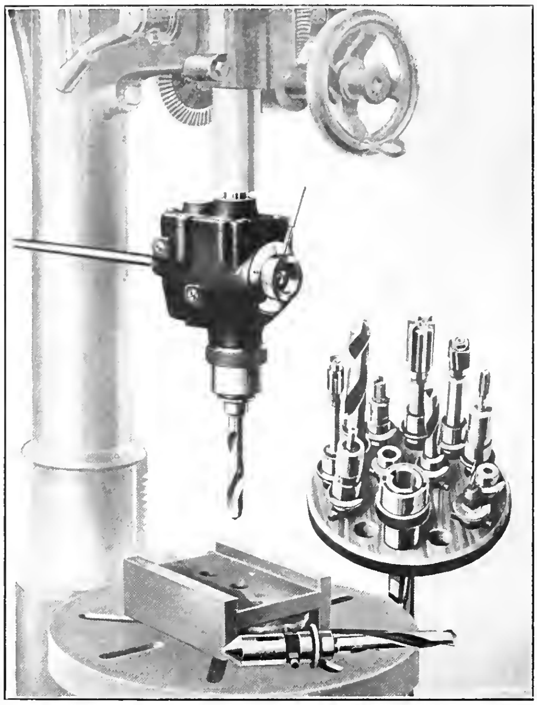

Fig. 1. Drill Press equipped with McCrosky Attachment

to be backed out of the work after the tapping operation is completed. The tapping may be done at slow speed and the tap backed out at high speed.

All bearings are bushed—the four main bearings with special cast iron and the loose gears with phosphor-bronze. There are no sliding gears, the transmission being effected by two positive clutches. All gears are of hardened steel. Taps, large drills and similar tools should be run at the slow or direct speed and for such work the gears run idle. The direct speed is the same as the speed of the drill press spindle and, of course, can be easily regulated to suit the work in hand. The intermediate speed is about two and one-half times faster than the direct speed, while the high speed is about five times that of the spindle.

This attachment is regularly furnished with the "Wizard" quick-change collet chuck. This chuck is used in connection with individual collets which are kept on the different tools which are used in succession in machining a piece of work. By holding the knurled sleeve on the chuck back against the rotation of the spindle the collet carrying the tool which has finished its operation may be removed without requiring the machine to be stopped. A fresh tool is mounted in the chuck in the same way, it being merely necessary to hold the sleeve

back against the rotation of the spindle and then slip the collet up into the chuck. In Fig. 1 a drill press is shown equipped with one of these McCrosky variable speed and reversing attachments. Beside the table of this machine a rack will be seen in which a series of tools mounted in collets are carried. The ability to operate the tool at the most desirable speed and to make quick changes from one style of tool to another materially reduces the cost of machining operations.

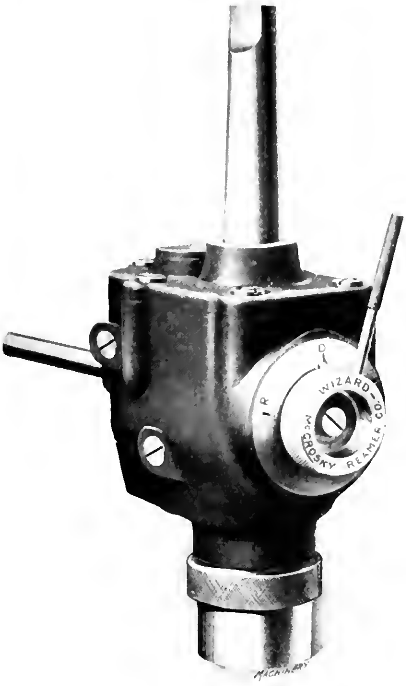

Fig. 2. McCrosky Variable Speed and Reversing Attachment

WALDEN COMBINATION SOCKET WRENCH

The No. 6 combination ratchet socket wrench set shown in the accompanying illustration is a product of the Walden Mfg. Co., Worcester, Mass. Referring to this illustration, it will be seen that the equipment consists of a 9-inch ratchet wrench, an extension bar, a universal joint and sixteen assorted sizes of sockets, including a long spark plug socket. The sockets cover a range of sizes from ½ to 1¼ inch and fit cap-screws from 5/16 to 1 inch, U. S. S. nuts from ¼ to ¾ inch, and A. L. A. M. nuts from 5/16 to ⅞ inch. The wrench is packed in a fiber box and weighs five pounds.

The No. 6 Walden Combination Socket Wrench

A No. 4 combination wrench set of similar design is made by this company which consists of the wrench, a universal joint, an extension bar and a set of eight sockets. A No. 10 set is also made which includes three wrenches, 5, 9 and 12 inches in length; an extension bar; a universal joint; and a set of thirty-one sockets. These wrenches are primarily intended for the use of automobile owners and mechanics employed in garages, but the same style of wrench could be used to advantage in many machine and assembling shops. The different combinations that are possible will be evident from the illustration.

ACME SEMI-AUTOMATIC NUT TAPPERS

To meet the demand for a nut tapping machine of simple construction, capable of turning out a large production, the Acme Machinery Co., Cleveland, Ohio, maker of forging, nut making and threading machinery, has brought out a line of semi-automatic nut tapping machines, the 1-inch size of which is shown in Fig. 1. The machine illustrated has a capacity for tapping either square or hexagon nuts from ⅝ to 1 inch (this is the diameter of the tap used). It is possible to obtain a much greater output with this machine than with the older types of six-spindle machines, the increase in production ranging from 50 to 100 per cent.

Each tap-holding spindle is operated independently. It is counterweighted to prevent breakage of taps and is provided with an automatic lifting device consisting of a worm and auxiliary mechanism. By means of this device the tap is lifted after one nut has been tapped, allowing the next nut to be fed in automatically from the chute to the nut holder. The operation of the feeding mechanism of the machine can be seen more clearly by referring to Figs. 2 and 3. As the tap passes through the nut, the worm shown at the top of the spindle drops, and in so doing comes in contact with a bronze washer or collar. This collar, through a bell-crank arrangement of levers, pushes a shoe into contact with the threads of the worm, whereupon the latter rises and lifts up the tap and the nuts on it clear of the nut holder, allowing another nut to be fed in. The nut is fed in by a feeding finger, operated from a rod at the rear of the machine, through a system of levers which come into action as the spindle is lifted.

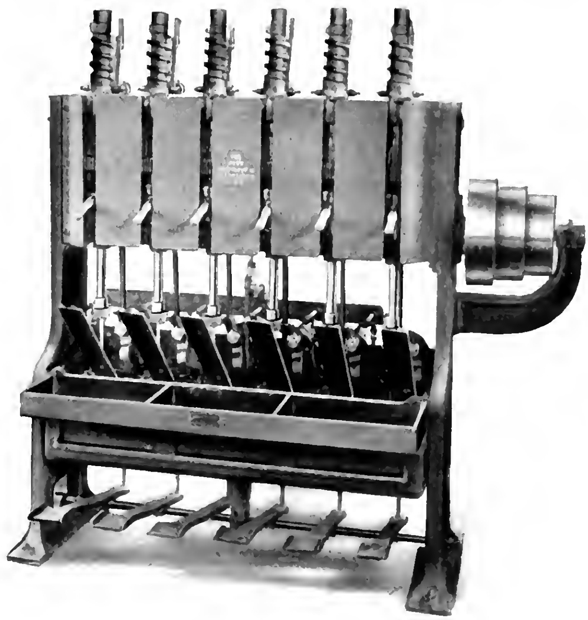

Fig. 1. One-inch Size of Acme Semi-automatic Nut Tapping Machine

Fig. 2 shows the tap spindle in the "up" position and the feeding finger pushing another nut into the nut holder. Fig. 3 shows the tap just as it has passed through the nut being tapped. The cycle of operations outlined is repeated until

the shank of the tap is filled with nuts, whereupon the tapping spindle ceases to operate, owing to the filled tap preventing the worm from contacting with the bronze collar previously mentioned. As soon as the tapping spindle ceases working the operator removes the filled tap by depressing the foot-lever. This lifts the spindle, and consequently the tap, clear of the nut holder, enabling the tap to be easily removed; quick-acting ring chucks are provided so that this can be done while the spindle is rotating. The nuts are then slipped off the shank of the tap, the latter is replaced in the quick-acting chuck, and as the operator removes his foot from the foot-lever the machine begins operating again.

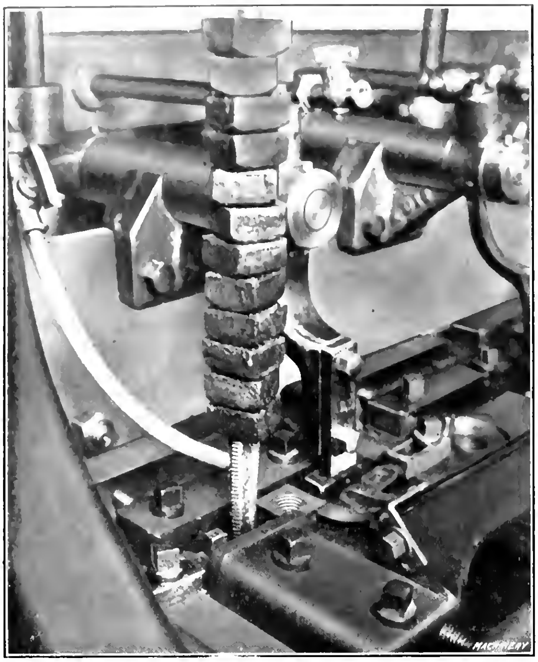

Fig. 2. Close View showing Tap raised and Nut being fed in

The worm cannot drop until the threads on the tap have cleared the nut, so that if the trips on the machine are properly set it is impossible for two nuts to be on the threaded portion of the tap at the same time. The nuts are fed to the machine through a chute, which can be adjusted to suit various sizes of nuts within the range of the machine, as can also the nut holder. A rotary oil pump is furnished so that a copious supply of cooling liquid is supplied to the taps at all times, keeping them cool and clean and allowing the maximum speed to be obtained. Movable chip pans with screen bottoms are provided which allow the oil to drain from the chips and permit the chips to be easily removed.

This type of nut tapper is also built in ½-inch size. The regular equipment furnished with the machines consists of a rotary pump, a countershaft, the necessary wrenches, a chip pan, and six quick acting ring sockets of any size within the capacity of the machine. This equipment can be changed, however, to suit individual requirements.

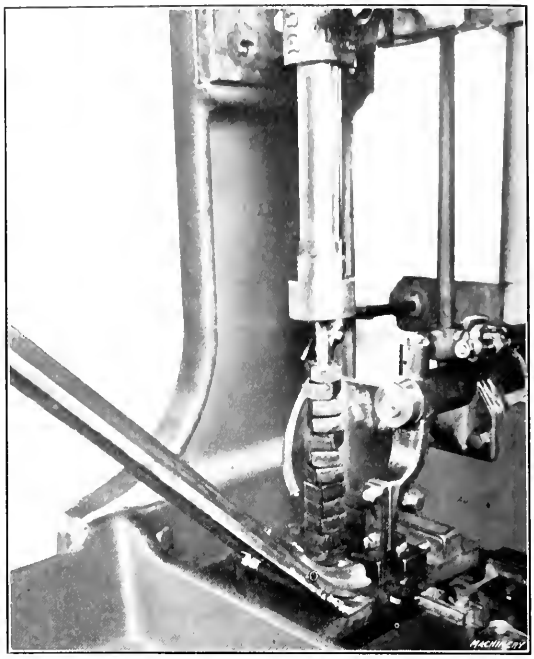

Fig. 3. Close View showing Tap in Action

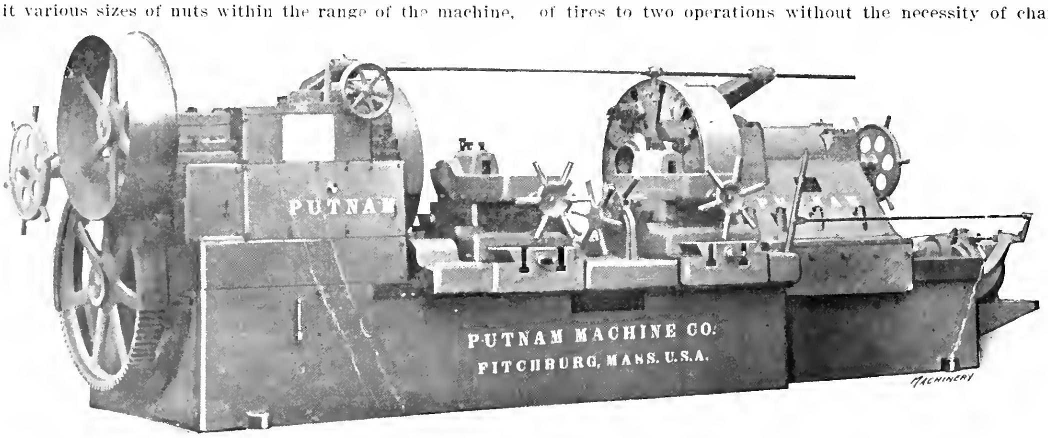
PUTNAM COACH WHEEL LATHE

In the May, 1913, issue of MACHINERY a 42-inch coach wheel lathe manufactured by the Putnam Machine Co., Fitchburg, Mass., was illustrated and described. Since that time the design of this lathe has been improved in several ways, which add materially to its efficiency of operation. These improvements will be described in the following:

An improved form of combination tool-slide which has been applied to the lathe reduces the work of turning a pair of tires to two operations without the necessity of changing cutting tools except in the case of tool failure or breakage. This tool-slide is self-contained and is not dependent upon compressed air or manual labor for its function of holding the cutting tools. In case of tool failure, the arrangement is such that a change of tools can usually be effected while the companion tool is cutting and without loss of time. The



Putnam Coach Wheel Lathe of Improved Design

divided nut on both the transverse and longitudinal feed screws in the tool blocks provides for taking up any backlash which may develop. The tool-slide has one roughing and one full width forming tool mounted side by side, each of which is readily detachable for the insertion of a fresh tool. The single screw tool clamp is positive in action and holds the cutting tools rigidly under all operating conditions. It is only necessary to tighten a single screw to clamp the tools. The binder arm is of steel and hardened on the contact point. The tools are clamped down onto the hardened steel plates having corrugated surfaces.

Another improvement consists of the provision of power longitudinal movement of the tailstock in connection with an automatic tailstock clamping device. The tailstock motor is started up under no load, the control being entirely mechanical. The tailstock is run forward until taper surfaces engage with corresponding surfaces on the bases of the tool blocks to automatically stop the tailstock and clamp it to the bed. The motor is then released by a friction relief. Reversal of the tailstock motor releases the clamping device and allows the tailstock to be run back away from the headstock. When the tailstock is clamped the downward force of the work against the cutting tool and the force tending to lift the tailstock up off the bed counteract each other. This result is obtained by having the tool block overlap a projection on the tailstock, a similar construction being used between the tool block and headstock.

NIAGARA BOTTOM FLANGING MACHINE

The accompanying illustration shows a bottom flanging machine recently built by the Niagara Machine & Tool Works, Buffalo, N. Y. This machine is intended for turning out bottoms and tops for barrels, tanks, etc., and it is particularly useful where it is required to produce heads of different diameters, as it would often be out of the question to make dies, owing to the limited number of pieces to be formed. Other shaped flanges besides the square ones shown in Fig. 2 may be formed by substituting the required shape of rolls. The machine may also be used for cutting circular disks and for slitting sheets, in which case rotary cutters are substituted in place of the flanging rolls.

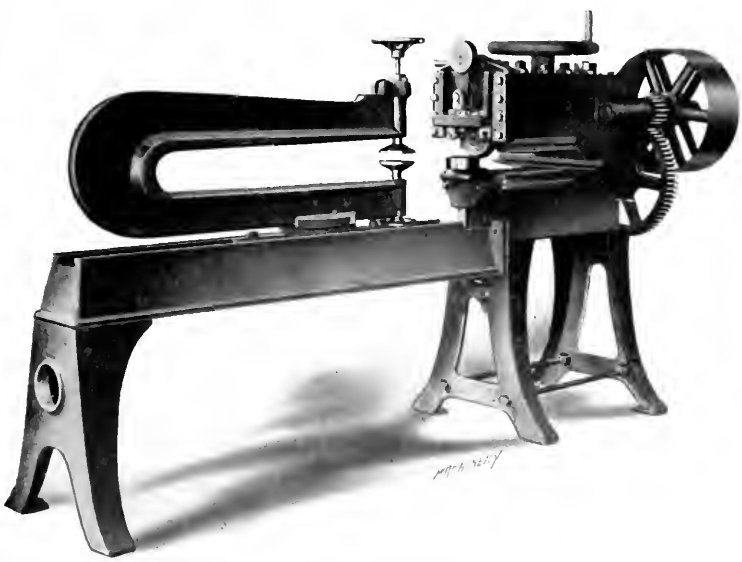


Fig. 1. Niagara Machine for forming Flanged Tops and Bottoms for Barrels or Tanks

The machine is single back-geared and provided with tight and loose pulleys. The main gear is mounted on the lower shaft, from which power is transmitted to the upper shaft through a compensating connecting gear. The lower flanging roll is mounted on a vertical shaft that is driven from the main shaft through bevel gears. The upper shaft can be adjusted laterally to allow for variation in the thickness of the material. For this purpose there is an eccentric segment lever located at the front of the machine within easy reach of the operator. The upper shaft may be raised and lowered, but always kept in horizontal alignment by means of an arrangement of screws and gears operated by a handwheel located at the top of the machine.

In order to prevent the metal from becoming distorted during the flanging operation, two hold-down rolls are provided on the slide in front of the upper flanging roll; and to facilitate the removal of flanged disks, the hold-down rolls can be quickly raised and lowered by an eccentric lever. The machine shown in Fig. 1 will flange disks from 14 to 60 inches in diameter. For material up to No. 10 gage soft sheet steel, the maximum height of the flange that can be produced is 1½ inch. The machine will cut metal as heavy as No. 8 gage and disks can be cut ranging from 8 to 53 inches in diameter.

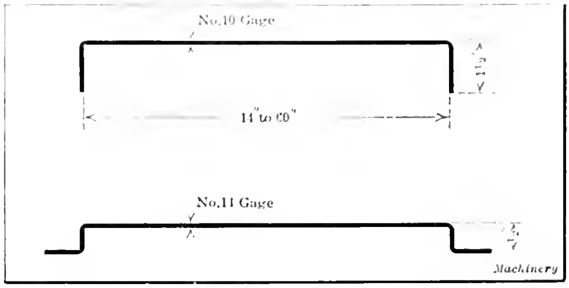

Fig. 2. Range of the Machine in Nos. 10 and 14 Gage Soft Steel

LANDIS PLAIN GRINDING MACHINE

The accompanying views are of a large motor-driven plain grinding machine just completed by the Landis Tool Co., Waynesboro, Pa. This machine has a capacity for work 30 inches in diameter and 20 feet in length. As will be seen, it is driven by three motors; one for driving the grinding wheel, one for revolving the work and traversing the grinding wheel, and one for driving the water pump. The work and traversing motor drives the gear box at the end of the machine which is arranged with a clutch mechanism so that the drives can be started and stopped independently, or together independent of the motor. The motor runs at a constant speed and the speed changes of both the work and wheel traverse are made by an arrangement of gear shifts and clutches, all of which are operated from one position at the front of the machine. There are sixteen different work speeds, ranging from 2 to 45 revolutions per minute; and ten changes of wheel traverse speed, ranging from 2½ to 84 inches per minute.

The grinding wheel is driven by a variable speed motor, the speed of which is controlled by the electric apparatus shown mounted upon the main wheel carriage. The standard size wheel for this machine is 30 inches in diameter and has a wearing range of 8 inches on the diameter, the electric controller being arranged to give the proper cutting or peripheral speed with the wheel at any size within its range of wear. As will be seen by the rear view, the grinding wheel motor is mounted upon a separate carriage which travels on a track formed on the base of the machine. The wheel and motor carriages are entirely independent except for an arm connection for propelling the motor carriage with the traversing movement of the wheel carriage. The motor carriage is mounted on large rollers which are fitted with ball bearings. The track surfaces upon which this carriage travels are protected by metal guards. The electric current is transmitted to the wheel motor through sliding contact shoes and feed wires located along the body of the machine.

These wires are also protected by a shed formed metal guard to prevent anything falling on them from directly above.

The grinding wheel slide, for feeding the wheel to and from the work, is arranged with a rapid mechanical feed mechanism which is operated by the vertical lever located between the feed handwheel and the motor controller as shown in Fig. 1. This is for the purpose of moving the wheel away from the work quickly when changing from piece to piece, or from one size to another, in case various diameters are being ground on the same piece and for feeding the wheel in quickly to the grinding position. The transverse movement of the wheel is in the same direction as the movement of the operating lever; to feed to the work the lever is pulled in the same direction and *vice versa*. In addition to this, there is the usual hand feed, as well as automatic feed for feeding the wheel at the reversing points.

The grinding wheel motor is controlled by an automatic motor starter and field rheostat with rheostat relay. This makes a very efficient arrangement, as the controller can be set to give the wheel the proper peripheral speed for any size of diameter within its wearing range, and the motor is then operated by an ordinary knife switch. This arrangement gives a positive control of operation and with the automatic starter the speed picks up gradually after the starting switch has been thrown into contact. Another feature of the construction of this machine is that all bearings of spindles which run continuously while the machine is in operation are made of bronze, and the spindles are of hardened and heat treated steel.

The starting box of the water pump motor is mounted directly upon the motor itself, which places it in a very convenient position for the operator. The starter for the work-drive and wheel-traverse motor is not shown, as this is mounted to meet existing requirements when the machine is installed. This machine is intended for grinding a line of large shaft work, the largest piece to be handled occupying the full distance between centers, and the diameters will range up to 24 inches. It is strictly a manufacturing grinder and is particularly well suited for such work as engine crankshafts, steam turbine shafts, armature shafts and heavy roll work. This machine is also built for 40 inches swing when desired.

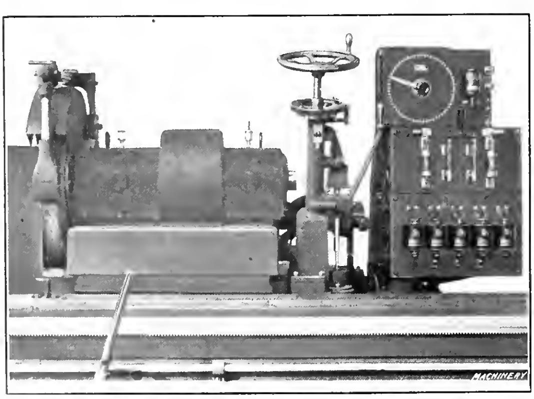

Fig. 3. Electrical Apparatus for controlling Grinding Wheel Motor

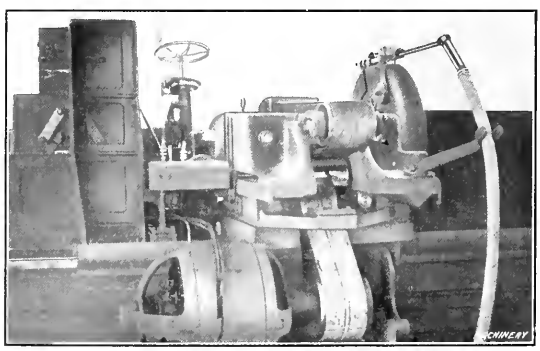

Fig. 4. Rear View showing Wheel Drive and Pump Connection

NORTON PLAIN GRINDING MACHINE

The Norton Grinding Co., Worcester, Mass., is now building the small machine for grinding cylindrical work shown in Figs. 1, 2 and 3. It is made to swing 3 inches in diameter in order to afford room for suitable steadyrests for supporting work ranging from 1/8 inch to 1 inch in diameter and up to

18 inches in length. The machine is particularly adapted for handling work from $\frac{1}{8}$ to $\frac{1}{2}$ inch in diameter and is designed for finishing cuts where there is not more than from 0.004 to 0.008 inch of stock to be removed from the diameter of the work. It is especially useful for grinding small twist drills, tool work, and the parts of cream separators, sewing machines, electrical apparatus, phonographs, roller bearings, and similar classes of work.

The machine is self-contained, no overhead works being

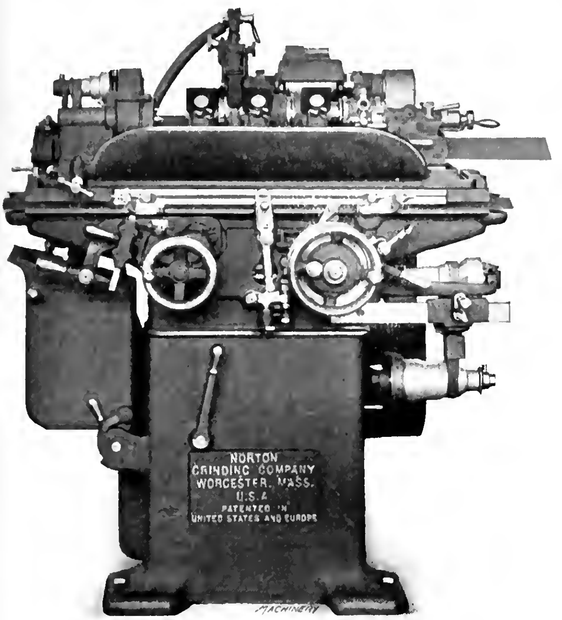

Fig. 1. Front View of Norton 3 by 18-inch Plain Grinding Machine

required. The drive is by a belt either from above or below, or by a motor placed on the floor at the back of the machine. The table reverse is pneumatically cushioned, making it possible to operate the table at a maximum speed of 27 feet per minute. Eight table speeds are provided, the slowest of which is 17 inches per minute. The automatic and hand cross-feed, while of entirely new design, sacrifice nothing in the matter of accuracy in sizing the work. The control of the revolution of the work and of the table traverse is unusual, in that while either can be started separately or both simultaneously, the stopping of the work always stops the table and the table cannot be started unless the work is revolving. Stopping the table connects the handwheel for moving the table by hand, and this handwheel is disconnected when the table is started. The footstock covers the dovetail ways on which it slides and protects them from damage. The steadyrests are especially designed for small work; they are provided with micrometer stops and arranged for quick handling. Three universal steadyrests are furnished with the machine and also a set of hardened steel work shoes for one diameter of work. These shoes are designed to give a quick change from one size of work to another; they provide convenient means for making adjustments and rigid support for long work of small diameter. The work shoes are of steel, hardened and ground.

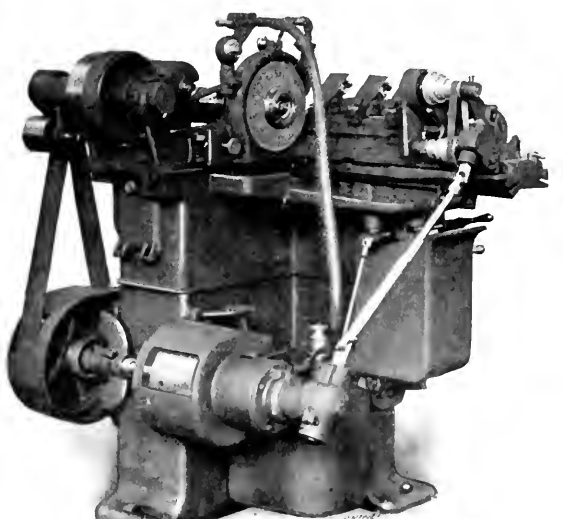

Fig. 2. Rear View of Grinding Machine shown in Fig. 1

Four work speeds are provided, ranging from 160 to 640 revolutions per minute. The wheel spindle is a chrome-nickel steel forging carefully heat-treated. The shafts are self-oiled and the loose pulley runs on a self-oiling roller bearing. The footstock spindle, in common with a number of other parts of the machine subjected to wear, is hardened to insure satisfactory wearing properties. The pump provides an ample supply of lubricant to the wheel and work, and the settling tank is conveniently arranged for cleaning. The machine carries wheels 10 inches in diameter by $\frac{3}{4}$ inch face width, and tapers up to 2 inches per foot can be ground.

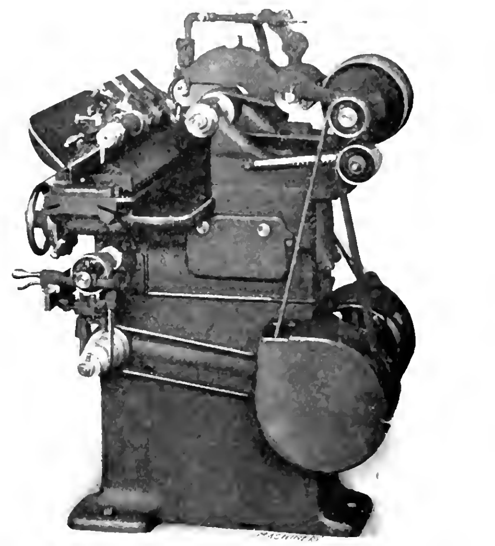

Fig. 3. Right-hand End of Norton Plain Grinding Machine

The regular equipment provided with the machine includes two wheels, three complete universal steadyrests, three work shoes for one size of work, a diamond for dressing the grinding wheel, a center grinding attachment and a suitable equipment of wrenches. All belts are furnished in place ready for use with the exception of the main driving belt. The weight of the machine is about 1950 pounds.

WILLEY ENGINE LATHE

In bringing out the lathe illustrated in Figs. 1 and 2, the purpose of the Willey Machine Co., Jeffersonville, Ind., was to meet the demand for a small machine equipped with a simple and reliable motor drive. When desired, this lathe can also be driven by a belt from the countershaft. It is a standard lathe with a standard motor and a standard cone drive from the motor to the lathe.

The bed is made narrow under the headstock so that the belt can pass down to a cone pulley on the countershaft. The countershaft is provided with means for vertical adjustment to take up slack in the endless belt. The motor is started and stopped by a handle near the headstock. There is one large

vee at the front of the bed and a flat way at the back of the bed upon which the carriage and tailstock are mounted. The motor regularly used in this lathe develops 1/4 horsepower and is found to be ample for the requirements of the average shop. A 1/2 horsepower motor is required to pull the lathe to the limit of its capacity. The cone pulleys take a belt 1 1/2 inch in width. The diameter of the front spindle bearing is 1 3/8 inch,

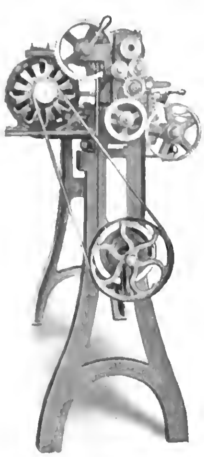

Fig. 1. End View of Willey Lathe

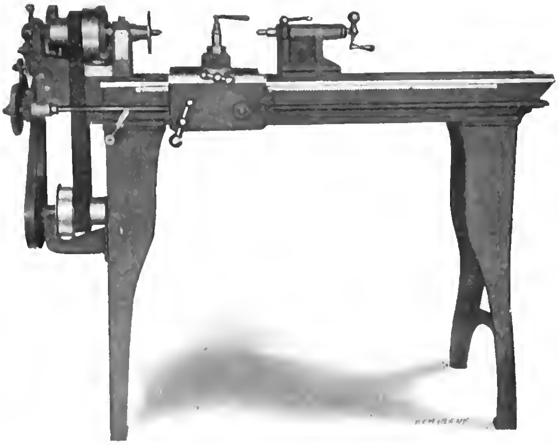

Fig. 2. Front View of Willey Engine Lathe

and the diameter of the back spindle bearing 1 1/8 inch. The lead-screw is 7/8 inch in diameter, and the lathe swings 10 1/4 inches over the bed and 6 inches over the carriage. The weight of the machine is about 500 pounds.

GREAVES-KLUSMAN GEARED HEAD LATHE

The accompanying illustrations show a 17-inch quick-change geared-head lathe with single pulley drive, which is a recent product of Greaves, Klusman & Co., Cincinnati, Ohio. In the design of this lathe the use of frictions in the geared head has been entirely eliminated, all speed changes being obtained through sliding gears. The arrangement is similar to the sliding gear transmission used on automobiles; it consists of few parts, and thorough tests have demonstrated its durability. In the automobile sliding gear transmission the operation of two levers is required for throwing out the friction clutch and obtaining speed changes. On this lathe a single vertical lever on the headstock operates the speed changes and engages the friction clutch driving pulley. Before any speed changes can be obtained it is necessary for the operator to disengage the friction clutch. This relieves the gears of all strain and allows them to slide freely and without shock or jar.

Ten spindle speeds are provided, any of which can be obtained instantly without stopping the lathe and while the tool is cutting. A single in or out movement of the vertical lever operates the friction clutch on the driving pulley to start or stop the lathe, and by moving this lever to the right or left into notches which are plainly marked, any desired spindle speed can be instantly obtained. The action of this vertical lever is self-locking, and in connection with the notched segment and direct reading index plate, it forms a most convenient method of control.

The horizontal lever at the top of the headstock provides for driving the spindle either direct or through the back-gears. By placing this lever in the neutral position, the spindle is disengaged to provide for revolving it by hand. Power is transmitted through heat-treated steel gears which are driven by a single friction-clutch pulley which delivers ample power to the cutting tool under all conditions. The spindle is driven at a point close to the front bearing, thus reducing vibration and torsional strain on the spindle to a minimum. The arrangement of the gearing is such that only those gears required for any one speed can be engaged and there are no idle revolving gears to add to the frictional load.

An interior view of the headstock is shown in Fig. 3. The initial driving shaft transmits power through gears to a driven shaft having a cone of five gears. Power is then transmitted to a second driven shaft having a cone of three sliding gears which engage with three of the cone gears on the first driven shaft. On one end of the three sliding gears there is a positive stepped clutch and by sliding these three cone gears along on the shaft they connect with a spring tensioned cone of two gears with a positive stepped clutch. When in this position, the five sliding cone gears are connected and power is transmitted to the fourth cone gear on the second driven shaft. By sliding these five gears still further along, the fifth cone gear on the second shaft is engaged. This makes

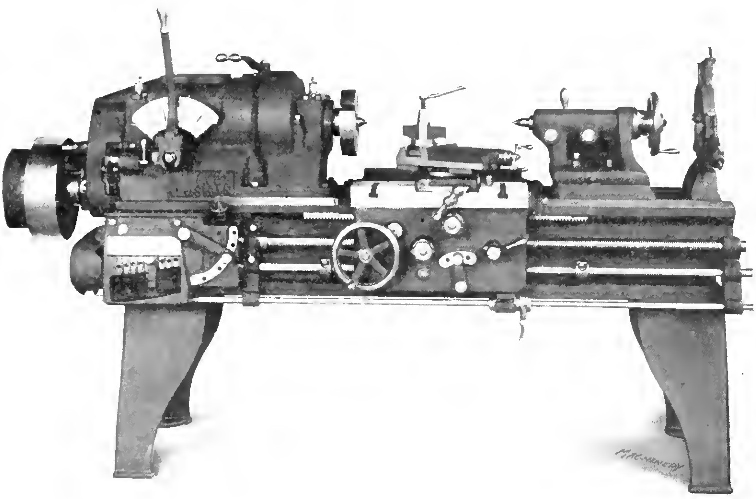

Fig. 1. Greaves-Klusman 17-inch Quick-change Geared-head Lathe with Single Pulley Drive

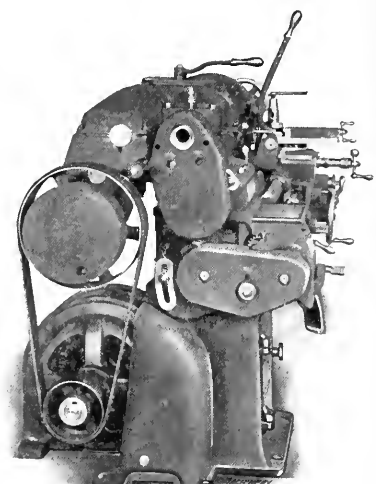

Fig. 2. End View of Greaves-Klusman Lathe with Motor Drive

five changes of speed direct to the spindle, and by engaging the back-gears, five additional speed changes are available, giving a total of ten speeds, all of which are controlled by the vertical lever. Both cone shafts are mounted in anti-friction ball bearings at both ends and in the center. Two of these ball bearings on the second driven shaft are placed close to the face wheel pinion to carry the heavy load that is imposed upon this pinion.

The headstock is of box section with the sides extending up to the center line of the spindle. Heavy internal braces extend both lengthwise and crosswise and make an exceptionally rigid construction. The headstock forms an oil reservoir which keeps the gearing well oiled, increases its efficiency and reduces wear. All of the mechanism is located inside the headstock and the top of the headstock is hinged to afford access to the gearing and other parts. The spindle is of chrome-nickel steel with the front bearing hardened and runs in phosphor-bronze boxes. The spindle bearings are lubricated by sight-feed oilers. The end thrust is carried by alternate hardened steel and bronze thrust washers. A phosphor-bronze flanged sleeve is secured to the headstock and the friction driving pulley runs on this sleeve, thus relieving the driving shaft of all belt pull. The driving pulley is enclosed at the outer end and the hub is provided with an oil well, the construction being such that the oil passes through a felt pad which filters it before it reaches the bearing. In addition to the vertical lever on the headstock for engaging the friction clutch pulley, connection is made direct to the apron so that the operator can start or stop the lathe without leaving the working position. For this purpose a lever is attached to the lower left-hand end of the apron, as will be seen in Fig. 1.

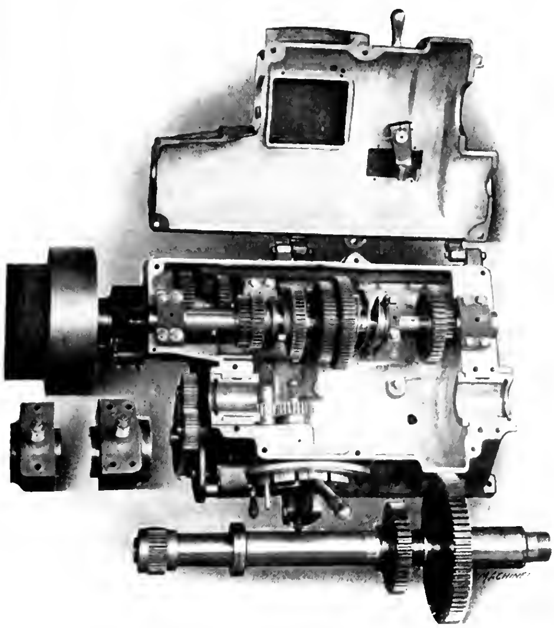

Fig. 3. Interior of Headstock of Groaves-Klusman Lathe

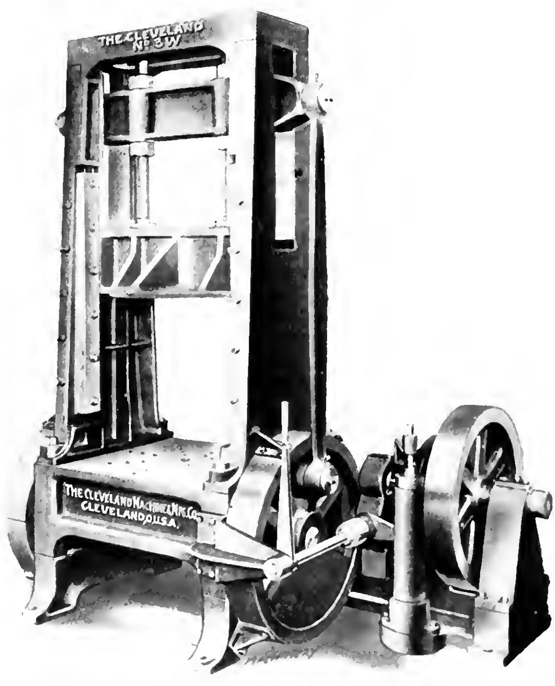
With the constant speed single pulley drive, the lathe can be belted direct from the lineshaft, or a single speed tight and loose pulley countershaft or a double friction pulley countershaft may be used. Fig. 2 shows the end view of a lathe equipped with individual motor drive which requires no additional floor space. The motor is attached to an oscillating plate inside the cabinet leg, this plate being pivoted to allow the motor to be raised and lowered. This affords means of obtaining the desired belt tension at all times, and as the motor is located close to the floor, it does not have any tendency to produce vibration in the lathe. If desired, direct-connected motor drive may be employed by substituting a friction gear for the friction drive pulley and mounting the motor upon the rear of the cabinet lathe. Any standard make of direct- or alternating-current, constant- or variable-speed motor may be used. All of the features of Greaves-Klusman lathes are included in this machine, among which may be mentioned the heavily reinforced bed; the elimination of tool overhang when turning work of the largest diameters; the double clamp, single-acting tailstock; a double walled apron with double supports for all studs and shafts; and the feed-rod supported at each end of the apron with automatic stop in both directions.

CLEVELAND WIRING AND FORMING PRESS

The long stroke wiring and forming press illustrated herewith is a recent product of the Cleveland Machine & Mfg. Co., Cleveland, Ohio. This machine is intended for deep forming operations on light sheet metal parts and for wiring the edge of wash tubs, water pails, ash cans and similar articles. The bed area is 32 inches square, and the stroke of the slide is 20 inches. In order to secure a rigid frame and proper gib construction, the uprights or housings are made unusually deep from front to back and they are heavily ribbed to obtain the desired stiffness. Lugs on the back of the gibs fit into cored pockets in the housings and take the pressure of the adjusting screws. The construction gives an unusually good bearing for the slide, and at the same time permits the slide to be removed from the machine without taking down the housings.

The machine is double-geared, the ratio of the gearing being 10 to 1, and it is belt driven through the flywheel which acts as a pulley. A cone friction clutch mounted in the flywheel is operated by a cam on the main shaft under the bed, which automatically releases the clutch on the up stroke and applies a brake to the driving shaft. Pressure on the foot treadle releases the brake, and the clutch is thrown in by a weight which is cushioned in a dash-pot. For setting dies, the automatic arrangement of the clutch can be disengaged by loosening a nut on the lever shaft and the machine can then be operated by means of the hand lever shown. The total weight of this wiring and forming press is 7000 pounds.



Cleveland Wiring and Forming Press

CLEVELAND 7 3/4 INCH AUTOMATIC SCREW MACHINE

The following description will give some of the most interesting facts concerning the largest and most powerful full automatic screw machine that has ever been built. This machine, a front view of which is shown in Fig. 1, is the product of the Cleveland Automatic Machine Co., Cleveland, Ohio, it will handle round rough bar stock up to 7¾ inches and varying 1/16 inch in diameter anywhere along the bar. A ten foot bar of 7¾ inch round stock weighing 1584 pounds is handled with the same ease, and fed out to the same exactness, as regards length, as a two-inch bar. This machine represents an unusual development in automatic machinery for producing parts from bar stock; with suitable magazine attachments it will also handle castings and forgings.

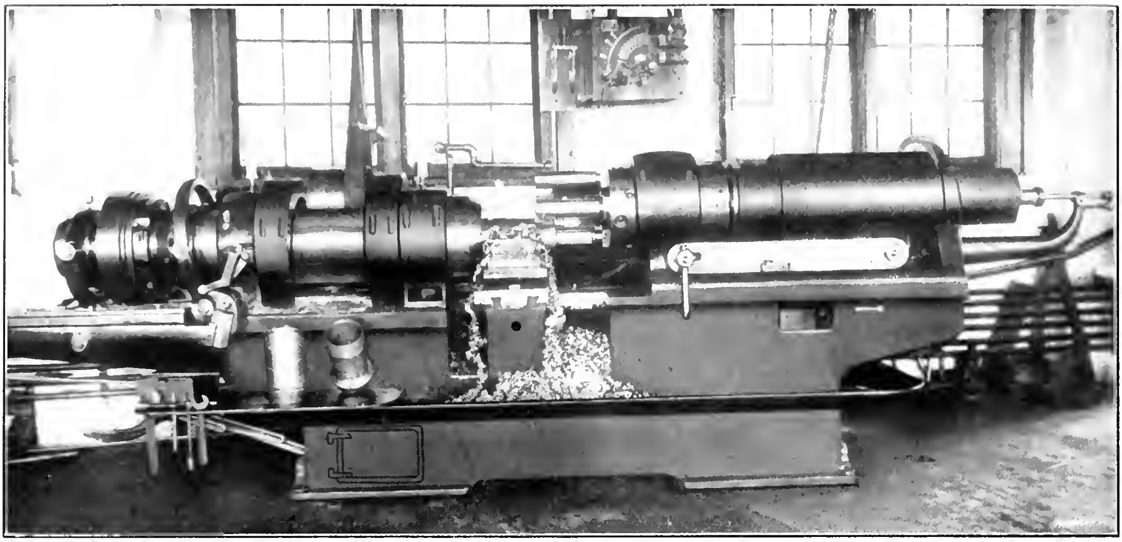


Fig. 1. Front View of 7¾-inch Cleveland Automatic Screw Machine (Gear Guards removed)

The Head and Spindle

Some idea of the massiveness of the machine will be gained from a study of the head. The work-spindle, made from a semi-steel casting, is 58⅞ inches long, has an average diameter of 12¼ inches, and weighs 1100 pounds. The bronze bearings of the work-spindle have a total bearing surface of 630 square inches. The chucking pressure is approximately 1500 pounds. In order to operate the chuck by hand when setting up the machine, it was necessary to provide a powerful toggle-joint device, which the operator brings into action by a long lever, as shown in Fig. 3. This toggle is disconnected from the chuck opening and closing mechanism, when the chuck is operated by power. The greatest length of stock feed is 16⅝ inches, and this mechanism is operated by a cam on the rear shaft, the variations in length of feed being effected by adjusting the feed slide along the bed extension provided for that purpose. The chuck is closed and opened by another cam on the rear shaft. The hood on the nose of the spindle which envelops the work-holding chuck is 15⅝ inches in diameter, and the spring chucks used are of the "pad" type; that is, those parts of the chuck which grip the bar are in the form of pads held by screws in the chuck proper.

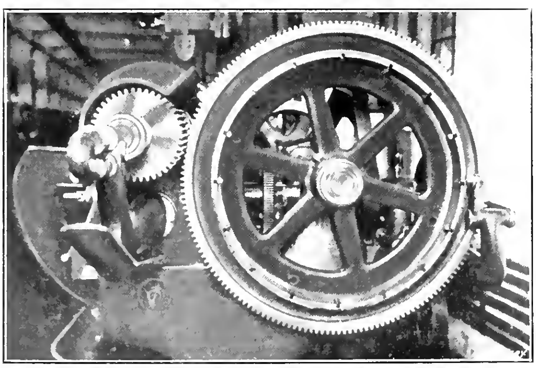

Fig. 2. End View of Cleveland Automatic, showing Regulating Drum and Auxiliary Mechanism

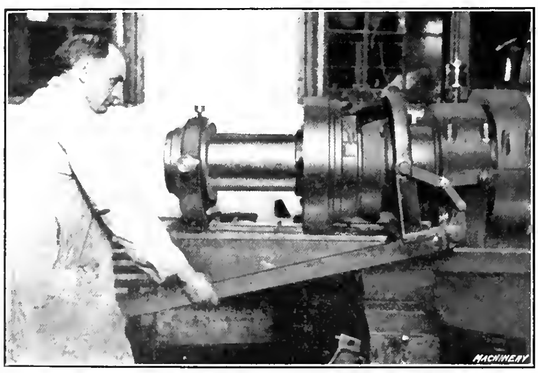

Fig. 3. Operator closing the Chuck by Hand when setting up—Chucking Pressure 1500 Pounds

Turret and Turret Head

The turret, which is of the barrel or drum type, is 18⅜ inches long by 14¼ inches diameter, and weighs 555 pounds. It is provided with four 2¼-inch holes for holding the end-working tools. The turret head has a longitudinal adjustment along the bed of 7¼ inches. The shortest distance between the face of the chuck and the end of the turret, with the turret advanced is 10 inches, whereas the greatest distance between these two members, with the turret advanced, is 17¼ inches. The greatest length of bar that can be turned is 9 inches. The turret is advanced at the proper speed by means of a regulating drum (see Fig. 2) through a friction feed, differential and worm-gearing. The cam which controls the forward advance of the turret is held on the turret-operating drum, and rotates against a roll which is rigidly supported on the machine bed. This roll is presented at a slight angle to the line of pressure on the turret tools, which not only tends to increase rigidity, but enables much heavier feeds to be taken as well. Variation in the feed given to the tools is accomplished by shifting the positions of strip cams on the large regulating drum, this action changing the position of the friction roll between the friction disks. When indexing the turret, bringing the tools up to the work, etc., the turret and all the automatic movements are operated at fast speed, being driven direct and not through the friction disks.

Cross-slides and Other Details

The cross-slides comprise one solid casting 37⅞ inches long by 11⅝ inches wide, weighing 410 pounds. This slide, which generally carries a forming tool on the front and a cut-off blade at the rear, has a travel of 13¼ inches and is operated through a bell-crank lever receiving power from cams on a drum held on the rear shaft. The feed of the cross-slide tools is also controlled, in conjunction with the cams on the drum, by the large regulating drum located at the right-hand end of the machine.

Fig. 4. An Example which shows to a Remarkable Extent what this Machine will do. It removed 105 Pounds of Chips to form a Spring Collet in 48 Minutes

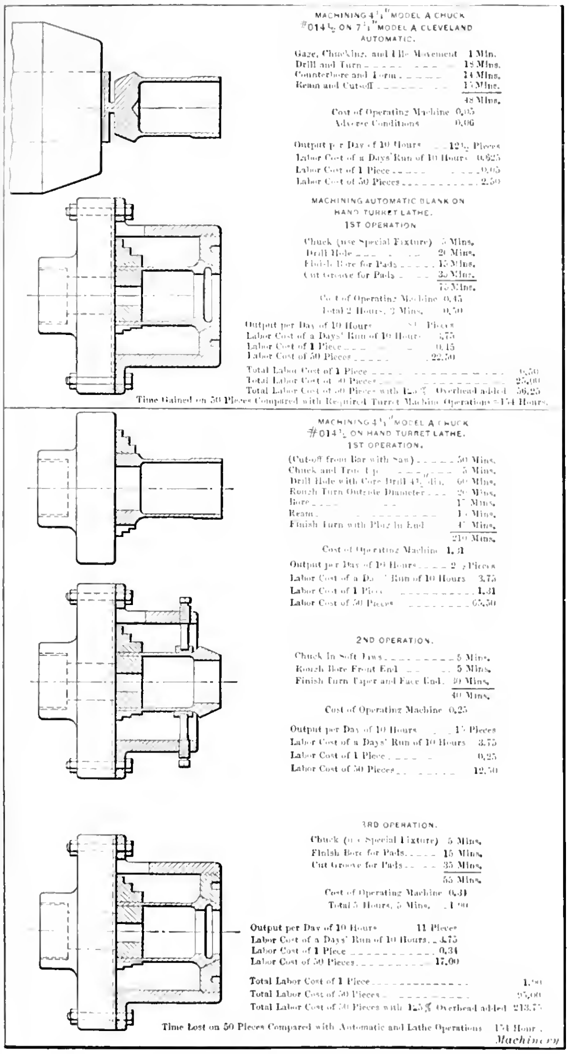

Fig. 5. Improved and Former Methods of making a Spring Collet, illustrating the Advantage obtained by performing First Operation on 7¾-inch Cleveland Automatic Screw Machine

The oil pump on this machine is positive driven and has an air cushion pressure chamber, which provides for a steady flow of the cooling liquid. It has a capacity for pumping oil at the rate of 23 gallons per minute. Oil is pumped to the end-working tools, such as drills, counterbores, etc., through a tube passing through the turret and connecting at each of the turret holes. The over-all length of the machine shown in Fig. 1 is 16 feet 6 inches, the bed casting weighs 6300 pounds and the entire weight of the machine, everything included but not crated, is 15,000 pounds—over seven tons. The machine is fully provided with guards over the exposed working parts and has ample chip room and oil guards.

Example of Work done on 7 3-4 inch Cleveland Automatic

An example of work which illustrates to a remarkable extent the productive capabilities of the machine shown in Fig. 1 is a spring collet or chuck for a 4¼-inch Cleveland automatic screw machine. Two of these collet blanks appear on the tray of the machine in the illustration. This spring collet is made from a rough round bar of 7½-inch 40-point carbon open-hearth steel. It is approximately 11 inches long, and the largest diameter is 7⅜ inches. Fig. 4 gives a comprehensive idea of the amount of work necessary to produce this piece, where it can be seen that 105 pounds of chips has been removed. A solid bar of 7½-inch stock equal in length to the spring collet weighs 143 pounds, whereas the spring chuck, in the condition in which it is dropped from the machine, only weighs 38 pounds. It requires exactly 48 minutes to complete one piece, so that approximately 2¼ pounds of chips is removed per minute—a somewhat remarkable performance for an automatic screw machine.

Another illustration of the economical manufacturing possibilities of this machine is a comparison of the present and former methods of making this spring collet for the 4¼-inch Cleveland automatic screw machine. In Fig. 5 the present and former methods are laid out diagrammatically. Here it can be seen that the time required to complete one of these spring collets on a hand-operated turret lathe was 5 hours 5 minutes at a labor cost of $1.90. The time now required to finish one chuck complete, including the hand turret lathe operations, is 2 hours 3 minutes at a labor cost of 45 cents; this represents a saving in time on each piece produced of 3 hours 2 minutes and a saving in labor cost of $1.45. The time gained by using the improved method on 50 pieces is 154 hours, and the saving in cost on this number, overhead charges of 125 per cent being added in both cases, is $157.50.

The reason for performing the third operation on the hand turret lathe is that this operation was added after it was found that the entire machining on the nose of the collet and in the hole could not be accomplished with the collet held in the manner illustrated for performing the second operation. The chief objection was that it was found impossible to get the hole to run true with the tapered end, owing to the heavy cutting necessary in producing the holes for the pads. The tapered end and the rear bearing of this collet is ground before hardening, the work being held on an arbor. This method was found to be much quicker than filing and polishing. The collet is not ground after hardening.

STANDARD ROLLING MILLS

The Standard Machinery Co., 7 Beverly St., Providence, R. I., is now building the two styles of cold rolling mills illustrated in Figs. 1 to 4. Figs. 1 and 2 show front and rear views of the No. 6 mill with rolls 8 inches in diameter by 10 inches face width. The No. 7 mill, front and rear views of which are shown in Figs. 3 and 4, has rolls 11 inches in diameter by 10 inches face width. The face width of the rolls on both machines can be varied to suit the requirements of different cases. On the No. 6 mill the rolls can be anywhere from 6 to 14 inches face width, while the No. 7 mill can be made with rolls from 8 to 18 inches face width. The standard No. 7 mill has rolls 10 inches in diameter by 15 inches face.

The No. 6 mill is direct connected to a type HF Westinghouse motor equipped with a special controller and special resistance coils in the circuit which are located under the bed of the machine. The motor develops 20 horsepower and

runs at 1150 revolutions per minute, it is capable of a 50 per cent decrease in speed with a corresponding decrease in horsepower. This variation of speed and power is governed by setting the controller lever in different notches and allows the operator to start the mill with heavy stock and then vary the speed and power as required. Roller bearings are provided on the roll journals which are said to effect a saving in power consumption of from 35 to 60 per cent. Without the use of roller bearings a 30-horsepower motor would be required to drive this mill. The rolls are made of chrome alloy steel with hardened journals and hardened bodies, the face of the roll being lapped to a mirror finish.

The adjusting screws seen directly below the large spur gear in Figs. 1 and 2 have a dial which is graduated to provide for making adjustments to 0.001 inch. The screws are left-hand and the gear ratio is 5 to 1; ample pressure is

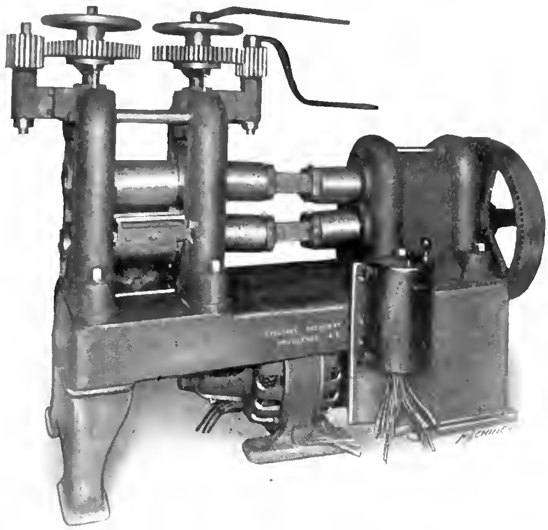

Fig. 1. Front View of Standard No. 6 Rolling Mill

supplied for rolling heavy and dense stock. The handwheels are provided for raising the screws rapidly when it is required to release the pressure from the work. The housings are of heavy construction. The machine is equipped with a running-out table at the rear, which is shown in Fig. 2, and a running-in swivel table with guides is provided at the front of the mill. Cut steel herringbone gears are provided in the gear housings and there are also two trains of spur gears exclusive of the motor train. The motor pinion is of rawhide and all other gearing is of steel with cut teeth.

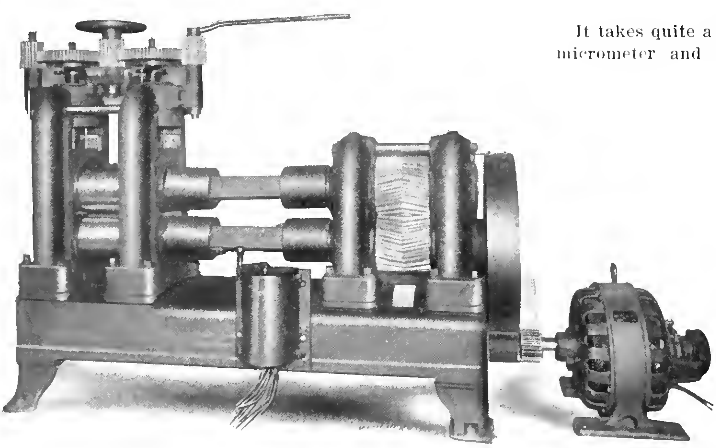

Fig. 3. Standard No. 7 Cold Rolling Mill

The No. 7 mill shown in Figs. 3 and 4 is of similar construction to the No. 6 machine. This mill is driven by a 30-horsepower alternating-current motor which runs at 1150 revolutions per minute. The same provision is made for varying both the speed and horsepower of the motor that was previously described for the No. 6 mill. The roll journals run in ball bearings, but the way in which the rolls are adjusted is somewhat different from that described for the

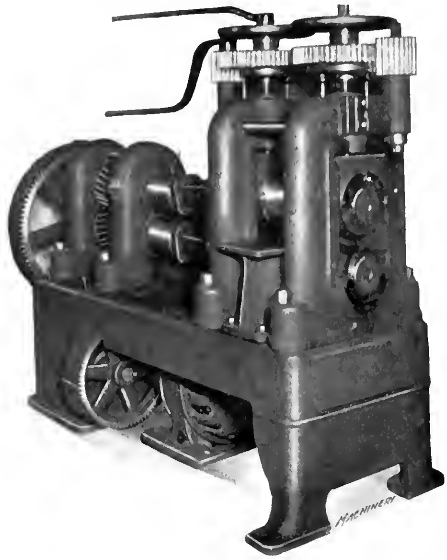

Fig. 2. Opposite Side of Standard Rolling Mill shown in Fig. 1

preceding machine. It will be seen that a center handwheel is provided which adjusts the two rolls simultaneously. The center pinion is so arranged that it can be slipped off, thereby allowing an independent adjustment from either of the screws or pinions. The screws are provided with dials for making adjustments to 0.001 inch. It will be seen that the motor is placed at one end instead of being underneath the bed of the machine. The transmission includes a pair of cut steel herringbone gears and three trains of spur gears. All of the gears, with the exception of the motor pinion, are of steel. The rolls are of hardened and ground chrome alloy steel, lapped to a mirror finish. The bed of the machine is cast in one piece. Below the inner gear housing there is a heavy rib which is bored at the same time that the outside bearings at the rear of the bed are bored; this affords a double bearing for each gear shaft. All of the bearings are bronze bushed.

BROWN & SHARPE DIRECT-READING MICROMETER

It takes quite a little experience to learn to use an ordinary micrometer and obtain the required measurement quickly,

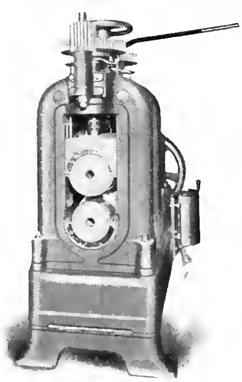

Fig. 4. Reverse Side of No. 7 Mill

and even the most experienced operator is likely to make a mistake in taking the reading. There are two classes of men to whom these difficulties are particularly objectionable, *i. e.*,

purchasing agents who desire to use a micrometer in measuring the gage of sheet metal, etc., and have not had sufficient experience to use the tool with any degree of rapidity; and inspectors who have to use a micrometer so often that the time involved in taking the readings is considerable. With the view of overcoming these difficulties, the Brown & Sharpe Mfg. Co., Providence, R. I., has brought out a direct reading

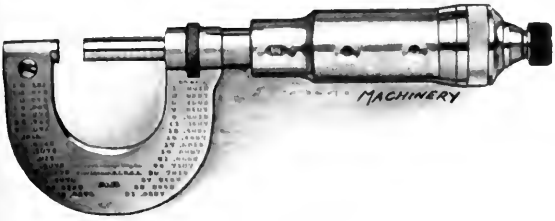

Fig. 1. Brown & Sharpe Direct Reading Micrometer

micrometer, shown in Fig. 1. This tool has a capacity up to 1 inch and is provided with the usual ratchet mechanism to prevent the possibility of damaging the screw. The micrometer, is used in the ordinary way, figures coming up in the three holes in the sleeve to give the reading direct. While arranged to give readings to 0.001 inch, the graduations on the collar enable the fourth decimal place to be accurately estimated.

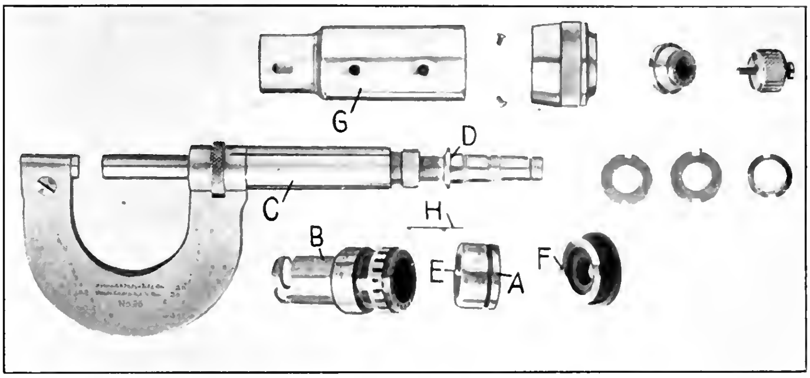

Fig. 2. Parts of the Brown & Sharpe Direct Reading Micrometer

The parts of the micrometer are shown in Fig. 2 and referring to this illustration the method of operation will be readily understood in connection with the following description. The part A is known as the first "counter" and is graduated with two series of figures as follows: 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, which are equally spaced around the counter. These figures indicate thousandths of an inch. The part B is the second counter which is similarly graduated, this counter indicating hundredths of an inch. The barrel of the micrometer C is graduated with one s t of figures, similar to the two sets on the counters A and B, these figures indicating tenths of an inch. The counter A is a press fit on the measuring screw D. This counter has a small pin E sliding in it engaging with the cam F which is held stationary in the sleeve G by means of two screws. The measuring screw is 50 pitch so that one revolution gives a lateral movement of 0.020 inch. Bearing in mind the graduation on the first counter A, it will be evident that one revolution of the screw causes all twenty figures on this counter to appear in succession through the hole in the sleeve.

When the counter A has made one-half revolution, the "carrier" pin E is pushed forward by the cam F so that it enters a hole in the end of the second counter B. At the same time the "locking" pin H, which normally fits into a slot in the counter B to prevent it from rotating, is drawn back through the action of a teat on this locking pin which runs in the cam groove in the first counter A. Under these conditions the counter B is moved through one-twentieth of a revolution to expose the "1" figure, indicating 0.010 inch. When this has been done, the teat on the locking pin H causes this pin to be pushed back into the next slot in the counter B and hold it stationary until the counter A has been rotated through another half revolution. When the locking pin is thrown back into engagement, the "carrier" pin E is moved back by the pressure exerted on its tapered end. This cycle is repeated each time the counter A is rotated through one-half revolution, which corresponds to a lateral movement of 0.010 inch of the measuring screw. For each half revolution of the counter A, the counter B is moved through one-twentieth revolution which also corresponds to 0.010 inch.

It has already been stated that the figures indicating tenths of an inch are graduated on the barrel of the micrometer. These figures are covered by the sleeve at the left-hand side of the counter B, the proper figure being exposed by a spiral groove cut through this sleeve which moves under the hole in the sleeve G. Each time the counter B has been rotated through one-half revolution so that ten figures have been brought up, a figure is brought up on the counter C indicating tenths of an inch. The principle upon which the operation of this micrometer is based will be clearly understood from the preceding description if it is borne in mind that the figure in each adjacent hole to the left has ten times the value of the corresponding adjacent figure to the right of it. The design of the mechanism has been cleverly worked out.

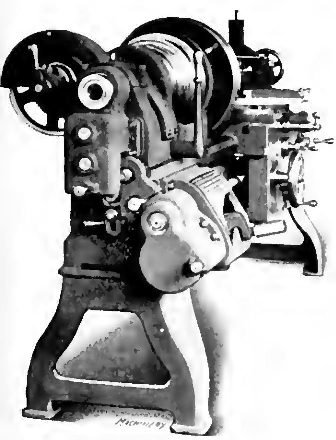

Fig. 1. End View of Cisco Lathe

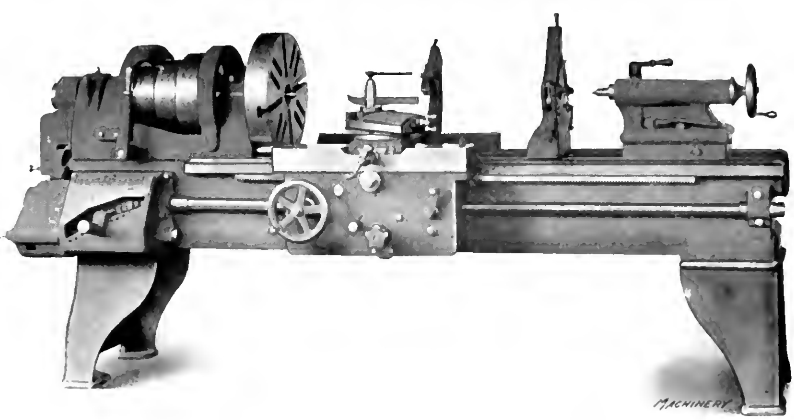

Fig. 2. Front View of Cisco 18-inch Lathe with Double Back-gears

CISCO EIGHTEEN-INCH LATHE

The Cincinnati Iron & Steel Co., Cincinnati, Ohio, has recently equipped its 18-inch lathe with a 3-step cone pulley and double back gears, a machine built in this way being shown in Figs. 1 and 2. The lathe is of very heavy construction and while nominally an 18-inch lathe it will actually swing up to 19½ inches. The hollow spindle will take

1⅞ inch stock and from 2 to 46 threads per inch may be cut. The ratios of the double back gears are 10 to 1 and 3.17 to 1, respectively. Particular attention is called to the sizes of the bearings which are 3½ by 5¾ inch at the front of the headstock and 3 by 1½ inches at the rear of the headstock. The lathe is of simple design and only two wrenches are needed for the entire machine.

All screws are hardened and all gears are of steel. All thread and feed changes are obtained instantly without requiring the removal of any gears or stopping the lathe. The thread and feed changes are obtained by means of two pull pins and the tumbler in the change gear box. The apron is worm-driven by means of a steel worm-wheel and bronze worm, the worm-wheel running in oil. A large graduated dial is provided for thread cutting, and the worm-wheel which operates this dial may be disengaged from the lead-screw when not in use by removing a single screw. The apron is of the double-plate type to provide back support for the studs. The design is such that the half-nut lever cannot be accidentally engaged and a non-interfering device makes it impossible to throw the feed and half-nut into engagement at the same time. The compound rest and cross-feed collars are graduated in the usual way. An efficient form of taper-turning attachment forms a part of the equipment. This lathe is built with beds ranging from 6 feet up. The 18-inch by 8-foot lathe weighs 3500 pounds and each extra foot of bed means an additional weight of 170 pounds.

HISEY-WOLF ELECTRIC DRILLS

The Hisey-Wolf Machine Co., Cincinnati, Ohio, has recently added to its line three types of universal electric drills which can be operated interchangeably on alternating or direct current. These drills are made in five sizes which have capacities up to 3/16, 5/16, ⅜, ½, and ¾ inch, respectively, and range in weights from 6 to 35 pounds. The motors have ample torque and speed characteristics and a liberal factor of safety has been allowed in designing. Their ability to operate on either alternating or direct current makes these drills particularly convenient; they are connected from an ordinary lamp socket.

One of the noteworthy features of these tools is their simplified construction. The electrical and mechanical units are entirely separate so that injury to the mechanical parts does not affect the electrical parts, or *vice versa*. Anyone can take the drill apart in a short time and no other tool than a screw-driver is required. The drill can be assembled with equal ease and without danger of misplacing the electrical connections. By simply taking out four screws the back cap can be removed to expose all of the working parts on the commutator end. The drill can be run with the back cap removed so that the operating of the brushes, commutator, etc., may be inspected. The bearing is not carried in the back cap, but is supported by a separate bracket, as shown in Fig. 2. Besides the convenience of this arrangement for inspecting or making repairs, it avoids binding of the bearings and causing any unnecessary frictional load. All strains are carried on the frame and not on the working parts.

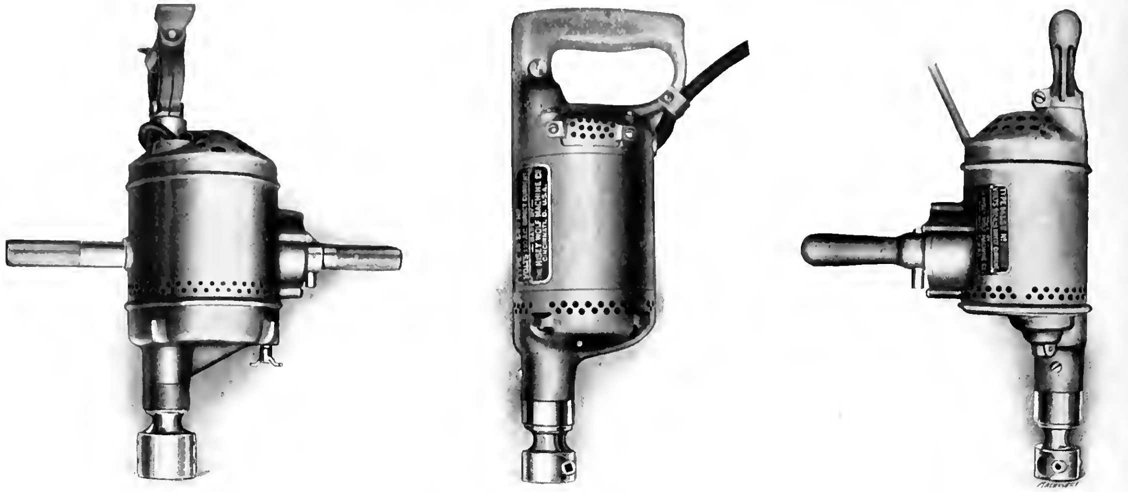

Fig. 1. Three Types of Hisey-Wolf Portable Electric Drills for use interchangeably on Direct or Alternating Current

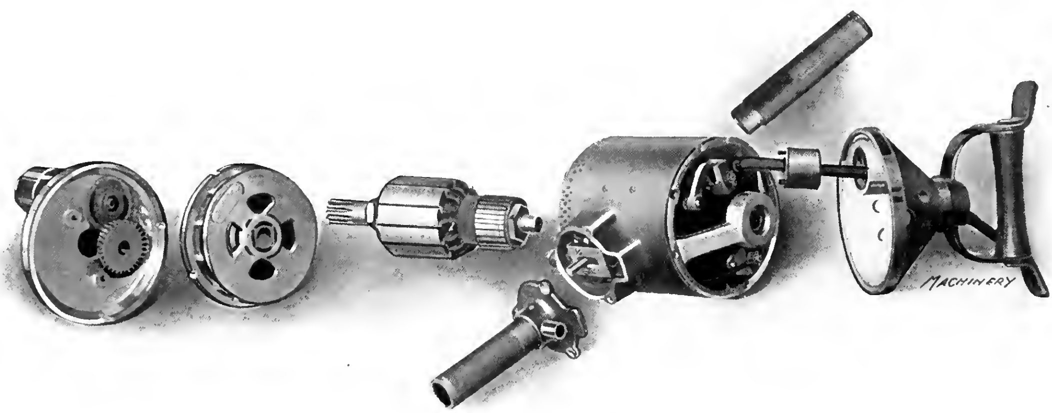

Fig. 2. Parts of a Hisey-Wolf Universal Drill

Taking out four screws will also enable the front cap containing the gears to be taken off to expose the armature, which can be readily removed without interfering with any of the wiring. The gears can be removed from the gear case with equal facility and all parts are interchangeable so that repair parts can be supplied. The leads to the motor are attached

to a terminal plate on the back bearing bracket. The cable is attached to corresponding terminals and protected by a fiber insulating cap. In case of damage to the cable, it can be readily replaced without danger of interfering with the motor connections. To do this, it is simply necessary to remove the insulating cap and attach a new cable to the terminals. The switch is of simple design and entirely enclosed. It is operated by a trigger in the permanent handle of the drill and the arrangement is such that the operator cannot get a shock.

All parts of the drill are made of aluminum where this material is suitable; other parts are made of steel. This construction insures the lightest weight that is consistent with satisfactory service. The armature shaft runs in ball bearings and a ball thrust bearing takes the load from the chuck spindle. All bearings are enclosed and run in grease. The gear-case is enclosed and all bearings on the chuck end of the drill are lubricated from the gear-case. The motor is air-cooled by a fan on the armature shaft.

TERRELL'S STEEL SHELVING WITH LOCKED DOORS

Steel doors that may be readily attached to any of the standard shelving units made by Terrell's Equipment Co., North Grand Rapids, Mich., provide tightly closed compartments for the safe storage of material that is too delicate or valuable to be kept on open shelves. These doors may be supplied with new shelving or added to existing installations, and like all of the other equipment built by this company, they are made on the unit plan which provides for expansion or rearrangement. They are hinged to a channel frame of special design, which is fastened to the unit in such a way that no bolts are exposed, making it impossible for the doors to be opened or removed without unlocking. The doors are furnished in four heights and widths, so that open and closed compartments may be combined in a single installation, as desired.

Steel racks equipped with these locked doors afford protection against the theft of material or loss from fire. The channel frames that carry the doors are provided with lugs by means of which they are bolted to the uprights. The attachment of the doors does not interfere with the adjustment of the shelving in any way. As previously stated, the doors are built on the unit system, each unit comprising a complete frame and pair of doors. The doors are fitted with a three-way locking device that secures them at three points, *i. e.*, a center latch and a locking rod at the top and bottom. The doors can be fitted with master-key locks, with padlock attachments, or without locks. The frames can be stacked, so that where the shelving is higher than the highest standard door, smaller doors may be used in double or triple tiers.

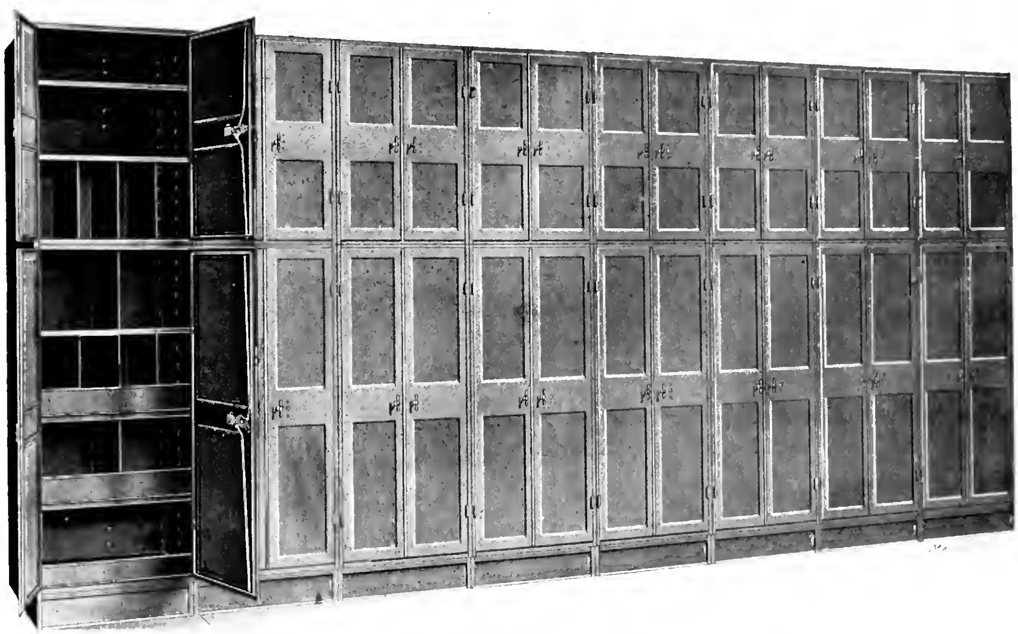

Fig. 1. Installation of Terrell's Steel Shelving provided with Locked Doors

NEW MACHINERY AND TOOLS NOTES

Motor-driven Grinder: Forbes & Myers Co., Worcester, Mass. This company is now building its motor-driven grinding machine mounted on a column which makes it entirely self-contained.

Fig. 2. Rear View of Door showing Method of Attachment

Polishing Machines: W. V. Robinson Co., Owosso, Mich. Two automatic polishing machines; one of these machines is intended for pipe polishing and the other is used for polishing stove tops, sad irons and similar classes of work.

Safety Lathe Dog: E. J. Michaud, Willimantic, Conn. A straight tail lathe dog which has no protruding set-screw that may endanger the operator. The screw boss or crown on the dog is longer than the screw, thus effectually covering it.

Nut Tapping Machine: Erie Machine Shops, Erie, Pa. An automatic nut tapping machine equipped with a stationary tap and belt conveyor for feeding work to the spindle. The machine is intended for tapping either square or hexagon nuts.

Electric Lamp Bracket: W. H. Hill, Cambridge Springs, Pa. An adjustable lamp bracket provided with universal adjustment that is particularly adapted for use in machine shops for obtaining the most advantageous light in the operation of machine tools.

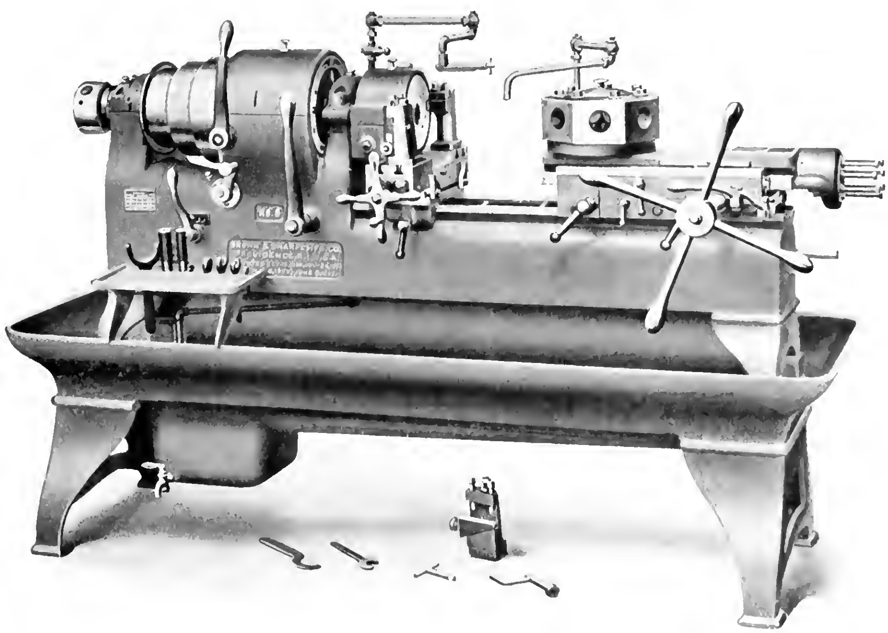
No Extra Collets

By means of a wrench furnished with the machine the jaws of the Automatic Chuck can be set the same as a Universal, to grip any size of stock within its capacity. The same chuck takes either round, square or hexagonal stock with equal facility.

This Saves Time and Equipment

An expensive stock of heavy collets is avoided. There is no time spent hunting up and adjusting collets when changing jobs. No long waits are necessary for collets to hold odd sizes of bars. The machine is always ready.

The adjustment of the chuck is easily and quickly made. The grip is unusually strong because of the powerful leverage. It is always the same along the bar, for the chuck compensates for variations in the stock.



No. 6 Wire Feed Screw Machine
Capacity: Takes stock ½″ to 2″ in diameter. Turns 10″ long.

CO., Providence, R. I., U. S. A.

READ PAGE 67

Vise: E. A. Lueck Co., Milwaukee, Wis. A drill press vise equipped with a coarse pitch screw to provide for rapid operation. V-slots are provided for holding round work. The maximum opening between the jaws is 4⅞ inches and the vise weighs 31 pounds.

Factory Truck: George P. Clark Co., Windsor Locks, Conn. A shop truck provided with a lifting device operated by the handle of the truck. This lifting device is controlled by an arrangement of cams and gears which reduces the effort required in lifting the load.

Two-spindle Drilling Head: Nelson-Blanck Mfg. Co., Detroit, Mich. The spindles of this head are adjustable to adapt it for handling a large variety of work requiring two holes to be drilled. The maximum distance between centers is 8¾ inches and the minimum 1⅝ inch.

Alligator Shear: Hilles & Jones Co., Wilmington, Del. A motor-driven shear mounted upon a truck to adapt it for portable service. The knives are 14 inches long and the machine operates at 50 strokes per minute. The capacity is up to 1½ inch square soft steel bars cut cold.

Straightening Rolls: Hilles & Jones Co., Wilmington, Del. A set of heavy plate straightening rolls which are said to be among the largest rolls of this type which have been built in this country. The machine is operated by a 100 horsepower Westinghouse variable speed motor and weighs 120,000 pounds.

Crank-driven Planer: Newton Machine Tool Works, Inc., Philadelphia, Pa. The notable feature of this machine is the incorporation of a geared speed box which provides a useful range in cutting speeds with a single pulley drive. The machine may also be equipped with electric motor drive when so desired.

Lathe: Von Wyck Machine Tool Co., Cincinnati, Ohio. A 16-inch quick change gear lathe equipped with double back gears. The machine has a chasing dial which permits thread cutting to be handled without stopping the lathe or reversing the lead-screw. The double back gear ratios are 12 to 1 and 3½ to 1.

Keyseating Machine: Newton Machine Tool Works, Inc., Philadelphia, Pa. A keyseat milling machine built for the C. Morgan Smith Co., York, Pa. This machine is intended for milling the keyseats in locomotive engine axles, the full depth, width and length of the keyseat being finished in a single operation.

Milling Machine: John Steptoe Shaper Co., Cincinnati, Ohio. This company has improved its hand milling machine by adding a quick return mechanism for the table feed, a new lever latch, and a table of increased length. These improvements have been added to the regular screw elevating knee type of milling machine.

Multiple Punch: Cleveland Punch & Shear Works Co., Cleveland, Ohio. A large multiple punching machine for use in steel car fabricating work. The machine has a capacity for punching sixty 3/16-inch holes in a 1 1/2-inch steel plate. The punches are arranged in two rows of thirty each and their positions are adjustable.

Milling Saw: Henry Disston & Sons, Inc., Philadelphia, Pa. A 36-inch high-speed segmental milling saw composed of six segments. The spaces between these segments take up temporary strains which might damage a solid saw. Making the saw in segments is also said to afford a possibility of getting better results in hardening.

Lathe: National Lathe Co., Batavia, Ohio. A 17-inch lathe. The carriage of this machine is gibbed front and back and the apron is equipped with an interlocking mechanism. The head is provided with a reverse mechanism which adapts the machine for cutting right- and left-hand threads. The change gear device is of a special patented construction.

Hydraulic Steam Pump: Hydraulic Press Mfg. Co., Mt. Gilead, Ohio. A line of steam-driven hydraulic pumps equipped with a new form of speed and pressure regulator. Based on the steam end dimensions, this line of pumps comprises twelve sizes, and on the water end dimensions, seventy-one sizes. The pump is of the single cylinder, double-acting pattern.

Multiple Spindle Drilling Machine: Moline Tool Co., Moline, Ill. A multiple spindle machine built along the established lines which are followed in the construction of the machines of this company's manufacture. This machine is intended for hollow milling work; it is equipped with drill chucks for holding the work and hollow mills made by the Modern Tool Co.

Boring Tools: Davis Boring Tool Co., St. Louis, Mo. A set of boring tools which has some unusual features, among which the following may be mentioned. The cutters are unusually heavy and the bodies of the tools are also made heavier to afford the necessary support for boring operations on a particularly tough grade of steel. The bodies are made flat on two sides to afford the necessary chip clearance.

Milling Machine: American Milling Machine Co., Batavia, Ohio. A No. 1½ plain milling machine in which particular attention has been paid to the provision of safeguards over all dangerous parts. Another noteworthy feature of the design is the simplicity of the operating mechanism. Twelve geared feed changes are provided which are in geometrical progression and cover a range from 0.005 to 0.030 inch per revolution of the spindle.

Belt Tension Scale: Tabor Mfg. Co., 18th & Hamilton Sts., Philadelphia, Pa. A gage particularly adapted for use in textile mills where there are a large number of small belts of the same approximate thickness and length. This device is placed on the belt and a handle is turned which causes tension to be applied by means of a spring, the tension being indicated on a scale. In this way accurate information may be obtained as to whether the belt requires tightening.

Shop Goggles: T. A. Willson & Co., Inc., Reading, Pa. Improved shop goggles for use in operating grinding machines and similar classes of work. The lenses are pivoted to the bridge so that they may be adjusted to fit closely around the nose and eyes of different wearers. A special flange construction is said to make it impossible for the glass to be forced inward in event of the lenses being broken. The usual form of gauze guards are provided to prevent chips from flying into the workman's eye from the side.

Multiple Drill Head: Covington Multiple Drill Co., E. 5th & Scott Sts., Covington, Ky. A drill head adapted for clamping directly to the spindle sleeve of an ordinary drilling machine. The main driving gear of the head is driven by a double-end key placed in the tang slot or drift hole of the spindle. The head is made to take drills with No. 2 Morse taper shanks in sizes up to 29/32 inch. The head has a maximum spread of 11 1/16 inches and a minimum of 4 5/16 inches. The body of the head has a circular dovetail around it. The brackets holding the spindles are gibbed to this dovetail and may be adjusted to different positions.

NEW YORK STATE COMPENSATION ACT FOR WORKMEN

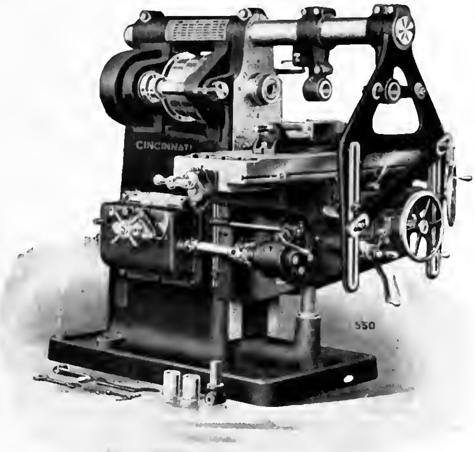
The New York State Legislature passed a workmen's compensation act December 12 which is said to be the most carefully drawn compensation law yet passed by any American state. Following are the principal features of the law:

1. It requires employers in forty-one enumerated groups of the hazardous industries to insure the payment of compensation to their injured employes and makes such compensation the exclusive remedy.
2. It gives employers the choice of four methods of insurance: (*a*) in the state fund created by the act; (*b*) in employers' mutual insurance associations; (*c*) in casualty companies; or (*d*) to carry their own insurance on satisfying the state compensation commission of their financial ability to pay all lawful claims.
3. It creates a compensation commission of five members to administer the state fund and to investigate, settle and pay the claims of all injured employes, acting as the agent of the state fund or of the other insurance carriers.
4. It gives this commission adequate powers to organize the force of deputies, actuaries, examiners, etc., necessary to the efficient performance of its duties.
5. It prescribes a carefully balanced scale of compensation, based on two-thirds of the wages of the injured employe and the limit of $15 a week as a standard, and includes all of the important provisions suggested by European and other experience. The payment of compensation begins on the fifteenth day after the injury.
6. It requires employers to provide medical attendance, medicines, surgical appliances, hospital care, etc., "to a reasonable amount" from the time of the accident until sixty days thereafter, but with careful limitations designed to protect employers from unreasonable charges and to prevent malingering.
7. It authorizes employers in any one of the enumerated groups to organize mutual associations for the prevention of accidents and to draft rules, which when approved by the industrial board, shall have binding force.

* * *

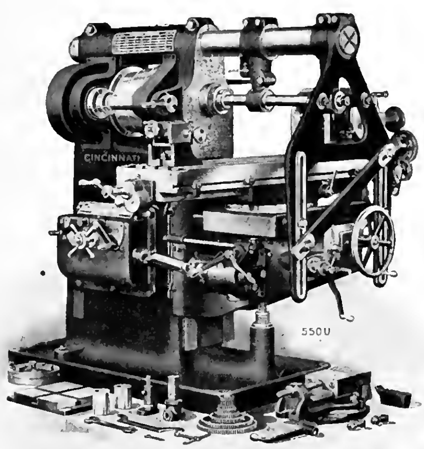
The Red D steamship *Zulia* sustained a peculiar accident while loading a forged steel shaft weighing several tons at her pier in Brooklyn December 8. The shaft, which was about eighteen feet long, was encased in a wooden shipping box, and as it was being hoisted aboard by a sling around the middle, the shaft overbalanced and one end swung downward. The heavy shaft broke through the box and plunged into the hold, breaking a hole through the bottom of the vessel. The hold was flooded with water, causing a loss of $25,000 to the cargo.

Much of the Milling in most Shops is not Heavy Cutting



The No. 4 Plain High Power Miller with Cone Drive

Front or operator's side showing arrangement of all operating levers



The No. 4 Universal Power Miller with Cone Drive

On this work the very powerful single pulley millers do not increase production.

An up-to-date, properly designed, cone-driven machine like our No. 4 Horizontal often proves the better investment.

It is our High Power Miller with cone-driven spindle.

We have simply replaced the Single pulley, Geared Spindle Drive box with a Double Back Geared Cone of large diameter.

It has ample power for all that work requiring a large machine, but not excessively heavy cutting.

It can be depended upon for long, hard, continuous service, because of its massive "High Power" construction.

Its maintenance cost is low because of its simplicity.

AND IT IS HANDY.

The Feed Changers and Back Gear Lever are where the operator stands to shift the belt.

The Table always feeds in the direction in which the Engaging Lever is set.

This same lever also reverses the feed.

All Controlling Levers are at the front of the knee and saddle. So is the Quick Return.

Everything that has to do with its operation is within easy reach.

And there is an additional lever at the side of the knee controlling the feeds from behind the table, for end-milling or boring or similar work which can't be successfully done when the operator stands in front, as he must do on all other Millers.

Let us help on your milling problems. We make the largest variety of machines and therefore can recommend the ones best suited for your work.

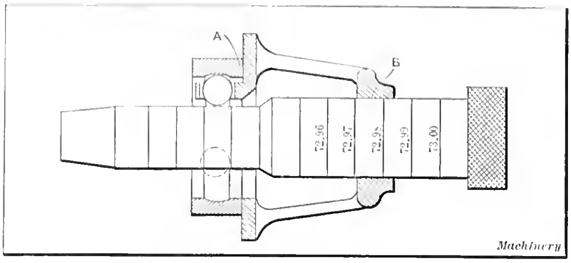
GAGE FOR BALL BEARING RACES

The accompanying illustration shows a gage for measuring ball bearings, which was recently patented in Germany. This gage has a new shape of mandrel which gives reliable and accurate readings without the addition of delicate parts. Instead of a conical tapering shape, the mandrel has a series of steps or cylindrical surfaces of varying size. These steps differ very little in diameter, the difference depending upon the degree of accuracy required. The contact bodies between the



Gage for testing Ball Bearing Races

gage and the race to be measured should, preferably, be of the same steel as the balls to be used in the bearing. Three or more of these balls are inserted in the race, and the face of the supporting frame of the gage is placed against the finished face *A* of the ring. The cylindrical portion or shank of the mandrel passes through guide ring *B* and the step-shaped measuring end is pushed through between the balls. The face of the guide *B* forms an edge from which the reading is taken, as indicated by the graduations.

WESTINGHOUSE MACHINIST TWENTY-TWO YEARS ON ONE MACHINE

In the East Pittsburg Works of the Westinghouse Electric & Mfg. Co. is a man who has worked constantly at one machine for over twenty-two years, and furthermore holds the remarkable record of having been late to work in the morning only once during this period of years. The man posses-

Charles Heisler and the J. & L. Machine on which he has worked Twenty-two Years

sing this record is Charles Heisler, who was born in Gutenberg, Germany, in 1864 and came to this country in 1881. After working in several different machine shops he secured employment in April, 1891, at the Westinghouse Electric Co.'s shops then located on Garrison Alley, Pittsburg, Pa. The young machinist was assigned to work on a two-inch Jones & Lamson turret lathe and has operated it continuously ever since.

This constancy in his daily work is entirely of his own choosing, as Mr. Heisler has on several occasions been offered work on other machines and of more modern design necessitating less labor to operate, but he has consistently refused, preferring, like the shoemaker, to "stick to his last." But long service is not a rare occurrence at the East Pittsburg works; in the same division with Mr. Heisler, which employs something like seventy men, there are eight employes whose time of service with the company ranges from seven to twenty-two years. In fact, most of the men now occupying the highest executive positions with the company have attained them through promotions from their respective departments. In the case of Mr. Heisler, the conditions surrounding his work were not particularly conducive to his advancement along the lines that some of the others followed, but his devotion to his work and continuity of purpose show a record seldom equaled and rarely exceeded in industrial circles.

* * *

PERSONALS

I. H. Page has retired from the position of treasurer of the Stevens-Duryea Co., Chicopee Falls, Mass.

W. H. Shafer, factory manager of the Rochester Boring Machine Co., Rochester, N. Y., has resigned his position. Mr. Shafer has as yet made no plans for the future.

J. M. Schaeffer of Waterbury, Conn., who has been the European representative of the Waterbury Farrel Foundry & Machine Co. for the past year and a half, has returned to Waterbury from abroad.

W. S. Parrish, who for the past three and a half years has been acting manager of the Kirkham Motor Mfg. Co., Bath, N. Y., has resigned his connection with the company. Mr. Parrish has made no definite plans for the future.

E. W. Cleveland, formerly chief draftsman for the Fox Machine Co., Grand Rapids, Mich., and designer of the Fox line of adjustable multiple spindle drills, is now with the National Automatic Tool Co., Richmond, Ind., in a similar capacity.

Dr. Ing. Herbert Kienzle, a German electrical engineer, who is interested in the design and construction of automatic screw machines and has written a book on the subject, is at present in this country with the intention of visiting the various concerns making automatic machinery. Dr. Kienzle expects to stay a month in America.

David L. Ballard on January 1 severed a connection of seventeen years standing with the Jones & Lamson Machine Co. in the selling field. His territory ranged from the Middle States to the Pacific Coast, but he is known and loved as "Uncle Dave" the country over among machine tool sellers and machine tool buyers. His friends in Chicago and vicinity gave him a farewell banquet on December 5 at the Auditorium Hotel. Here the older men to whom he has been a brother, and the younger men to whom he has been a father, met to express their regard for him, and to do him the honor at his retirement that the character of his active life has so richly merited.

* * *

OBITUARIES

William Deering, founder of the Deering Harvester Co., which was absorbed into the International Harvester Co., died at his winter home in Cocoanut Grove, Florida, December 9, aged eighty-seven years. He began the manufacture of harvesting machines at Plano, Ill., in 1873. His estate is valued at $12,000,000 to $13,000,000.

DANIEL M. BARTON

Daniel M. Barton, general purchasing agent of the General Electric Co., died at his home in Schenectady, N. Y., December 8 after an illness of only five days, aged seventy years. Mr. Barton was one of the oldest employes of the General Electric Co. He was born in Moriah, N. Y., in 1843; he lived there but a few years, his parents moving to Ware, Mass., when he was still a child. At the age of nineteen he enlisted in the army, with his brothers, in the Tenth Regiment Massachusetts Volunteers and fought at Fredericksburg and Gettysburg. In 1883 the Thomson-Houston Electric Co. was formed by citizens of Lynn, Mass., and a brother, Silas A. Barton, was an active organizer of the new company. Three years later Daniel M. Barton became production manager of the company. In 1893 Mr. Barton was made assistant purchasing agent of the newly organized General Electric Co., and a few years after the main office of the company was established at Schenectady he became general purchasing agent, which position he ably filled to the time of his death. He was well and favorably known throughout the business world, and his many friends and business associates will read of his death with regret. Mr. Barton is survived by his wife, a daughter, Mrs. Robert E. Nivison, and three grandchildren. He also leaves a brother, Silas A. Barton of Waltham, Mass., and a sister, Vila Barton of Northampton, Mass.

COMING EVENTS

January 3-10.—Fourteenth Annual Automobile Show, Grand Central Palace, New York City, under the auspices of the Automobile Chamber of Commerce, S. A. Miles, manager.

April 4-11.—First National Efficiency Exposition and Conference, Grand Central Palace, New York City. Walter H. Tallis, director, Efficiency Society, Inc., 41 Park Row, New York City.

May 1-October 31—Anglo-American Exposition, London, England, to celebrate the centenary of peace between the United States and Great Britain. American executive offices: Woolworth Bldg., New York City. Charles J. Kiralfy and Albert E. Kiralfy, commissioners general.

September 20-25 (1915).—International Engineering Congress, San Francisco, Cal., in connection with the Panama Pacific International Exposition. W. F. Durand, chairman, Foxcroft Bldg., San Francisco, Cal.

NEW BOOKS AND PAMPHLETS

The Metric Carat. 12 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Circular No. 43 of the Bureau of Standards.

The Testing of Materials. 89 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Circular No. 45 of the Bureau of Standards.

House Heating Fuel Tests. By W. H. Meeker and H. W. Wagner. 85 pages, 6 by 9 inches. 16 illustrations and diagrams. Published by the Engineering Experiment Station of the Iowa State College, Ames, Iowa, as Bulletin 33.

Coal-Mine Accidents in the United States and Foreign Countries. Compiled by Frederick W. Horton. 102 pages, 6 by 9 inches. Published by the Department of the Interior, Bureau of Mines, Washington, D. C., as Bulletin 69.

Preliminary Report on Uranium, Radium and Vanadium. By Richard B. Moore and Karl L. Kithil. 101 pages, 6 by 9 inches. Published by Bureau of Mines, Department of the Interior, Washington, D. C., as Bulletin 70, Mineral Technology 2.

Fees for Electric, Magnetic and Photometric Testing. 23 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Circular No. 6 of the Bureau of Standards.

This pamphlet quotes the charges made for testing electric, magnetic and photometric apparatus by the Bureau of Standards at Washington.

Mechanical Refrigeration. By H. J. Macintire. 346 pages, 6 by 9 inches. 121 illustrations. Published by John Wiley & Sons, Inc., New York City. Price $4 net.

This treatise for technical students and engineers describes the progress of mechanical refrigeration during the last decade. Not only has the construction been improved, but experimental work has been done to determine the properties of the refrigerants, etc. The contents by chapter heads are: Types of Refrigerating Machines and Their Construction; Auxiliaries; The Theory of Mechanical Refrigeration; Refrigerating Mediums—Their Choice and Properties; Testing the Refrigerating Machine; Insulation; Applications—Cold Storage; Applications—Cooling of Air; Applications—Cooling of Liquids and Solids; Economy of Refrigeration, etc. The chapter on refrigerants has been made as complete as possible, comprising experimental tests on anhydrous as well as aqua ammonia installations. Four chapters are devoted to applications. The work is one that should meet with appreciation by students and engineers and others identified with refrigerating plants.

Electrical Blue Book 1913-14. 227 pages, 9 by 12 inches. Published by the Electrical Review Publishing Co., Chicago, Ill. Price $2.

The sixth edition of the "Electrical Blue Book" represents an improvement on previous editions, the aim of the publisher being to provide in the most compact form possible complete information regarding the rules of the National Electrical Code. The list of approved fittings as published by the Board of Fire Underwriters and illustrations of the products of the leading manufacturers of electrical material which have passed tests recommended by the National Fire Protection Association as conducted by the Underwriters' Laboratories are features. The National Electrical code is illustrated and explained. This code has grown out of the efforts on the part of the fire insurance organizations to prevent installation of defective electrical wiring. These rules were originally recommendations but they have been so clearly formulated and so promptly modified to meet changing conditions that they are now regarded as little less than mandatory laws, specifying the rules of safety for electric wiring apparatus. The electrician and electrical contractor will find the book not only a guide for the installation of apparatus but a directory of the electrical supply manufacturers furnishing approved apparatus.

Motion Study. By Frank B. Gilbreth. 116 pages, 5¼ by 7½ inches. Illustrated. Published by D. Van Nostrand Co., New York City. Price, $2.

This work describes the author's method for increasing the efficiency of workmen. It emphasizes the necessity of motion study in scientific management, the great field for such study and the variables involved. The variables of the worker include his anatomy, brawn, creed, earning power, experience, habits, health, mode of living, size, skill, temperament and training. Other factors which affect the worker's efficiency are his state of mind or contentment, his resistance to fatigue and his food or nutrition. Another set of variables designated as surroundings are appliances, clothes, color, entertainment, heating, lighting, quality of material, rewards and penalties, size of unit used, special fatigue-eliminating devices, surroundings, tools, union rules and weight of unit moved. A third set of variables are those of motion, being acceleration, automaticity, combination with other motions, cost, direction, effectiveness, foot-pounds of work accomplished, inertia and momentum overcome, length, necessity, path, play for position and speed. The author has taken bricklaying as a type of skilled labor to illustrate these principles of motion study. The book is one of much suggestive value to those interested in any phase of so-called efficiency engineering.

Questions and Answers on Automobile Design, Construction and Repair. By Victor W. Page. 622 pages, 5 by 7½ inches. 320 illustrations. Published by Norman W. Henley & Sons, New York City. Price $1.50.

This book embodies the general editorial experience of the writer while technical editor of an automobile journal. The endeavor was made to arrange the contents in logical, systematic order and to describe principles of construction with special reference to the requirements of the non-technical reader. The contents comprise the following chapters: Modern Gasoline Automobile and its Principal Parts; Action of Two- and Four-Stroke Cycle Motors; Parts of Gasoline Motors and their Functions; Fuels for Automobile Motors; Theory of Carburetion and its Application; Types of Carburetors and Their Action; How Gas is Exploded in Cylinder to Produce Power; Parts of Ignition Systems and their Purposes; Current Producers, Batteries, Dynamos and Magnetos; Low Tension Ignition Systems; High Tension Ignition Systems; Methods of Lubricating the Automobile Power Plant; Cooling the Gasoline Engine by Air; Typical Water Cooling Systems; Use of Clutch and Various Types Described; The Friction Transmission; Individual Clutch Change Speed Gear; Action of Sliding Gear Transmissions; Methods of Drive to Rear Wheels; Differential Gear Construction and Operation; Rear Axle Types; Automobile Frames and Springs; Steering Gear and Front Axle; Wheels, Rims and Tires; Automobile Bearings and their Care; How to Start and Control Automobile Power Plants; Methods of Speed Changing Outlined; Utility of Brakes and their Use; General Driving Instructions; Oiling the Automobile Chassis; Road Troubles and their Symptoms; Repairing Power Plant Group; Troubles with Power Transmission Parts; Chassis Troubles and their Elimination; Fixing Tire Defects; Equipment and Accessories.

Handbook for Machine Designers and Draftsmen. By F. A. Halsey. 494 pages, 8½ by 11 inches. Illustrated. Published by the McGraw-Hill Book Co., Inc., New York City. Price $5 net.

This work by Mr. Halsey, editor emeritus of the "American Machinist," was under consideration by him for years. Mr. Halsey had fifteen years experience in machine design before he became an editor eighteen years ago. His practical work showed him the weaknesses of existing handbooks, and in his editorial experience he had seen many valuable articles contributed to the technical press go into the "limbo of forgotten things" with much regret. The present work was compiled largely from the files of the "American Machinist," but other publications and the transactions of engineering societies were drawn from freely also. This matter has been condensed and rearranged where necessary to make it harmonize with the general plan. The page size, 8½ by 11 inches, was chosen because of the growing popularity of the standard typewriter sheet size and the fact that the book is not in any sense a pocketbook, but is intended for use on the draftsman's and mechanical engineer's desk. The large size page favors the use of diagrams and charts, which have been freely used. The contents comprise the following chapters: Mechanical Principles of Design; Plain or Sliding Bearings; Ball and Roller Bearings; Shafts and Keys; Belts and Pulleys; Flywheels; Cone Pulleys and Back Gears; Spur Gears; Bevel Gears; Friction Gears; Worm Gears; Helical Gears; Planetary Gears; Ropes; Chains; Brakes; Friction Clutches; Cams; Springs; Bolts, Nuts and Screws; Wire and Sheet Metal Gages; Hydraulics and Hydraulic Machinery; Pipe and Pipe Joints; Minor Machine Parts; Press and Running Fits; Balancing Machine Parts; Miscellaneous Mechanisms; Performance and Power Requirements of Tools; Cast Iron; Steel; Alloys; Steam Boilers; The Steam Engine; The Gas Engine; Compressed Air; Mechanics; Strength of Machine Parts; Weights and Measures; Mathematical Tables. The author's plan is to constantly revise the work, keeping it up to date by introducing new articles and excluding old matter pertaining to obsolete practice.

NEW CATALOGUES AND CIRCULARS

Eugene Dietzgen Co., 218 E. 23rd St., New York City. Circular of the Dietzgen electric blueprinting machine.

Rockwood Sprinkler Co., Worcester, Mass. Circular of the Rockwood pressed steel union with bronze seats.

Terrell Equipment Co., Grand Rapids, Mich. Circular of steel lockers, wardrobes, cupboards, shelving, etc.

New Departure Mfg. Co. (Hartford Division), Hartford, Conn. Catalogue of "New Departure" ball bearing shaft hangers.

Fort Wayne Electric Works of General Electric Co., Fort Wayne Ind. Instruction Book 3056 on Type A Form A oil transformers.

Sprague Electric Works of General Electric Co., 527-531 West 34th St., New York City. Bulletin 247 on round type direct-current motors.

Rich Tool Co., Chicago, Ill. Catalogue No. 15 of high-speed twist drills, reamers, track bits, flat drills, bonding drills, drill chucks, reamer chucks and rivet sets.

W. S. Rockwell Co., 50 Church St., New York City. Catalogue No. 20 of Rockwell furnaces, illustrating a large variety of furnaces adapted to all classes of service.

Betts Machine Co., Wilmington, Del. Catalogue of standard metal planing machines ranging in size from 36 by 36 inches to 150 by 144 inches, frog and switch planers, accessories, etc.

Wiley & Russell Mfg. Co., Greenfield, Mass. Pamphlet entitled "The Tale of the Lightning Tap" describing features of tap construction of interest to users of screw threading tools.

Mesta Machine Co., Pittsburg, Pa. Bulletin K of gears and rolling mill pinions, machine molded. A chart is included for determining the safe loads for molded gears and pinions of cast steel.

Putnam Machine Co., Fitchburg, Mass. (Manning, Maxwell & Moore, Inc., New York City, general sales agents.) Circular of the Putnam heavy pattern 42-inch coach and truck wheel lathe.

Fort Wayne Electric Works of General Electric Co., Fort Wayne, Ind. Bulletins 1145 on Type ML three-bearing belted direct-current generators with balance wheels, and 1147 on Fort Wayne transformers, Type A.

Kales-Haskel Co., Detroit, Mich. Circular of special washers, pipe and wire clips, cord holders, ratchet sectors, liners and shims, windshield hinge disks, screw machine products, etc., chiefly for automobile manufacturers.

Corbin Cabinet Lock Co., New Britain, Conn. Circular of the Corbin safety guard for presses and drops, providing an absolute preventative of injury to workmen without interfering with freedom of movement or the usual motion of hands and arms.

Herman Bacharach, 14 Wood St., Pittsburg, Pa. Pamphlet describing the Maihak indicator with Bottscher's power counter. This apparatus renders it possible to ascertain instantaneously the mean indicated horsepower of steam and gas engines.

American Tool Works Co., Cincinnati, Ohio. Circular of the "American" radial drilling machine built in 2, 2½, 3, 3½, 4, 5, 6 and 7-foot sizes, plain; 5, 6 and 7-foot sizes, full universal. The circular also contains data on drilling performed by the various sizes of the drills.

Ingersoll-Rand Co., 11 Broadway, New York City. Bulletin No. 8107 on "Little David" pneumatic drills. This machine is of the piston type, having four single-acting pistons connected to a crankshaft by connecting-rods. The connecting-rods are fitted with Hyatt roller bearings.

Wheelock, Lovejoy & Co., 23 Cliff St., New York City. Catalogue of "Blue Chip" high-speed steel and high-grade tool steels made by the Firth-Sterling Steel Co., McKeesport, Pa. The catalogue contains valuable information for all steel users, with illustrations of hardening room equipment, etc.

National Tube Co., Frick Bldg., Pittsburg, Pa. Safety calendar for 1913-14 illustrating in color a safety principle to be observed when crossing railroad tracks. Each page of the calendar bears a safety motto useful to superintendent, foreman and workman in shops, mills and factories. The motto of the calendar is "Safety Always."

Wells Bros. Co., Greenfield, Mass. Catalogue of the Wells self-opening threading dies, made in eight sizes ranging from ¼ inch to 3 inches capacity inclusive. The proper shapes of thread chasers for various metals are shown, and the construction details, making a catalogue of unusual interest to users of thread-cutting tools.

Joseph Dixon Crucible Co., Jersey City, N. J. Free to engineers, a limited number of booklets dealing with steam traps, unions for steam pipes, feeding graphite for lubricating purposes, etc. The booklets are treatises prepared by the well-known writer, W. H. Wakeman, who has contributed many articles on power engineering to the technical press.

Dodge Mfg. Co., Mishawaka, Ind. Catalogue 106A-14 of power transmission machinery, furnishing in condensed form information and price list of standard appliances embraced in the Dodge line. This condensed catalogue is offered as a more convenient form for ordinary uses than the company's complete catalogue containing about 600 pages.

McCrosky Reamer Co., Meadville, Pa. Catalogue of adjustable reamers, "Wizard" quick change chucks and collets, "Wizard" variable speed and reversing attachment for drilling machines, McCrosky expanding mandrels, "Searchlight" universal lamp brackets, "Nevastop" combination faceplate and dogs for facilitating rapid lathe work, etc.

Wanderer Works, Schoenau near Chemnitz, Germany. Catalogue of "Wanderer" milling machines of the knee, vertical spindle and planer types; automatic gear cutting machines; tool grinding machines; automatic dividing and engraving machines; tool accessories, etc. The catalogue is printed in English and illustrates a variety of interesting machine tools.

Ingersoll-Rand Co., 11 Broadway, N. Y. Pamphlet on steam, belt-driven and electric motor-driven air compressors Type 10. The pamphlet is unique in its typographical makeup, the text being a reproduction of typewriting with "thumb-nail"

MACHINERY

FEBRUARY, 1914

ADJUSTABLE AND MULTI-CUTTING TURNING TOOLS

DESIGN AND APPLICATION FOR THE TURRET LATHE AND BORING MILL

BY ALBERT A. DOWD*

THE cost of tool equipment for the manufacture of interchangeable work is an item which should be proportionate to the number of pieces to be machined. The saving in time which can be made by the use of special tools should also be carefully considered, as there are many cases where special equipments are designed for work which could be handled to advantage by the judicious use of standard tools. In order to obtain the greatest possible production from their machines, there have been instances where machine tool builders have sold tool equipments of expensive design, when a standard equipment would have done the work very nearly as well. Undoubtedly there was some gain in production, but it is doubtful whether the saving in time would pay for the special tools. The upkeep of special tools is also a factor which must be taken into consideration. It is interesting to note that the present aim of machine tool builders is to so design standard tool equipments that they can be adapted readily to a great variety of working conditions. A great deal of time is spent by manufacturers in devising and experimenting with various tools in order to perfect them to such an extent that they will conform to these conditions.

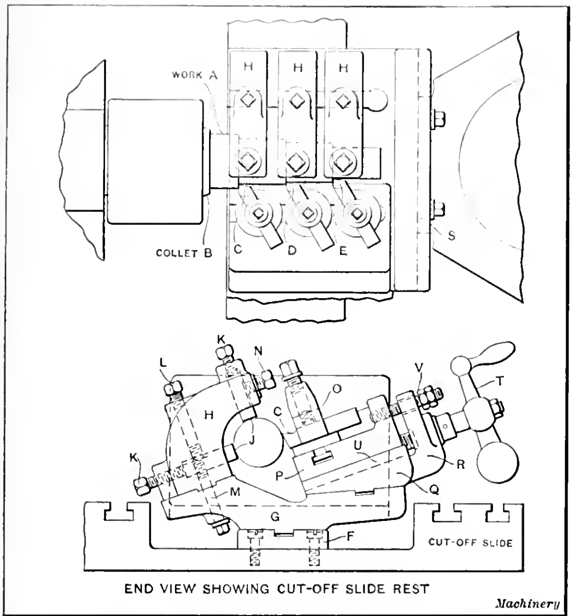

Fig. 1. Special Multi-turning Tool for Bar Work

The rapid growth of the automobile industry in the past ten years is largely responsible for the broader development of our machine tools. The enormous quantities of interchangeable parts which are required in this industry and the manufacturers' desire for increased production have brought into existence a great variety of multi-cutting tools. Tools of this kind may be designed for a variety of uses, and tool-holders capable of containing several tools can also be designed to handle a considerable range of work.

Adjustable tools and those having cutters for turning several diameters are sometimes combined with boring-bars, drills, or cutter heads, these being applied to some one of the various types of turret lathes. They are also occasionally designed for use on a vertical boring mill.

When used on the turret lathe, the cut-off slide is frequently equipped with a gang of tools so that the operations of turning, boring and facing can be carried on at the same time. Quite frequently the tools are so arranged that from nine to twelve are working at the same time, with the result that there is a considerable gain in production. There are a great many varieties of so-called "box-tools" on the market, and these are principally used for bar work on turret lathes or screw machines having a collet mechanism. Tools of this type are usually a part of the standard equipment furnished with screw machines adapted to bar work, and they will not be discussed in the present article.

The design of multi-cutting turning tools for castings and forgings which have several diameters to be machined, is a subject well worth considering, for it is safe to say that nearly any manufacturer who uses horizontal or vertical turret lathes can greatly increase the productive efficiency of his machines by the judicious use of multi-cutting tools. The several designs of turning tools illustrated in this article have been built for various purposes, and a careful study of the types shown may be of assistance in suggesting methods which can be used to perform some piece of work requiring tools of a similar kind. Some of the important points in the design of tools of this nature are given herewith.

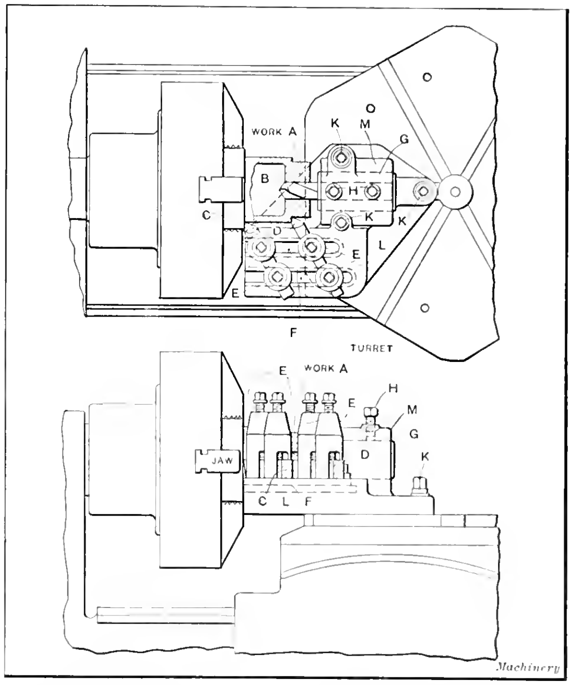

Fig. 2. Multiple Tool-holder for the Turntable Type of Lathe

General Points in Design

1. Rigidity: Avoid overhang as much as possible unless some sort of outboard support can be used. Pilot the tool if practicable.

2. Arrangement of tools: They should be perpendicular to the plane in which the turret rotates when indexing, be-

* Address: 84 Washington Terrace, Bridgeport, Conn.

cause variations in diameters are less likely to take place when tools are arranged in this way. Unequal indexing of the turret has very little effect on the radial position of the tools under these conditions, so that sizes can be held much closer than if they are placed in a plane parallel to the turret rotation. Use standard rectangular stock for the cutting tools so that the upkeep will be inexpensive and reforging be avoided.

3. Try to make the block containing the tools removable so that it can be replaced easily by another block with tools arranged differently to handle other work.

4. Make the tool-block adjustable if possible.

5. Back up the tools with adjusting screws.

6. See that provision is made so that cutting lubricant can be directed on the faces of the tools when forgings or steel castings are to be machined.

7. Arrange the tool-block in such a way that the thrust of the cut does not come against it; it is much better to have the thrust come on the body of the tool.

Multi-turning Tool for Electric Motor Shafts

One example shown in Fig. 1 is given of a multi-turning tool for bar work. This tool was designed for use on the

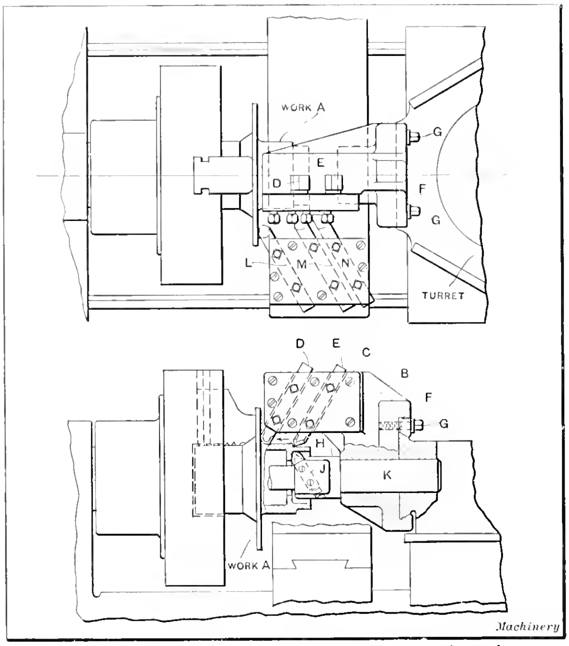

Fig. 3. Multiple Tool-holder for machining Automobile Hubs

electric motor shaft shown at *A* in the illustration. The work was handled in short lengths although the stock is a regular commercial product. Roughing and finishing operations were performed with the same type of tool. The work was held in collet jaws. Something like twenty varieties of shafts having different diameters and shoulder lengths were handled by these tools.

A Pratt & Whitney turret lathe with collet mechanism was used for this work; as this type of machine has a turret with dovetail faces, the body of the tool *G* was arranged to fit the dovetail and the gib *S* held it in place. The cut-off slide was planed off at the center and the hardened steel block *F* was secured to it. It will be noted that this block acts as a support for the tool, and the tongue assists in preventing lateral movement. The cast-iron block *Q* is fastened to the body of the tool and it is dovetailed at *U* to receive the tool-slide *P*. This is of steel and it is T-slotted so that standard toolposts *O* can be used. It will be seen that the tools *C*, *D*, and *E* are held in such a way that they can be adjusted readily both for different diameters and for shoulders of varying lengths. The slide is screw controlled and is operated by the handle *T*. A positive adjustable stop is provided by the check-nuts *V*. The back-rests *J* are of tool steel and are contained in the brackets *H*. The screws *K*, *L*, and *N*, are used for binding and adjusting, while those at *M* pass down through slots in the body of the tool and permit adjustment of the back-rests in a longitudinal direction.

Points worthy of notice in this tool are the method of supporting the body by means of the block on the cut-off slide, the flexibility of the tool adjustments, and the ease with which any tool may be replaced if broken or used up. The

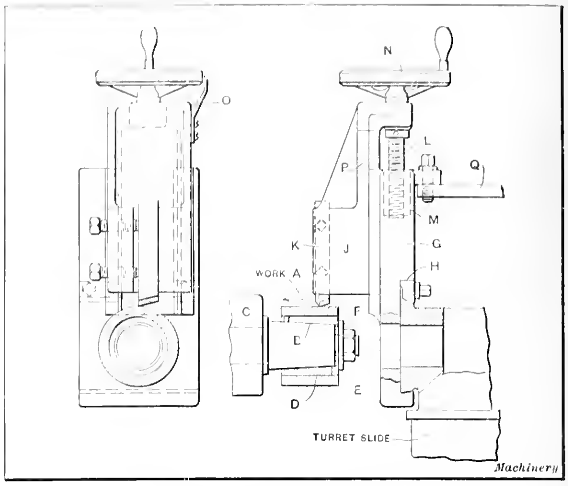

Fig. 4. Adjustable Turning Tool for finishing the Outside of Short Bushings

tools are of standard section and therefore require no machining except cutting off and grinding.

Multiple Tool-holder for the Turntable Type of Lathe

The bronze nut shown at *A* in Fig. 2 is an example of a piece of work which is to be drilled and turned on two diameters at the same time. There were six pieces of this kind varying slightly in size, which had to be machined in lots of twenty-five. Two tool-holders were used to do the work, one tool being arranged as shown in the illustration,

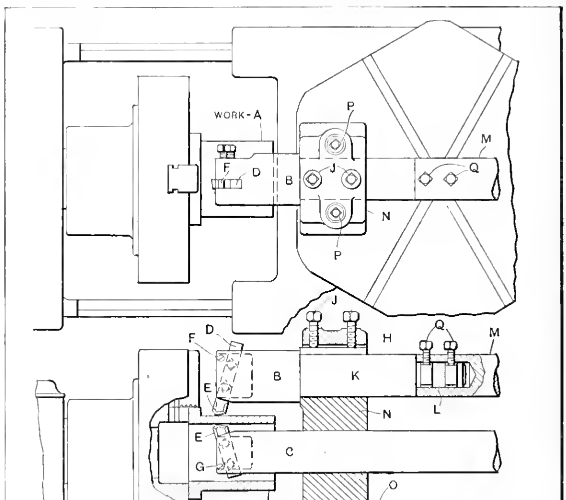

Fig. 5. Boring-bars for turning Concentric Packing Rings

while the other contained a boring tool in place of the drill *B*. The holder *L* was made of cast steel and was T-slotted in two places at *F*, so that tool-holders *E* of the standard type could be used. These carry the tools *C* and *D*, and attention is called to the way in which two posts are used for each

tool to insure the maximum rigidity. The body of the holder is fastened to the turret face by the screws *K*, and is tongued on its under side to fit the slot. A semi-cylindrical boss *M* contains the split bushing *G* which holds the drill *B*. Two screws *H* are employed to clamp the bushing. This holder is simple, easily made and quite adaptable for work within its capacity. There are likely to be slight variations in the diameters turned due to imperfect indexing of the turret, but for general commercial work these usually are not great enough to cause any serious trouble.

Multiple Tool-holder for an Automobile Hub

The piece of work shown at *A* in Fig. 3 is an automobile hub, and the tool-holder is arranged so that the operations of turning and boring can be carried on simultaneously with the facing. The tools *L*, *M* and *N* are secured in a special block on the cut-off slide. The tool-holder *B* is of cast iron and well ribbed; it fits the dovetailed face of the turret, being secured in position by the screws *G* and the gib *F*. The turning tools *D* and *E* are mounted vertically, and the steel cap-plate *C* contains the necessary holding screws. The boring-bar *H* is piloted in a chuck bushing at its forward end and contains the tool *J*, which stands in a vertical plane like the turning tools. The shank of the bar *K* is secured by the turret binding screw and an additional set-screw in the holder itself. A tool of this type will produce more accurate work than the type shown in the preceding illustration, on account of the position of the cutting tools with reference to the turret indexing. A feature of some importance is the piloting of the boring-bar, as this assists in the prevention of vibration. Care should be taken in the design of tool-holders of this type, that the overhang from the turret face is not too great, for if this is excessive, a certain amount of chatter is inevitable.

Adjustable Turning Tool for Short Bushings

A number of short bushings such as that shown at *A* in Fig. 4 were to be refinished on the outside. The bushings were of various diameters ranging from 2¼ to 4 inches, while the lengths varied from 1½ to 3 inches. The pieces were held on arbors *B*, in collet jaws *C*. A split sleeve *D* was expanded inside the work by the action of collar *E* and nut *F*. The body of the tool *G* was secured to the dovetailed face of the turret by gib *H*. The tool-slide *J* is a steel casting dovetailed at *P* and fitted with an adjustable taper gib to take up the wear. The cutting tool *K* is placed in a slot in the slide and is secured by the screws shown. The screw *L* is journaled in a lug at the upper end of the slide and enters a steel nut *M* in the body of the tool. Radial adjustment is obtained through this screw by means of the handwheel *N*. The rim of the wheel is graduated and the pointer *O* permits accurate readings to be made. This tool is very good indeed for light work, and accurate results can be obtained by its use. When two tools are used, a tie-rod *Q* assists in making the combination more rigid.

Holder for Adjustable Boring- and Turning-bars

The work shown at *A* in Fig. 5 is a cast-iron pot from which concentric packing rings are to be cut, and the boring and turning are done at the same time. Two cast-iron holders *N* are tongued at *O* and secured to opposite sides of the turret by the screws *P*. The turning- and boring-bars *B* and *C* pass through the holders and extend entirely across the turret. The boring-bar *C* is of the same diameter along its entire length, and it is secured in the holders by shoe binders similar to that shown at *H* but located in the sides of the holders. The boring tools *E* are of rectangular section and secured by set-screws in the slots at the ends of the bar. The screws *F* and *G* help to stiffen the ends of the bars where they are slotted. The upper or turning-bar is made in two sections *K* and *M* so that the tools may be swung radially to bring them into their proper position when the turret is set off center for turning larger diameters. The end of one bar is turned down at *L* to fit the hole in the other bar and the screws *Q* make a firm joint. A set of bars and holders of this kind is a very useful adjunct to a turret lathe equipment, and it may be adapted to a variety of uses. The double tie feature across the turret gives exceptional rigidity.

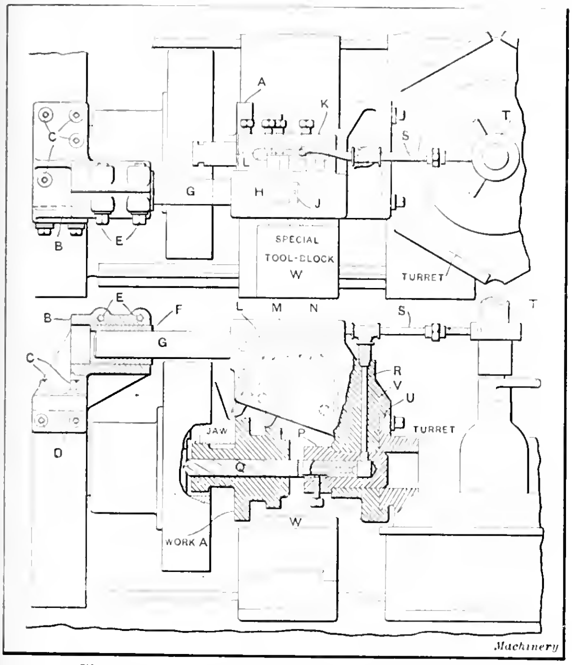

Fig. 6. Piloted Multiple Turning Tool for Gear Blanks

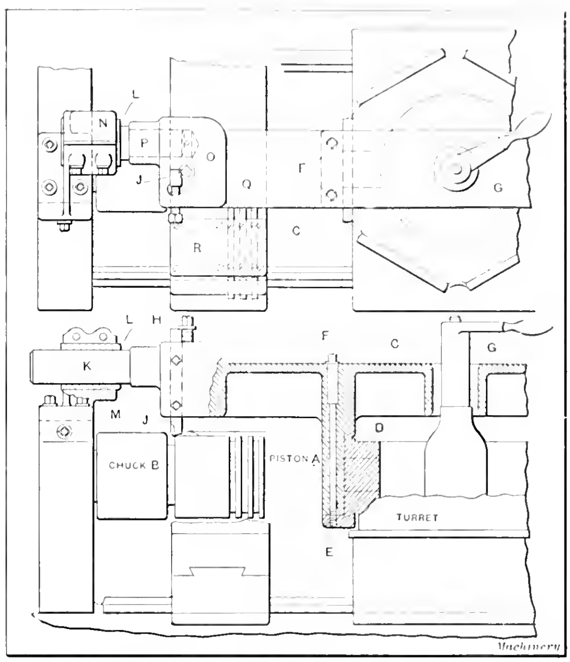

Fig. 7. Double-end Piloted Turning Tool for Pistons

Piloted Multiple Turning Tool for Steel Gear Blanks

The automobile jack-shaft gear blank shown at *A* in Fig. 6 is of alloy steel and it is held in special chuck jaws so that it can be drilled, turned and faced simultaneously. A special tool-block on the cut-off slide performs the latter operation, while the turning and drilling tools are carried by the turret. The body of the turning tool *V* is made of cast iron and is fastened to the dovetail turret face by the gib shown at *U*. The tool-block *K* is of steel and is slotted to receive tools *M* and *N*. An oil groove is cut at *L* along the top of the block and it is supplied with oil from the special piping system shown. The pipe *S* leads to the distributing collar *T* which, in turn, is connected with the cutting lubricant piping system on the machine. The slots in the tool-block are of sufficient width to permit an ample supply of fluid to run down and

reach the cutting ends of the tools, thus assisting greatly in prolonging the life of the tools and also allowing higher cutting speeds. The oil-drill *Q* is held in a steel supporting bushing *P* which fits the body of the tool-holder. It is supplied with lubricant through the hole *R* which is connected to the piping system. The steel pilot *G* is shouldered at *H* and is forced into the body of the holder. The small hole *J* is put in so that air pressure will not be generated when the pilot is pressed into place, as this would tend to deceive the fitter by making him think he had a good fit when, in reality, it was compressed air that made the pilot hard to force in. I have seen pilots fitted so that they were apparently all right at the time when the work was done, and yet when the time came for the tools to be used, it was found that they were loose enough to cause trouble. The air hole will prevent trouble of this kind.

A special bracket is shown at *B* and it is screwed to the spindle cap by the screws *C* and *D*. The bronze bushing *F* receives the end of pilot *G*, and it is clamped by the binding screws *E*. This method of supporting a turning tool is very successful and assists greatly in permitting heavy cutting without chatter. Another feature of this tool is the manner in which oil is conveyed to the cutting tools. Attention is also called to the position of the tool-block, this being at the rear of the body so that the thrust of the cut is brought directly against the heavier part of the casting. The method of mounting the tools is also a little out of the ordinary, in that the block and tools form a unit which can readily be removed, permitting the substitution of another block with tools arranged differently, to handle other work requiring different spacing. Two turning tools on opposite sides of the turret were used for this particular piece, one being used for roughing and the other for finishing.

Double-end Piloted Turning Tool for Pistons

The piston *A* shown in Fig. 7 is held by the inside on a special expanding pin chuck *B*. The arrangement of tools is that recommended by the Pratt & Whitney Co., for turning automobile pistons on their horizontal turret lathe. The turning tool-holder *C* is of cast iron and is double ended, reaching entirely across the turret, and the two ends are exactly the same. The body or arm is of U-section and it is cored out at the center so that the turret binder-lever can pass through it, as shown at *G*. A careful fit is made on the dovetail at *D*, and two special bolts *F* pass down through the body of the tool and pull up the gib *E* against the lower dovetail, thus clamping the tool securely. The tool *J* is backed up by the collar-head screw *H* and is secured by means of two screws. The steel pilot *K* fits the bushing *L* in the spindle cap bracket *M*, as in a previous instance. It will be noted that an air hole *O* is provided where the shank *P* enters the end of the tool body. In connection with the turning tools a special block on the cut-off slide is used to cut the ring groove in the piston. This block and tools are shown at *R* and *Q* in the upper view. This style of equipment is very well known and has given universal satisfaction.

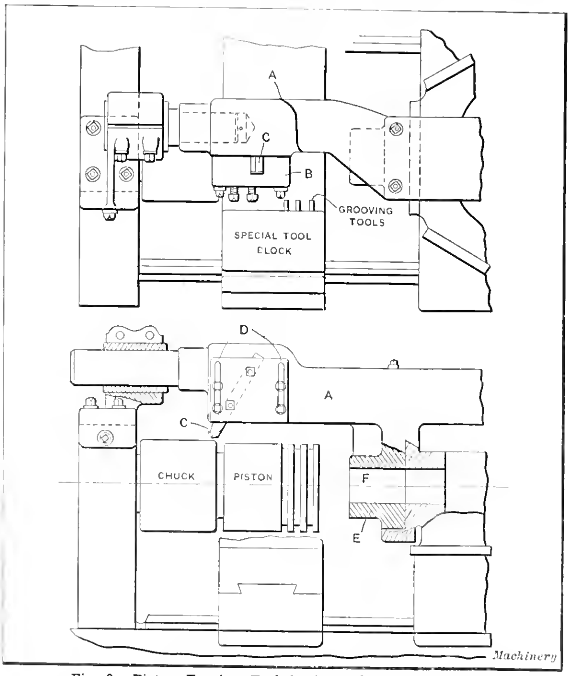

Fig. 8. Piston Turning Tool having Adjustable Tool-block

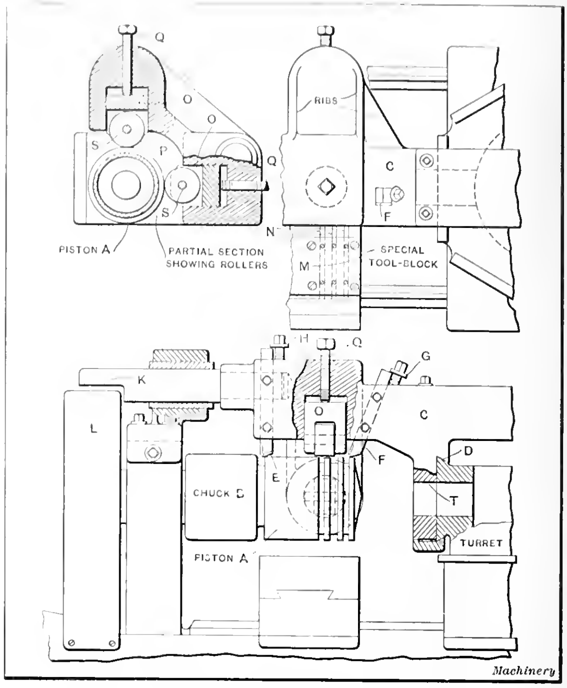

Fig. 9. Multiple Turning Tool equipped with Pilot and Roller Back-rest

Piston Turning Tool having Adjustable Tool-block

A development of the preceding tool is shown in Fig. 8. It will be noted that although the general construction is about the same, in this instance the tool-block is made separate so that other blocks may be substituted having more than one tool. Considerable adjustment is also permissible by means of slots shown at *D*. It is obvious that this method of construction requires the tool-block *B* to be of steel and somewhat heavy, so that it will properly resist the thrust of the cut. The screws which hold the block in position must also be of ample size. As this particular tool was designed for use in turning and boring ring pots, in addition to piston work, the boss *E* was supplied and bored at *F* to receive a boring-bar.

Special Multiple Turning Tool with Roller Back-rest

In a great many instances the design of an automobile piston is such that it is permissible to center the solid end, and this gives a chance to support the end by a conical rest. While the ring grooves are being cut some support is essential, and in the case of the piston shown in Fig. 9 the use of roller supports in place of a center rest was found necessary for the reason that centering was not permitted. The piston *A* is held on the special chuck *B* and the two tools *E* and *F* are held in a double-end tool-holder. Adjustment is obtained by means of the collar-head screws *H* and *G*. The turning tool body *C* fits the turret dovetail at *D* and it is clamped, as previously stated. The end of the pilot *K* is cut away on its under side in order to clear the gear guard *L*. The steel supports *O* are backed up by the screws *Q*, which are also used for adjusting purposes. The hardened and ground steel rollers *P* are hung on the pins *S*. (See detail view.) A special tool-block *M* contains the grooving tools *N*. This equipment also was very successful.

Adjustable Piloted Turning Tool for Large Diameters

A somewhat different type of tool is shown in Fig. 10, this being adjustable for various diameters from the 12-inch casting *A* down to a diameter of 6 inches or a trifle under that size if necessary. This tool was rather heavy and cumbersome and not entirely successful on heavy cuts. On the lighter variety of work, however, it proved satisfactory and adaptable. Two tools were used on opposite sides of the turret; the flat steel tie-bar *L* helped to prevent sagging.

The body of the holder *B* is of cast iron cored out so that the walls are ½ inch section, and it is tongued along its lower face to fit the turret at *M*. The forward end holds the steel pilot *C*, which is supported and guided by the bushing *D*. The bracket *E* is fastened to the head of the machine by the screws *F*, thus insuring a rigid support for the end of the pilot. The tool-slide *N* contains the tool *O* and it is securely gibbed by the two steel straps *P*. A taper gib (not shown) provides adjustment for wear on the sides. The bracket *K* is screwed to the top of the tool body and journals the operating screw *H*. A graduated collar permits accurate settings to be made without trouble. A bronze nut in the body of the slide at *J* receives the operating screw.

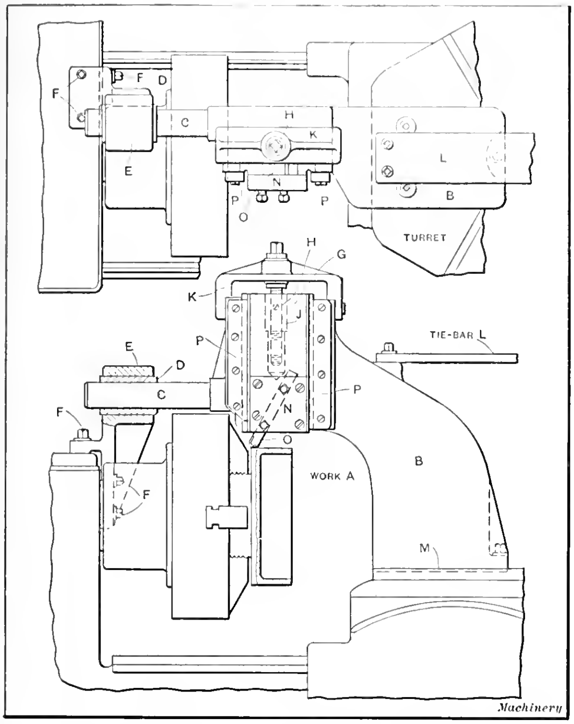

Fig. 10. Adjustable Piloted Turning Tool for Large Work

Multiple Turning Tool for the Vertical Turret Lathe

The vertical turret lathe is less frequently supplied with multiple tools than the horizontal type of machine, for the reason that the regular equipment supplied by the manufacturers is adapted to a wide range of conditions without very much special tooling, and, in addition, the class of work for which this machine is more likely to be used is of such a nature that multiple turning tools are less likely to be required. There are instances, however, when a considerable increase in production may be made by the use of the multiple type of tools. Take for example the special gear shown at *A* in Fig. 11. This piece of work is held by the inside of the rim in special jaws, and the tools in the side-head turret are used to face and turn the gear portion while the special multiple tools are at work on the hub. Before the operation illustrated takes place, the work has been bored, reamed and faced on the other side.

The body of the tool *H* is of cast iron and it is fastened to the turret face by the screws *J*, while the plug *K* centers it in the turret hole. The turning tools *E* and *F* are secured in the slots and a steel cover-plate *G* gives support for the set-screws which hold the tools in place. A steel shank *B* has a revolving roll *C* fastened to its lower end by the shouldered screw *D*; this roll acts as a pilot in the finished hole. The construction of this device is simple and the results obtained by its use are excellent

Piloted Multiple Turning Tool for Triple Gear Blank

A radical departure from regular methods is shown in Fig. 12. The work *A* for which the equipment was designed is a cast-iron triple gear blank. Attention is called to the fact

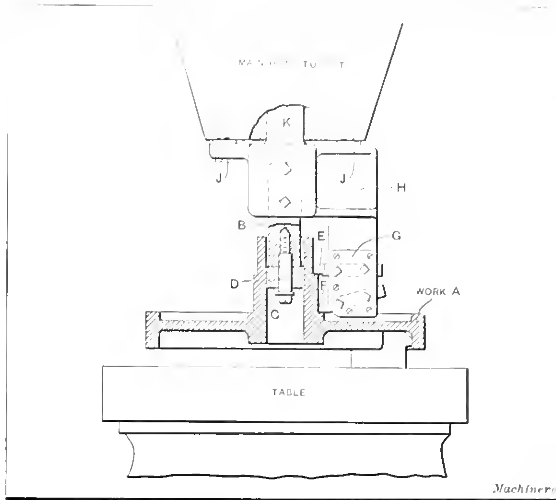

Fig. 11. Multiple Turning Tool for Vertical Turret Lathe

that in this illustration the side-head is shown in a false position in order to show the cutting action more clearly. The body *H* of the multiple turning tool is fitted to the turret and held in position by the screws *C*. A steel bushing *G* acts as an outboard support for the tool, and it is a sliding fit on the pilot *P* which is shouldered in the supporting bracket *N*. This bracket is heavily ribbed and is fastened to the bed of the machine. The adjustable washers at *M* are used to align the bracket properly. A tool-block *D* contains the two turning tools *E* and *F*, and the boring-bar *K* is held in the hub *J*. The arrangement of the side-head, in this instance, is a little out of the ordinary. A special tool-block *Q* contains the two facing tools *R* and *S*, and these work simultaneously with the turning tools, thereby making production very rapid.

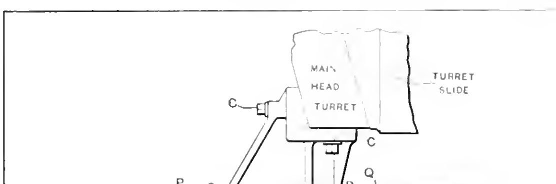

Fig. 12. Piloted Multiple Turning Tool for Triple Gear Blank

Multiple Toolpost Turret for the Side-head

The cone pulley shown at *A* in Fig. 13 was machined in one setting. The casting was held by the inside of the lower or largest step of the cone and a driver (not shown) was

placed against the interior ribbing, as the jaws were not sufficient to hold the work securely against the cutting action of the four turning tools. A special side-head turret toolholder was designed for this piece of work, and the facing and turning tools *D*, *E*, *F*, and *G* were held in it as shown in the illustration. One set of tools was used for roughing and a duplicate set on the other side of the turret post was used for finishing. The entire group of tools pivoted on the stud *H*. While these cutters were operating on the outside of the pulley, the boring-bar *B* (held in the main head turret

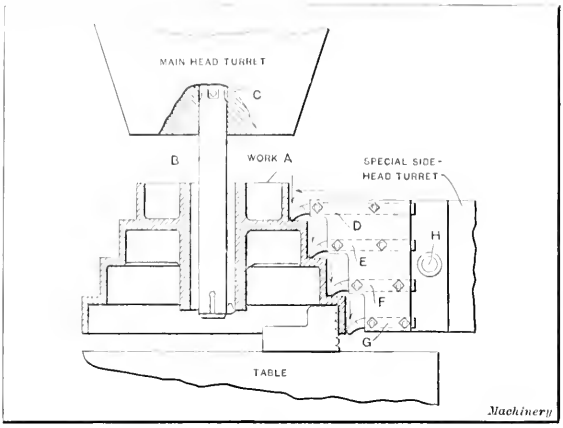

Fig. 13. Multiple Toolpost Turret for the Side-head

and driven by the pin *C*) was slowly boring out the hole. A forming plate was used to give the desired crown to the steps. The production could have been improved if a special turning tool had been used in the main head for turning the four steps of the cone, and the side-head used for facing only. These operations could have taken place at the same time, and the speeds would have been more nearly correct. The boring could have been done at a higher rate of speed. However, the

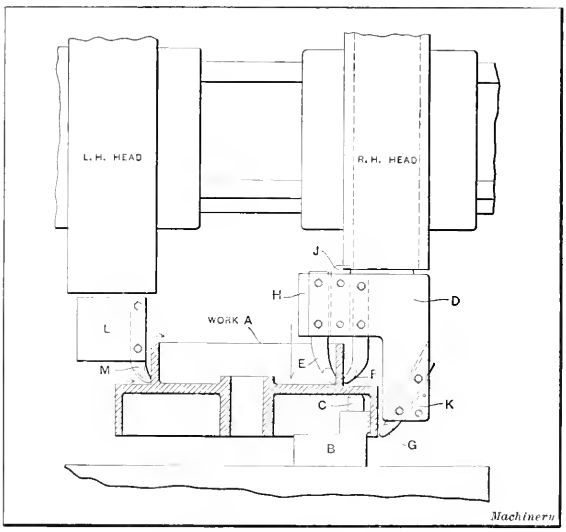

Fig. 14. Application of Multiple Turning Tool to Vertical Boring Mill

results obtained with the arrangement shown in the illustration were satisfactory.

Multiple Turning Tool for the Vertical Boring Mill

The vertical boring mill is seldom equipped with multiple turning tools, but there are cases where production can be increased considerably by their use. One example only is given of the use of an equipment of this kind. Fig. 14 shows a large pulley at *A*, and this is held by the inside of the larger step in the special jaws *B*. The buttons *C* give a three-point support to the work. A special tool-holder *D* is slotted out to receive the tools *E*, *F* and *G* which are used for the turning and boring. The plate *H* is fastened over one end of the tool-holder in order to tie it together, and the filler-block *J* gives additional strength while its upper end engages the right-hand ram and acts as a driver. Another block *K* ties the lower end of the tool-holder together. The left-hand head contains the toolpost *L* which supports the tool *M*. This tool is used for facing while the other tools are turning.

Other instances of multiple turning might be given, and illustrations shown, but these would be much on the same order as those which have been mentioned and would be of no particular value as representative types. Tools have been selected for this article which seem to best illustrate the principles of design required in the various types.

HARROUN KEROSENE CARBURETER*

The high price of gasoline and the rapidly increasing consumption have given great interest to the efforts of inventors to produce a practicable and efficient carbureter for automobile and other internal combustion engines using kerosene for fuel. The accompanying diagrammatic illustration shows the principle of the Harroun kerosene carbureter invented by Ray Harroun and now being marketed by the Harroun Co., of Indianapolis, Ind. Part of the exhaust gases are diverted

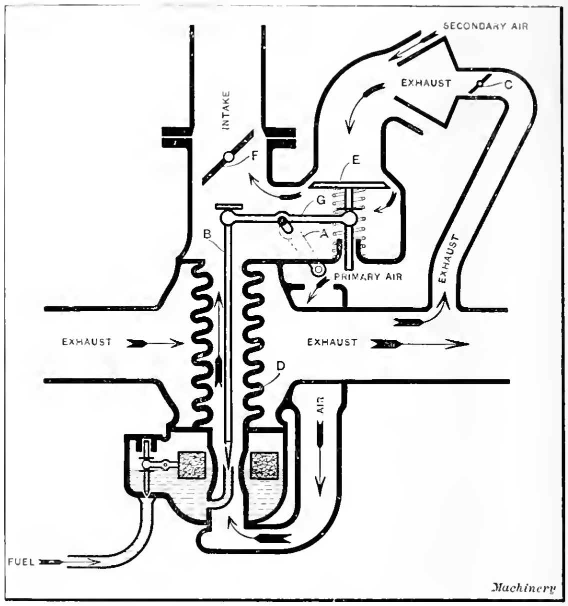

Diagram showing Principle of the Harroun Kerosene Carbureter

into a space surrounding a spirally corrugated chamber *D*. As the dense atomized fuel is drawn through this chamber by the suction of the motor, the heavier parts are thrown to the outside against the heated surface by centrifugal force and the more volatile portions of the fuel remain in the center. As the fuel is sprayed from the nozzle and comes into contact with the hot walls of the chamber it is turned into a vapor. This vapor is partially mixed with air coming in from the bottom of the chamber and is further diluted with cold air coming through the secondary air valve. The needle valve *B* in the opening of the fuel nozzle is automatically opened and closed by the action of the secondary air valve *E*. The carbureter requires but one adjustment, this being effected from the driver's seat through a suitable connection to the lever *A* on the side of the carbureter. This lever raises and lowers the fulcrum of the rocker arm *G* which is inside of the carbureter and raises and lowers the needle *B* as it is actuated by the air valve *E*.

One of the original features claimed for this carbureter is that of diverting a small portion of the exhaust gas back into the charge through the air valve opening. The discovery was made that a part of the exhaust gas mixed with the charge eliminates the disagreeable sounds which are always more

* For further information on kerosene carbureters see "Solving the Fuel Problem for the Motor Truck," October, 1913.

evident with kerosene than with gasoline fuel. Water has been used considerably to accomplish this result, but the use of water results in complications; a water supply is hard to regulate, besides being likely to freeze in cold weather. This gas mixing feature is claimed to be an advantage also with gasoline, as it eliminates "carbon knock" in any motor and also increases the efficiency of the fuel at variable speeds.

The butterfly valve *C* is provided as a means for regulating the amount of exhaust gas used. This may be worked from the dash. It provides regulation of the maximum expansion period in relation to the piston travel under varying running conditions. For example, it is a well-known fact among engineers that the fuel consumption ranges from one-half to three-quarters pound per horsepower hour when the motor is running at about 1000 feet per minute piston speed. The consumption increases rapidly, however, with either an increase or a decrease of the piston speed, sometimes being as much as one and one-half pound per horsepower hour at about 500 and 1600 feet per minute piston speed. This undesirable condition is due to the fact that the speed at which a correct mixture will burn most efficiently happens to be just right at 1000 feet per minute piston speed. A device that will retard the speed of combustion without retarding the spark timing at slow motor speeds will obviously increase the thermal efficiency. Under actual running conditions, an automobile motor is rarely pushed to its maximum or even its normal load.

The Harroun carbureter operates with either gasoline or kerosene without change of adjustment. In fact it is claimed to be a highly developed gasoline carbureter having the added feature of operating satisfactorily on cheap grocery store coal oil. The mileage obtained is ten per cent greater when using kerosene than when using gasoline. Recent tests have shown that with kerosene fuel fed to the engine through this carbureter, a motor will haul one ton one mile for one-third cent.

MACHINING ARMATURE SHAFTS*

TURNING AND GRINDING OPERATIONS WHICH ARE HANDLED AT A RAPID RATE

The method of machining armature shafts has been developed to a high degree of perfection in the plant of the Robbins & Myers Co., Springfield, Ohio, manufacturers of the "Standard" line of motors, generators and fans. The armature shafts are made from 0.30 carbon machine steel, and vary in length according to the motor, fan or generator in

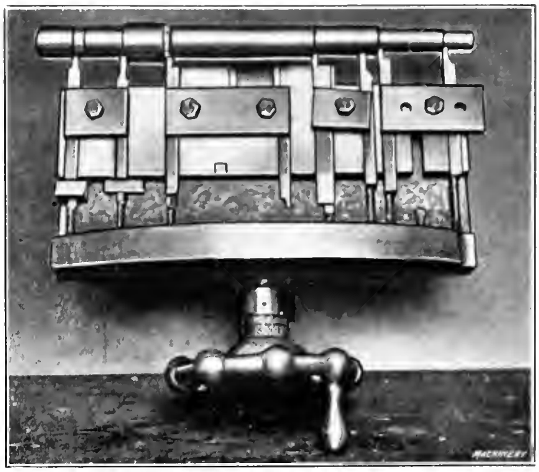

Fig. 2. Attachment used on the "Lo-swing" Lathe for necking Armature Shafts and facing the Shoulders to the Correct Length

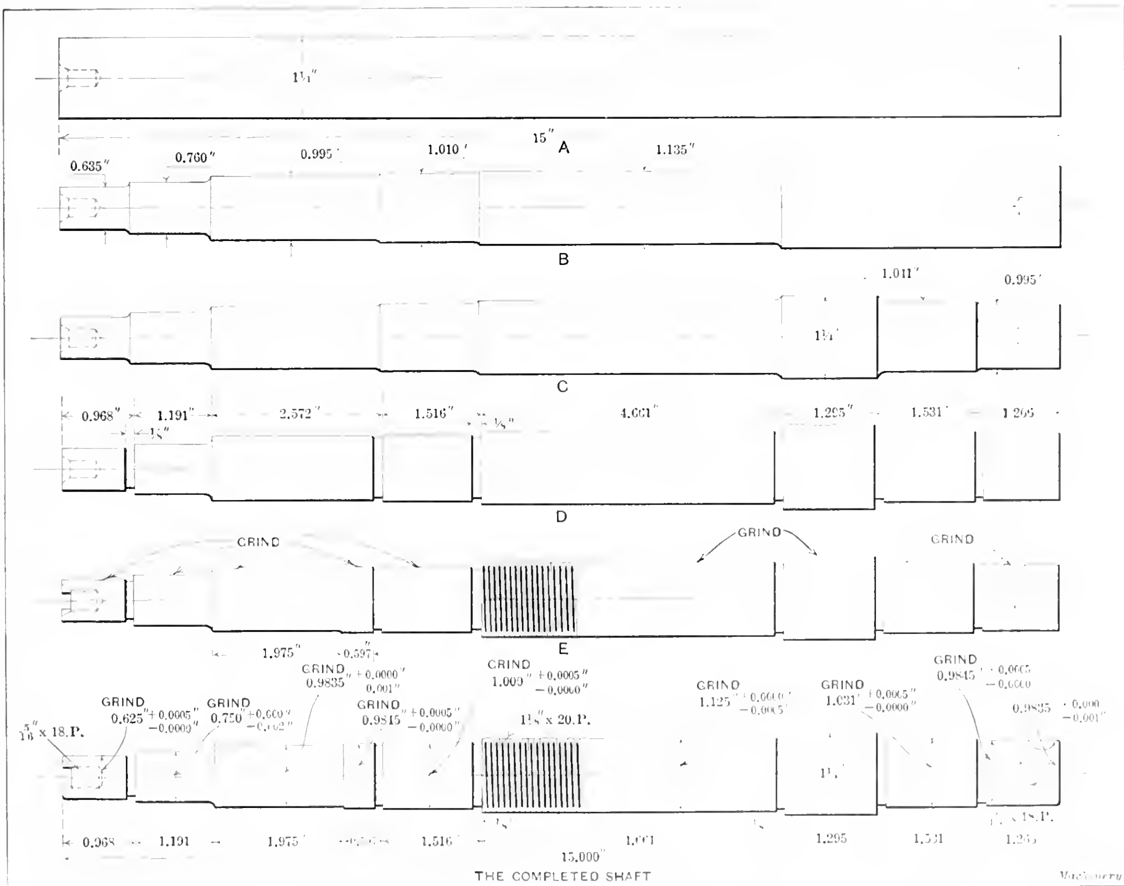

Fig. 1. Sequence of Operations on the Armature Shaft

* For articles on shaft turning previously published in MACHINERY, see "A Lo-swing Lathe Test on Motor Armature Shafts," April, 1913; "Multiple Shoulder Shaft Turning on the Cleveland Automatic," November, 1912, engineering edition; "Turning Shafts in the Cleveland Plain Automatic," April, 1911, engineering edition.

which they are used, the one illustrated being 15 inches long. They are carried through in lots of 500, special trucks being used to accommodate this number. The operations on the shafts are given in the order in which they are handled, only those that have interesting features being illustrated and described in detail.

Preliminary and Lathe Turning Operations

The first operation on the armature shaft is shown at *A* in Fig. 1. This consists in cutting it off to the desired length and drilling and centering both ends in a No. 4 Warner & Swasey hand screw machine. Following this operation, the shaft is rough-turned in the "Lo-swing" lathe as illustrated in Fig. 3. Five different diameters are turned in one setting with multiple tools. This operation completes one-half the shaft in a setting, as shown at *B*, and when the operator has finished the entire lot the machine is reset and the other end of the shaft machined. Handling the work in this manner has proved very satisfactory and enables a production of 100 shafts in ten hours to be obtained. The bar, to start with, is 1¼ inch in diameter, rough stock, and is reduced to the dimensions shown at *B* and *C*. The operations following the rough-turning consist in squaring the shoulders to accurate lengths and under-cutting for grinding, as shown at *D*. These operations are also accomplished in the "Lo-swing" lathe, which is equipped with a special tool-holder as illustrated in Fig. 2. This tool-holder, or slide, carries seven parting or under-cutting tools that reduce or neck the shaft for grinding, and at the same time finish the different shoulders to their exact lengths. The time for necking is included in the product of 100 shafts per day.

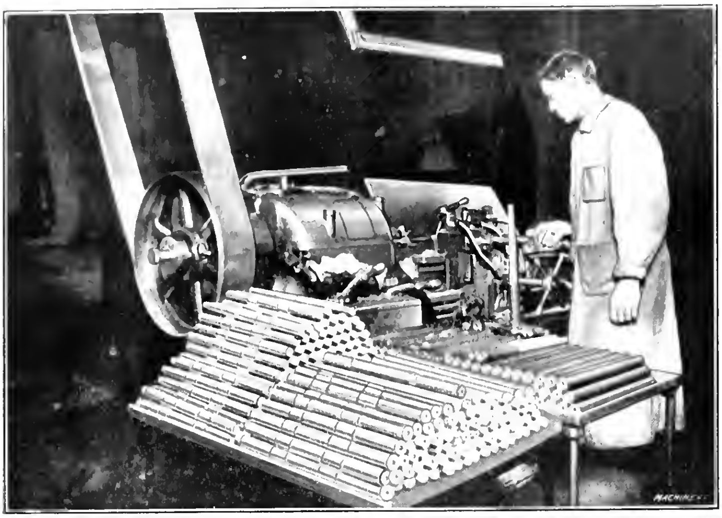

Fig. 3. Rough-turning Armature Shafts in a "Lo-swing" Lathe

Following the necking operation, the holes in the ends of the shaft are tapped in a Cincinnati drill press, and the keyway in one end and the slot in the other end are cut in a Whitney hand miller. One end of the shaft, as shown at *E* in Fig. 1, is threaded and this operation is accomplished in the hand screw machine, using a self-opening die.

Finishing Operations on Armature Shafts

The final operation on the armature shaft is grinding the different shoulders to the exact diameters, which is accomplished in the 6 by 32 Norton plain grinder shown in Fig. 4. The operator, instead of finishing one shaft at a time, puts through the entire lot by grinding only one diameter at a setting and by using a 2¼-inch wheel and feeding it directly in to the work instead of traversing the table. This procedure is followed except in cases where the bearing on the shaft is longer than the width of the wheel used, which would necessitate traversing the table. By referring to Fig. 1 it will be be seen that all but one bearing can be ground without traversing the table. It will also be noticed that the bearing on the extreme right end of the shaft is tapered an amount equal to 0.001 inch in its length. This is accomplished by truing the wheel with a diamond, the table being set over the required amount. In operation, the wheel is fed directly in to the work—not traversed.

On an average of 0.010 inch is left on the diameter of the shaft for grinding, except on the 1¼-inch diameter where it is necessary to remove about 1/32 inch. As shown at *E* in Fig. 1, there are eight bearings or shoulders on the shaft that can be ground in the manner previously described; that is, by feeding the wheel directly in to the work—not traversing the work longitudinally. As each shoulder on the lot of shafts is ground at a setting, it is not necessary for the operator to change the position of the table in relation to the wheel, any slight variation in the depth of the centers being taken care of by the nicks in the shafts. As soon as the wheel becomes slightly glazed or clogged, it is trued up with a diamond and straightened so that the bearing produced is accurate as regards diameter and straight from one end to the other. The automatic cross-feed and knock-out on the machine are used, and when one shaft is being ground the operator is placing a dog on the other, so that the only time lost is that required to remove and replace the shafts on the centers of the grinding machine. When all the bearings less than 2¼ inches in length have been ground, the machine is reset to grind the remaining long bearing, thus completing the grinding operations. The limits on the grinding operations are in many cases only 0.0005 inch. The grinding of only one bearing at a time has been found to be highly economical and efficient, as a production of 105 completed shafts in ten hours proves.—D. T. H.

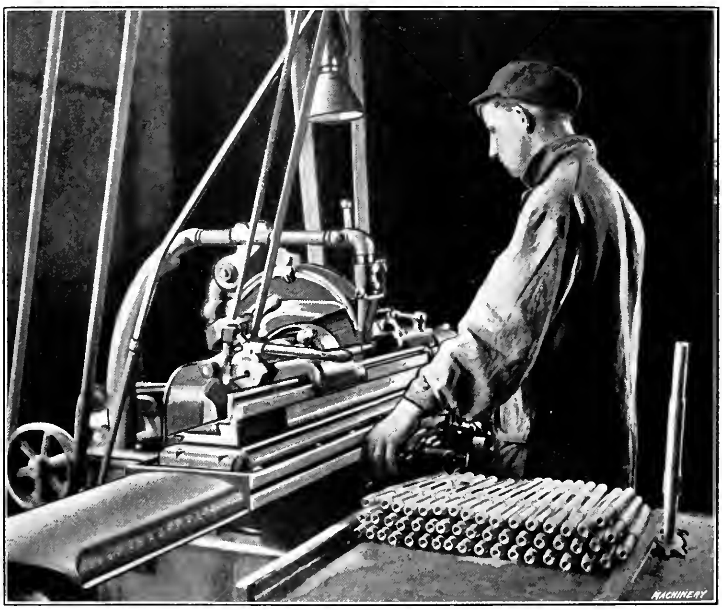

Fig. 4. Grinding Armature Shafts on a Norton Plain Grinding Machine

* * *

It is very unsafe to say that a thing cannot be done or that it must prove a failure. It is by far the safer course, at least in things mechanical, to admit that while it does not seem probable—you never can tell.

FOUR-SPINDLE REAMING ATTACHMENT FOR MOTOR CAR CYLINDERS

BY C. BOELLA*

In order to increase the production of cylinders for small motor cars, cast *en bloc*, the attachment shown in Fig. 1 was designed for application to a regular drilling machine to avoid buying an expensive machine. These cylinders were required in large quantities and high-grade machine work was necessary. A large Niles vertical drilling machine which was already used to ream cylinders, was fitted with the special attachment.

The attachment has a heavy cast-iron base firmly bolted to the machine table. This base has two perpendicular side walls provided with finished surfaces at the ends which are exactly square with the base. The base of the cylinder which, previous to the reaming operation is planed to the exact size, is placed in the fixture between the vertical sides. The latter are fitted at the back with suitable stops, against which the cylinder base bears. The cylinder is held to the fixture by four pivoted clamps which are inserted through suitable square

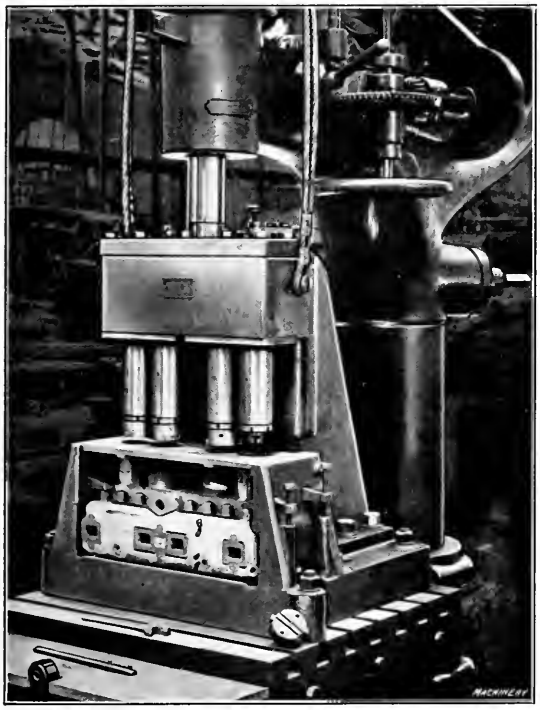

Fig. 1. Four-spindle Reaming Attachment and Fixture with Cylinder in Place

holes in the uprights. These clamps are tightened by screws in the ends which engage projecting lugs, as shown. A large channel at the base of the fixture just under the casting, provides room for chips and makes it easy to remove them.

The four tool spindles are mounted in a slide which is carried by a strong, heavily ribbed column that is bolted to the base of the fixture. Fig. 2 shows a plan view of the spindles and slide. In order to insure exact alignment of the slide during its traverse, it has been fitted with a central dovetailed guide *A*, which being narrow relative to its length, insures accurate movement of the slide. The taper gib *B* is adjustable endwise for taking up wear, the holes for the bolts being made oval to provide play for the taper gib adjustment. The gear *D* fitted to the spindle drives gears *E* and *F* which, in turn, drive gears *H* and *G*, these four gears being fitted to the tool spindles.

Fig. 3 is a vertical section through the tool-slide. A shaft D_1 is screwed to the lower end of the spindle *J* of the machine, and gear *D* drives the tool spindles, as previously explained. A ball bearing *K* is provided to take the vertical thrust of the tools, and plugs *L* screwed in the slide cover are used for vertical adjustment of the spindles. Each tool spindle is surrounded by a heavy steel tube *M*. This tube is fitted with a bushing *N* at its upper end and a smaller bushing *O* at its lower end. The latter is tapered externally and is adjusted by screwed ring *P*. The lower bearing is very close to the tool so that the spindle is rigidly supported.

The tools are fixed to the spindles in a peculiar way, each spindle being tapered to an angle of 20 degrees and fitted with a bayonet clutch. This clutch is engaged by a pivot that is

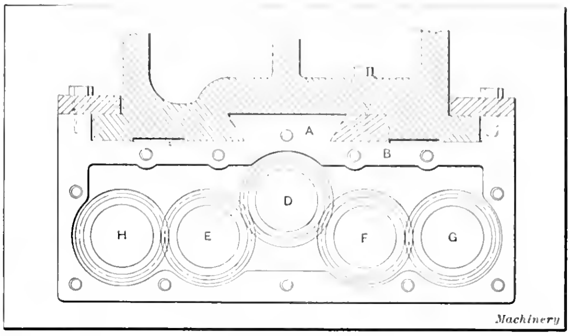

Fig. 2. Plan View showing Arrangement of Spindles of Reaming Attachment

integral with the tool-holder, thus holding the latter onto the taper part of the spindle. With this arrangement, the tools are centered accurately and are held rigidly even after long use; it also allows cutters to be easily removed. Fig. 4 shows the tool which is used both for roughing and finishing. It has a cylindrical body bored tapering to fit the conical end of the spindle. The lower face has a large dovetailed groove in which the two tools are held. These tools are of simple form and are fixed in position by tapering gibs. These tools permit heavy cuts to be taken with heavy feeds and high speeds without chattering.

Experience has proved that multiple cutters are not suitable for this kind of work because of the difficulty of setting them

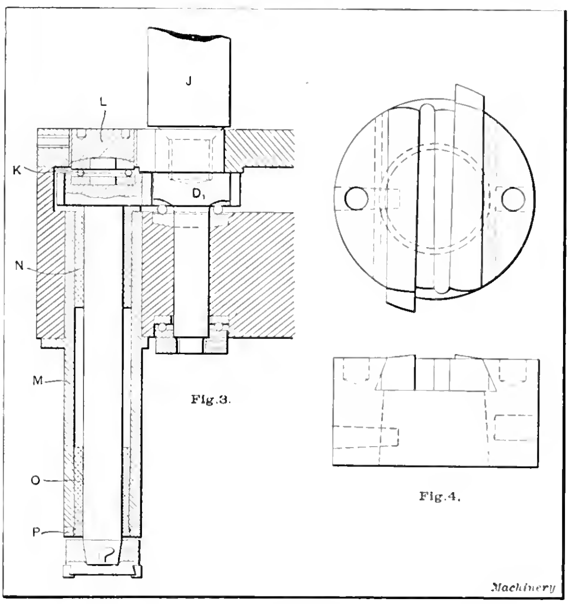

Fig. 3. Vertical Section of Spindle. Fig. 4. Cutter-holder and Cutters

up and fixing them rigidly enough to resist the strain of such hard usage. With the tools described, remarkable results have been obtained. A cylinder of 3- by 9-inch size is rough-bored in twenty minutes and finished in twelve minutes. Better results could be obtained were it not for the excessive heat generated, which is liable to impair the accuracy of the work. The depth of the cut during the roughing operation is about 1/8 inch and the finishing cut about 1/64 inch. The holes are

* Address: Via Massena, 58, Turin, Italy.

quite smooth, straight and parallel and are located exactly with relation to the base.

As the slide with its spindles is heavy, it is necessary to counterbalance it. It was not convenient to increase the counterbalance weight of the machine spindle, so the slide was counterbalanced separately. Two wire ropes were attached to the sides of the slide, as shown, and these pass over grooved pulleys attached to the ceiling and connecting with suitable counterbalancing weights. As changing the cylinders is easier than changing the tools, for repetition work, it is better to rough a quantity of cylinders and finish them afterward.

BROACHING VS. REAMING

BY FRANK J. LAPOINTE*

The broaching of round holes has been adopted within the last few years by many manufacturers on certain classes of work in preference to reaming. This change is due to two reasons: The cost of the operation is less and the finish on the particular work referred to later is superior to that of reaming. It might be of interest to the readers of MACHINERY to know some of the conditions connected with broaching round holes, and the comparative time between broaching and reaming them.

It is an acknowledged fact that the boring and reaming of seamless steel tubing, especially when the walls are light, is not a very satisfactory operation; in fact, the pieces are usually distorted, due to the method of holding them. One of the principal objections to reaming, and one reason why it is so hard to obtain a well reamed hole in steel tubing, is that the reamer tears or "bites in" at some point on the surface. This is due to the fact that the fibers of the steel are drawn lengthwise or at right angles to the cutting edges of the reamer, which is one of the reasons why it is so hard to obtain a good clean finish in steel tubing by reaming.

On the other hand, when broaching the hole in a tube, a very nice finish can be obtained because the fibers lie or are drawn in the same direction as the broach is operated. The ordinary seamless steel tubing is about 0.008 to 0.030 inch under standard size, which is just a nice amount to broach out. For broaching this material, with diameters up to 2 inches, we broach on the high speed of our broaching machine, or with the cutting tool traveling at about six feet per minute. There is no clamping of the work for this operation and the shell is not distorted anywhere nearly as much as it would be by boring or reaming. Six or seven pieces can be broached while one is being reamed.

The writer recently had the pleasure of visiting one of the largest automobile gear manufacturers in the country and was pleased with the results they are obtaining in broaching round holes. The operation is on sliding gears and differential gears. The method of machining these pieces has been changed from the ordinary way to the following: The work is placed on a drill press, in a suitable fixture, and the holes, which vary from 1 1/16 to 1 1/2 inch in diameter, are drilled in one operation with a drill 1/32 inch smaller than the finished size of the hole. On the spindle of the drill press a facing head is arranged so that after the hole is drilled, the spindle is fed down and the gear faced off by this facing head; this forms a flat surface which is square with the hole and is used for locating the work while broaching. The old method was to drill these gears, then follow with a light boring chip, and then a reamer. I was informed that the reduction in price on this work was 1½ cent per hole, which is quite an item when we consider that the original cost of machining the holes was very low, and to reduce it 1½ cent per gear was well worth changing the operation.

The results obtained by broaching are that a well finished hole is obtained in addition to greater production; moreover, the life of a broach is eight to twelve times that of a reamer. Another operation of broaching round holes that may be of interest is carried on in our own plant. All bearings of bronze under 2½ inches diameter, are broached instead of being reamed. This is done for several reasons:

First, broaching is our business; second, it is the most profitable way for us to handle the work; third, there is less waste of material; fourth, the production is eight times as great; and fifth, we always have plenty of broaching machines on the floor to be tested out. Take, for instance, the broaching of a 2-inch round hole in bronze castings 4½ inches long. We allow 1/8 inch of stock to be removed or 1/16 inch on each side, the hole being cored ⅛ inch smaller than the finished diameter. When we were boring and reaming these holes to size, ¼ inch was allowed and the average time was ten minutes per piece. They are now broached at the rate of one in 1¼ minute and the pieces are not clamped and do not lose their shape. The finish of the broached holes is better than was obtained by reaming. The trouble when reaming hard bronze is to overcome the chattering and waving of the reamer in the hole; this has been done by broaching.

The results when broaching round holes depend on the tool itself. The broaches are ground all over after hardening and are backed off at the proper angle to give them a nice cutting edge. The teeth are nicked to break the chips on the heavy cutting part of the broach, but the last six or eight teeth that do the sizing are not nicked. Following the last six or eight sizing teeth is a short pilot which supports and guides the broach. One very important thing in broaching round holes is the proper spacing of the broach teeth. At no time must there be less than three teeth in the work, in order to properly support the broach; if the teeth were so coarse that only one tooth was cutting while another was entering, it would give the broach a slight movement, causing waves in the work. The broach must always be made up with differential spacing of the teeth. If the teeth are all evenly spaced, as a rule very unsatisfactory results will be obtained.

When making broaches a number of things must be taken into consideration, *viz.*, material to be cut, length of work, amount of stock to be removed on the outside, and the shape of the work, so that the proper support can be provided. The length of the broach depends entirely on the metal to be removed. Of course in cases where the broaching operation is for sizing, a short broach is used, usually having about 10 inches of cutting edge. If the broach is to remove ⅛ inch of stock, the length may vary from 28 to 40 inches, depending on the length of the work.

* Address: J. N. Lapointe Co., New London, Conn.

* * *

In a discussion of the value of graphite as a lubricant at the December meeting of the metropolitan section of the Society of Automobile Engineers, Marcus A. Smith, lubrication engineer of the International Acheson Graphite Co., described some of the peculiarities of deflocculated graphite. The subdivision of graphite particles has been carried to such a point that they permeate the pores of the metal and in that way build up a surface layer in which the carbon particles are intimately associated with the metal. Such a surface is termed a "graphoid" surface. By adding one-quarter per cent of deflocculated graphite to lubricating oil it is possible to carry to all surfaces a material that is finer than the most minute pores of the metal and which will gradually saturate the metal with a lubricant that heat does not destroy. The minute size of these particles is indicated by the fact that 339,000 particles of deflocculated graphite, placed side by side, extend one inch. The claim is made that the benefits derived from deflocculated graphite diffused in oil are accumulative, for by continued use all the bearings, cylinder walls and piston rings are protected by a lubricant which impregnates the metal, and if at any time the supply of lubricant is shut off, the coefficient of friction remains practically unchanged for many hours of use.

The Bureau of Foreign and Domestic Commerce suggests in a recent consular report that all communications to the United States consular officers be addressed "The American Consul, at ——," the name of the officer not being given. Any communications so addressed will be opened and attended to by the person who happens to be in charge of the consular office at the time the communication is received. If addressed to the consul by name, it is likely to be forwarded to him unopened, should he be absent, and unnecessary delay would thus result.

REBUILDING A PIPE THREADER

BY A. P. CONNOR*

We were recently called upon to rebuild an old style manually operated Saunders pipe threader in order to take advantage of the increased facility with which a power driven machine could be operated. The provision of suitable gearing would evidently make it possible to change or reverse the speed at which the machine was driven; at the same time it was desired to retain the features of portability, adjustability and a degree of stability which would adapt it for rough usage. The machine had been in operation for a number of years but was still in good condition, so that the problem of rebuilding was limited to the change from hand to motor drive.

In order to have the machine as light as possible, it was decided to do away with the shelves that were located under the bed of the original machine. The lower shelf was replaced by a platform mounted on connecting stays secured to the legs. A ½ horsepower motor was mounted on this platform and means for adjusting the alignment of the motor spindle was provided by four bolts. It will be seen that two nuts are provided on each of these bolts, one nut being above the base of the motor and the other below it. By regulating these nuts, the alignment of the motor spindle can be adjusted to insure having the belt run properly. The arrangement is clearly shown in the illustrations, where it will also be noticed that the motor is located under the machine where it is out of the way.

The headstock housing was reversed in order to locate the driving mechanism at the opposite side of the machine from the position where the operator stands, and the whole machine was set over on the base a distance of 2½ inches toward the operating side in order to balance properly and avoid too much

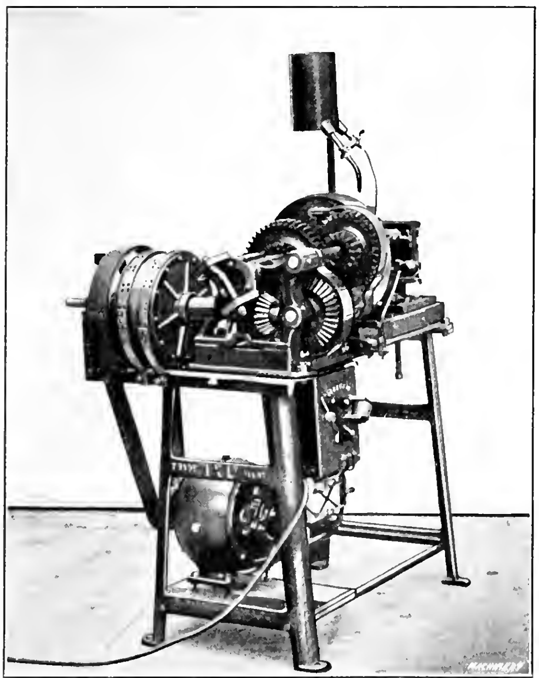

Fig. 1. Operating Side of the Rebuilt Pipe Threader

overhang on the driving side. The familiar form of planetary transmission used on automobiles was adopted, the gear reduction obtained in this way being one to three on the forward and slow reverse speeds. A high-speed reverse was also provided. All speed changes are obtained by a single operating lever. This lever is shifted to the right or toward the die carriage for threading; in order to reverse the direction of rotation of the stock for backing out the work, the operating lever is thrown into the left-hand position; and to stop the machine, the lever is moved to the middle. In order to obtain the high reverse speed, the operating lever is shifted a slight distance off center to the left. From the preceding description it will be noted that the motor connections are not touched in operating the machine and that it is unnecessary to alter the resistance of the electric circuit in order to obtain any of the results referred to.

A friction clutch mechanism is used in connection with the operating lever, which gives a very smooth action and avoids the possibility of breaking gears or otherwise damaging the machine or motor through sudden shocks. The full horsepower of the motor is available all the time that the machine

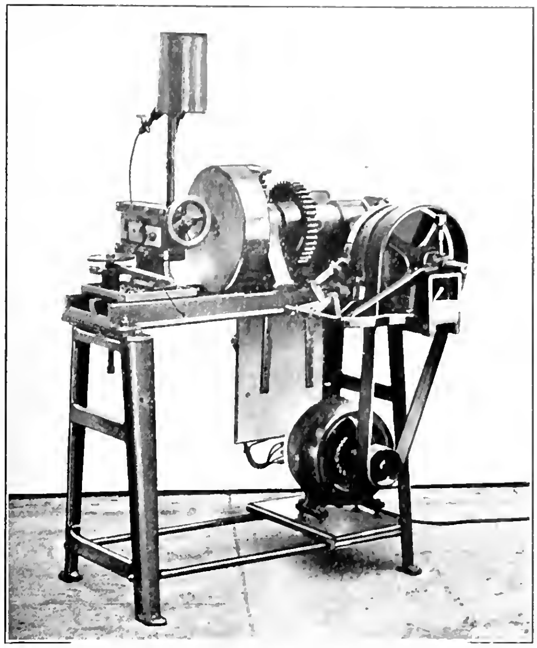

Fig. 2. Rear View of the Rebuilt Pipe Threader

is running. The belt speed must necessarily be high, owing to the type of motor used, and this would ordinarily entail the use of a large driving pulley on the machine. This objectionable feature was done away with by the use of the planetary gear reduction in connection with the regular gearing on the machine. It will be seen from Fig. 1 that the rheostat for the motor is mounted under the bed of the machine so that it is convenient for the operator and at the same time assists in counterbalancing the weight of the motor. The main circuit switch is placed under the rheostat. As the motor only develops ½ horsepower, it can be connected to an ordinary lamp socket with the usual form of attachment plug. The weight of the machine was held within a limit which enables it to be moved about from one job to another, and it is unnecessary to bolt it down to the floor. Solid dies are used, as they have been found most desirable for the class of work for which this machine is intended. The oiling arrangement is essentially the same as that used on the original machine.

MAKING COPPER WIRE BY ELECTRO-DEPOSITION

A process has been devised for the manufacture of copper wire by electro-deposition. According to the *Brass World*, previous attempts to manufacture wire by this process have been unsuccessful. A fine copper wire is used as a core and the additional copper is deposited on it while moving through a tank containing the solution. The fine copper wire is made endless and passes through a regular plating solution containing sulphate of copper and a little sulphuric acid. After leaving the tank, the wire passes through a small rinsing tank to remove the solution, and then, after making a number of turns around a reel, it returns to the plating tank. The plating is thus continued until a wire of the required diameter is obtained.

PRESS TOOLS FOR CLIPPING AND PIERCING BRASS SHELLS

BY JOHN F. FORBES

The illustrations show several interesting forms of press tools for performing clipping and piercing operations on brass shells. Fig. 1 shows the shell *A* which is to be clipped along the dotted line, and at *B* and *C* two views of the completed shell are shown. The die used for this clipping operation is illustrated in Fig. 2. The die *A*, over which the shell slips is a hardened steel collar which is made to fit the shell accurately. This die is driven onto the stud *B* and held in place by means of the dowel pin *C*. The stud *B* is a press fit in the die-bed and is prevented from turning by means of the key *D* which serves the additional purpose of locating the stud in the desired position.

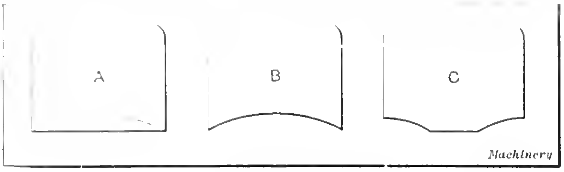

Fig. 1. Shell A to be clipped along Dotted Line and Two Views of Clipped Shell

The clipping punches *E* are mounted on two dovetailed slides in the die-bed. This construction will be readily understood by referring to the cross-sectional view of the die-bed along the line *X-X*. Allowance is made for any adjustment of the punches that may be necessary on account of grinding by the provision of elongated holes for the screws which secure the punches to the slides. In case any adjustment is made, a shim of sheet steel of the required thickness is placed between the back of the punch and the slide; this gives the punch a bearing on the slide and relieves the screws from the pressure of the cut. The punches are made to conform accurately to the cutting edge of the clipping die, the contour of this cutting edge being clearly shown by the dotted lines in the two views of the die which are shown in Fig. 2. The faces of the clipping punches conform to the circumference of the shell and the points *E* cut a little in advance of the remainder of the punch in order to insure having the shell clipped without leaving a fin or burr of any kind.

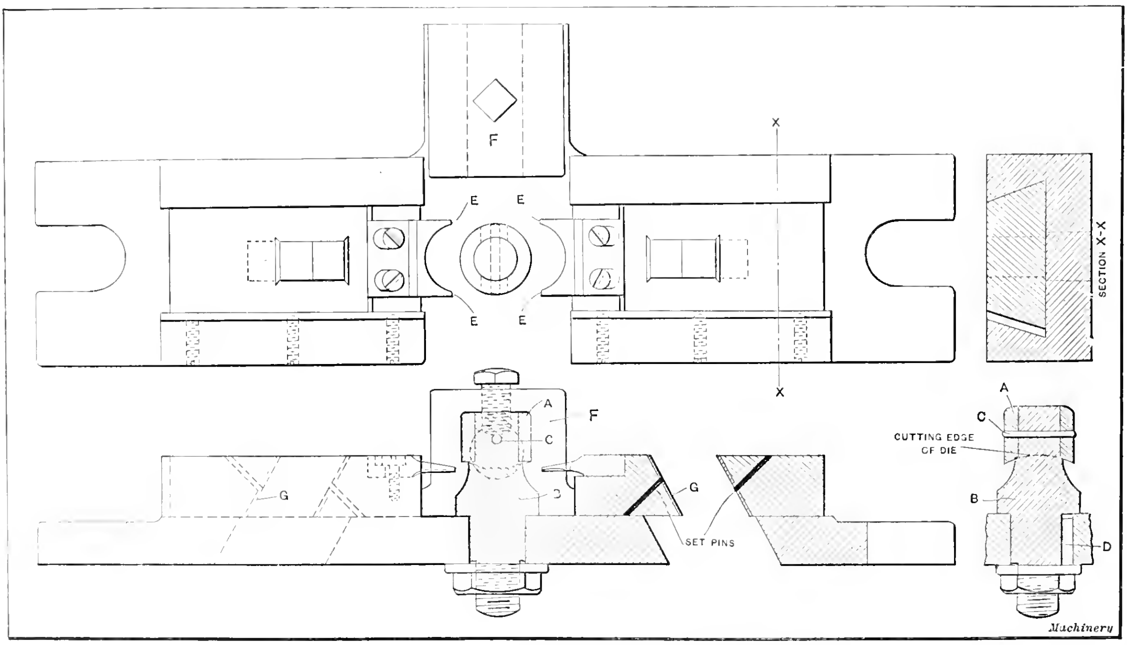

Fig. 2. Die-bed equipped with Tools for clipping Shell shown in Fig. 1

Operation of the Tools and Die-bed

In order to clip a shell with this set of tools, the work is placed over the die and the press is then tripped. The punch shown in Fig. 3 is held in the ram by means of the shank *A*. When the ram descends, the inner surfaces *B* of the arms which are inclined at 30 degrees, come in contact with the steel pads *G*, Fig. 2, in the slides that carry the clipping punches and move them in toward the die. This brings the clipping punches into action and causes the shell to be clipped. When the ram starts its return stroke, the outer surfaces *C* of the arms on the punch cause the slides which carry the clipping punches to be returned to their original positions. It will be obvious that this method of actuating the slides is positive in action and does away with the use of springs for returning the slides. It will be seen that the punch-holder *D*, shown in Fig. 3, has a small piercing punch *E* mounted in it.

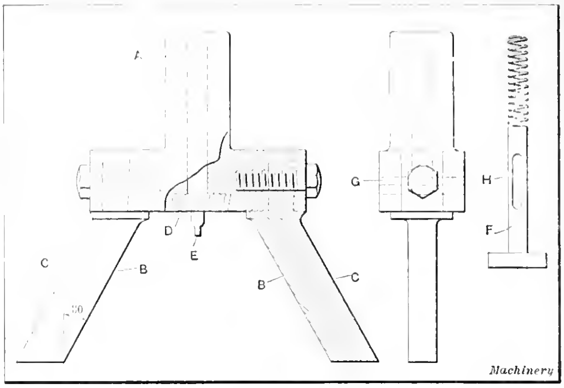

Fig. 3. Punch-holder with 30-degree Angle Arms to control the Movement of the Slides

This piercing punch is used in an operation that will be described in a subsequent paragraph. When the tool is used for the clipping operation, the piercing punch *E* and the punch-holder *D* are removed from the punch and the "hold-down" *F* is mounted in their place. This hold-down is held in place by means of a pin *G* which fits in the slot *H*, the length of the slot being sufficient to allow the hold-down the necessary amount of movement. This hold-down moves a little ahead of the clipping punches and thus comes into contact with the top of the shell and holds it securely in place

so that it cannot be raised off the die when the clipping punches begin to cut.

Construction of the Die-bed

The shells that are clipped or pierced on this die-bed are ordered in lots of not over 25,000. This fact made it desirable to make a die-bed that could be used for both clipping and piercing operations, and this advantage is obtained by the design shown in Fig. 2. This would not be of much advantage, however, if the work had been ordered in large quantities which would require the same set of tools to work day after day in order to get it out. In some cases, it was found desirable to provide special slides for a given set of punches and the clipping punches shown in place on the die-bed in Fig. 2 are an example of this kind. When these punches are removed, the slides are taken off with them and the regular slides can then be put in place on the die-bed in order to allow other tools to be set up. It will be seen that gibs are provided to enable any wear which may develop in the slides to be taken up.

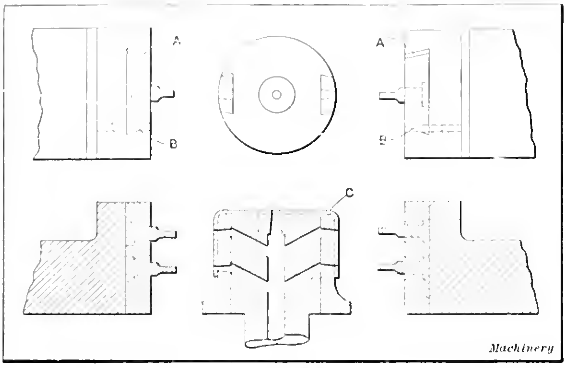

Fig. 4. Die set up for piercing Shell held in Vertical Position

The construction of the die-bed is such that shells can be held in either a horizontal or vertical position. This will be better understood by referring to Figs. 4 and 5 which show shells mounted in the vertical and horizontal positions. The shell *C* which is shown in position on the die in Fig. 4, has five holes pierced in it. Two of these holes are pierced in either side of the shell by means of piercing punches carried in the slides of the die-bed, while the fifth hole is pierced in the top of the shell by means of the piercing punch *E*, which is shown in position in the punch-holder in Fig. 3. The piercing punches for working on the sides of the shell are mounted in regular slides of the die-bed shown in Fig. 2. Referring to the top view in Fig. 4, it will be seen that these punches are mounted in dovetail holders which are held in the desired position by means of keys *A*. The pins *B* locate the punches in their proper positions and are particularly convenient in obtaining the desired alignment when setting up the tools after they have been removed for sharpening.

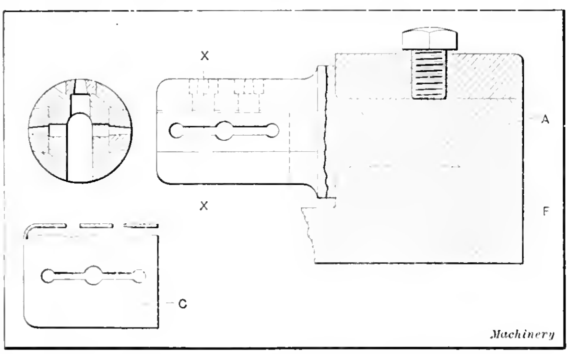

Fig. 5. Die set up for piercing Shell held in Horizontal Position

Fig. 5 not only shows the construction of the piercing die for piercing the shell *C*, shown at the left-hand side of the illustration, but also illustrates the way in which the work is held in a horizontal position in the same die-bed that is used for holding work in a vertical position. Referring again to the illustration Fig. 2, it will be seen that the part *F* at the back of the die-bed has a hole in it to receive the shank *A* of the piercing die-holder which is held in place by means of a set-screw. The shell *C* which is pierced on this die, could be pierced in a vertical position but this would necessitate a three-slide die-bed. Where the present method is used, the slot at either side of the shell is pierced by punches carried in the slides of the die-bed and the two small holes at the top of the shell are pierced by two punches carried in the punch-holder mounted in the ram of the press. In the case of the die used for piercing this shell, and all of the other dies referred to, it will be seen that a space is provided to allow the scrap and dirt to drop out at the bottom of the die.

HE DID NOT BELIEVE IN OIL

BY A. P. PRESS

Our friend Bill blew in the other day. He was the same old Bill that came in a year ago. The cigar with the gold band that he handed out was a little fatter, and it smelt a little more as though it came from Havana; his waist line had increased two inches—otherwise he was the same good fellow that we had always known.

"Well Bill, what are you doing?" was our question after he had settled down in the best chair in the office, pulled up his pants, and got his cigar to going.

"Well boss, I'll tell you. I am 'trouble man' for the Easy Car Co., and I am down this way to straighten out a little trouble. The trouble was so darned mean that I couldn't rest until I told someone about it, and so I came in to see you.

"About three months ago, we sold a big six-cylinder car to a dentist down here. The car was tested out. I took a ride in it myself, and it was shipped down to him in the usual way. The 'toothache man' took the car and paid for it, and wrote us a nice letter about how well pleased he was; then a week later, the trouble started in, and from that day until I came down a week ago, there has been nothing but kicks, complaints and cuss words.

"The 'Super' called me in his office last week, and said, 'Bill, go down there and fix that thing somehow. We don't know what's the matter, and we don't think the dentist does either, so find out.'

"Well, I came down, went over to the garage, and there my friend was waiting for me. I went all over the car, and I got down on my back and went under it; took off the crank-case, then took off one cylinder, and Mr. Press, what do you think? That darned fool—excuse my French—had been running that car for three months without a drop of oil in use anywhere. Transmission, engine, rear axle, in fact, the whole car, had never made the acquaintance of an oil-can. When I crawled out from underneath the car, I was mad clean through. There is no society for the prevention of cruelty to automobiles—if there was, I would like to be both secretary and president.

"When the dentist commenced to lamb it into me, I could not hold in a minute. 'Mr. Dentist,' says I, I said the words just as slowly and softly as I could, so as not to make a break, 'if I could buy you for what you really know about a car and then sell you for what you think you know, it would be the greatest gold brick proposition I know of. A man that would take a car like that, and run it three months without a drop of oil hadn't ought to be allowed to have a car. If you can't afford the oil, you should not have bought the car; and if you can afford the oil and don't know enough to put it in, you should not be allowed to drive a car.'

"What did he say? He turned red and yellow, and at last turned white and said that he supposed the garage man, or the errand boy, or the typewriter had always filled it up. I straightened the matter out. I told him before I started that it would cost $1 for every hour I spent on the car. He paid the bill like a man and gave me a dozen of these cigars, and I think you will agree that they are good ones too. So long." Then Bill went out.

FIXTURE FOR PLANING CLUTCHES IN THE SHAPER

BY C. BOELLA*

We had to manufacture a large number of four-tooth clutches for motor car starting handles. Formerly the teeth of these clutches were machined roughly with a milling cutter and finished by hand, but this method, besides being too expensive, was not giving uniform results. To avoid this defect and increase the production, a special fixture was designed.

This fixture is shown in Fig. 1 applied to a Hendey shaper. It consists of a cast-iron bracket bolted to the table of the

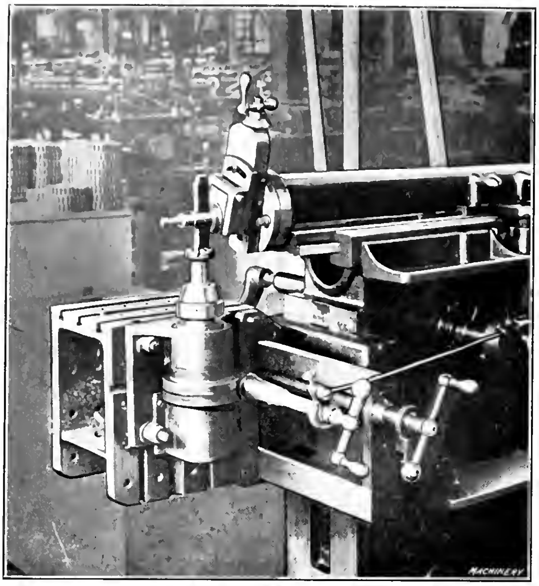

Fig. 1. Shaper equipped with Fixture for generating Helical Clutch Teeth

shaper, which has at its lower end, a hardened four-tooth half-clutch B_1 (Fig. 2) similar in form to the clutch to be made. The other half B of the clutch is also made of hardened steel and is fixed to the end of a spindle which both revolves and moves vertically. On the upper end of the spindle the work is held by means of a split collet. The spindle receives its rotary motion by a revolving sleeve driven by worm and worm-wheel A. The worm is rotated either by the handle shown at the end of the worm shaft in Fig. 1, or automatically by means of a ratchet and pawl which is similar to the device used for feeding the table. This automatic feed derives its motion from the regular feeding mechanism of the machine. A spiral spring keeps the rotating half of clutch B in contact with the lower clutch B_1 which is attached to the bracket.

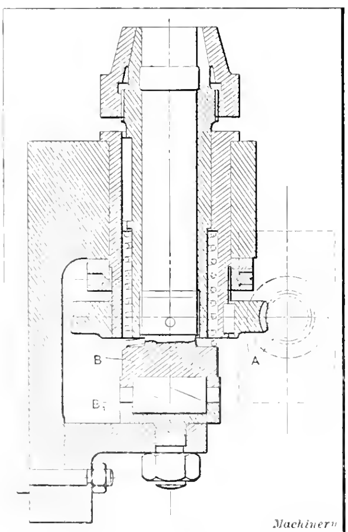

Fig. 2. Vertical Section of Fixture shown in Fig. 1

The fixture operates as follows: When the worm-wheel is revolved by means of the handle, the sleeve rotates driving with it the spindle carrying the work. This spindle, on account of the hardened four-tooth clutch fixed to its lower end, receives besides the rotary motion, an upward movement which lasts for a quarter of a turn; it then drops to its lower position and, as the rotary movement continues, it again rises, and so on for each succeeding quarter turn.

Prior to forming the clutch teeth, the tool-slide is inclined to a suitable angle and four slots are cut at points corresponding to the faces of the teeth and to a depth represented by the lowest position of the arbor carrying the clutch. The slotting tool is then replaced by a forming tool set as illustrated. As previously mentioned, the arbor turns and rises simultaneously for a quarter turn so that the planing tool generates a helical or spiral tooth. When the arbor drops to its initial position, the tool starts forming the second tooth, and so on until the whole clutch is finished. Good results as regards both output and accuracy are obtained with this simple fixture. The clutches are well machined and can be used without further finishing.

* Address: Via Massena, 58, Turin, Italy.

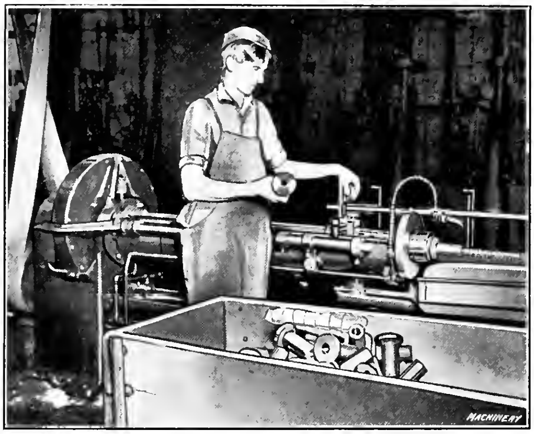
BROACHING VS. REAMING

Broaching, as generally understood, has been considered to be applicable only to the economical production of holes that are not round, such as square, hexagon, etc., but it has been found that round holes can be effectively broached for two reasons. First, the work can be much more quickly accomplished by broaching than by reaming; and second, the hole produced is smoother, free from objectionable "rings," and accurate as to size. An excellent example of the broaching of round holes was secured in Dodge Bros. plant in Detroit, where vanadium steel forgings used in the manufacture of the Ford automobile were being broached in a machine made by



Broaching 1 3/16-inch Round Holes 5½ Inches Long in Vanadium Steel Drop-forgings

the Lapointe Machine Tool Co., Hudson, Mass. The forging, which is 5½ inches long, is first rough-drilled in a high powered vertical drilling machine, from 0.005 to 0.010 inch being left on the diameter of the hole to be removed by the broach. The forgings are brought directly from the drilling machine to the broaching machine and the hole, which is 1 3/16 inch in diameter, is completed in one pass of the broach, a production of 750 being obtained in ten hours.

The fixture used is of very simple construction, consisting simply of a cast-iron ring fastened to the faceplate of the machine, against which the forging is held by the broach as it is drawn through. The spacing or pitch of the teeth in the broach is about equal to the diameter, and a small straight portion about 1¼ inch in length is provided on the end of the broach, which passes through the hole and gives it a burnished appearance. The hole produced by a broach is superior as a bearing surface to that produced by a reamer. This is because when the reamer is working in alloy steel, especially that containing a percentage of nickel, it usually tears rings around the hole, producing a rough surface. The broach, on the other hand, if it produces scratches or tears at all, makes these in a line parallel with the axis of the work, which is less detrimental to a bearing surface than annular grooves.

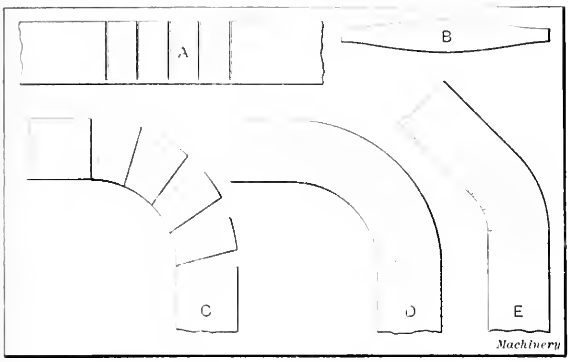
D. T. H.

MAKING BENDS FROM STRAIGHT SHEET METAL PIPES

BY FOREMAN PLATER

In large engineering works and factories, light sheet metal piping is used for various purposes such as ducts from ventilating fans, dust exhausting pipes from grinding and polishing machines and a number of similar uses. Wherever piping is used, right-, obtuse- or acute-angle bends play an important part, and it may be mentioned in this connection that the ordinary stove pipe bend or elbow cannot be used in a system of piping used in connection with a fan. The resistance produced by the sudden change in direction of the air moving at high velocity always has a serious impeding effect upon its movement. In order to reduce resistance as far as possible, right-angle bends should have the radius of curvature at the inside of the bend equal to at least the diameter of the pipe. Right- and obtuse-angle bends in sheet metal piping are generally produced by machinery, and most large firms carry a stock of the different diameters which they use. The machine-made bends are naturally cheaper than hand-made ones. However, in handling small jobs of sheet metal pipe work it is not always advantageous or advisable to use the ready-made bends.

It has often been the writer's experience to be called upon to make ventilating or dust collecting ducts that require bends



Method of making Bends from Sheet Metal Pipes

other than the standard forms which may be bought in the open market. There are several methods of making bends by hand in addition to those for producing them by machinery. The method generally adopted consists of laying out a development of the bend. The different segments are then cut from this development, sufficient allowance being made for joining, and connected by one of the usual methods followed in sheet metal work. These methods are adequately treated in many textbooks on sheet metal pattern drafting. In the majority of engineering work shops, however, such books are not always available when they are needed and many a mechanic has been at a loss to know how to proceed to lay out an accurate pattern for a bend of the radius and angle desired. It is for the use of such men that the present article has been prepared, illustrating a simple method of making sheet metal bends—either single or double and of any radius—from sheet metal pipes, without the necessity of laying out the developments to obtain the patterns.

Bends are more easily made from pipes of thicker gage, as the stouter metal lends itself more readily to bending. Special machines are generally used in marine and locomotive engine shops, but where the number of bends is limited, simple methods are generally employed. In bending pipes, two preliminary steps are necessary, *i. e.*, filling the pipe with lead or rosin to prevent the formation of wrinkles and irregularities, and annealing the pipe at the point where it has to be bent. The lead or rosin is melted out of the pipe after the bending has been completed. Fine sand is sometimes used as a substitute for the rosin, the sand being confined in the pipe by wooden plugs during the bending operation.

Before entering upon a discussion of the production of bends from sheet metal pipe, it may not be out of place to outline briefly the method of producing such pipe. When the diameter of the pipe is known, the circumference is obtained by multiplying the given diameter by 3.1416 or $\frac{22}{7}$, additional allowance being made for the lap. The sheet metal may be most satisfactorily bent between bending rollers, but if such rollers are not available, a round iron bar will answer the purpose. The seam or joint is either soldered or grooved, according to the requirements of individual cases. Where the sheet metal is to be bent by hand, an iron bar is generally used, around which the metal is formed with a box-wood mallet, or an ordinary plumber's dresser can be used with equally good results. The dresser covers a larger area at each blow and is not so likely to make indendations in the work.

A complete right-angle bend is illustrated at *D* in the accompanying illustration. In starting to make a bend of this type, the pipe is marked at the point corresponding to the center of the bend at the side of the pipe that will be at the outside of the bend. Equal distances are then marked on each side of this point so that a total of five marks has been made over the section of pipe to be bent. These marks are drawn almost all the way around the pipe. A hacksaw or chisel is then used to cut along these lines, care being taken not to cut completely through the pipe but to leave small portions to hold it together at the inner side of the bend. The method of procedure will be readily understood by referring to the diagram shown at *A*. The pipe is then bent to the form shown at *C* and the openings are closed up by pieces of sheet metal of the shape shown at *B*. Sufficient allowance is made in the size of these pieces so that they lap over on both sides to allow for soldering them in place. As previously stated, five such pieces will be required in making a right-angle bend. After these pieces have been cut out, they are slightly hollowed or peened by hammering them on a concave wooden block. After this peening operation has been completed, the pieces are bent around the pipe and secured in place, thus forming the complete bend shown at *D*.

Obtuse, acute or reverse bends are made in exactly the same way. An obtuse-angle bend is shown at *E*, where it will be evident that the construction is exactly the same as previously described, except that it was only necessary to make three cuts in the pipe instead of five. In the case of acute-angle bends it will be necessary to make more than five cuts, the number varying according to the bend. Reverse bends are made in the same way except that the cuts for the reverse bend are made on the opposite side of the pipe from those for the first bend. An ordinary mechanic will be able to make very satisfactory bends by this method without having had any extensive experience in sheet metal work.

* * *

LUBRICATION OF AIR COMPRESSOR CYLINDERS

The following information relating to the lubrication of air compressor cylinders is given in a pamphlet issued by the Fidelity & Casualty Co. Recent disastrous explosions in air compressor systems indicate the danger existing from the use of ordinary engine oil in air cylinders. Only a pure mineral oil with a flash point as high as good lubricating qualities will permit, should be used. An excess amount of lubricant should be avoided. As air receivers are liable to explosion from accumulated oil deposits, every receiver should be equipped with a pressure gage, safety valve and proper drains. All reservoirs and pockets in the air line where there might be deposits, should be drained frequently and cleaned. It is bad practice to have the air compressor inlet in a hot or dusty room. The air should be as cool and clean as possible. The practice of throwing kerosene oil into the compressor inlet to clean it is extremely dangerous. Lubrication of the air cylinder with soapsuds (preferably made of one part soft soap to fifteen parts water) for a few hours each week or less frequently if the load is light, will aid materially in keeping the cylinder clean. To prevent rust, discard the soap and feed oil into the cylinder about an hour before shutting down. The receiver blow-off should then be opened and the accumulation of oil and water drained off.

"INVOLUTE" GEARS AND CUTTERS

The report of the American Society of Mechanical Engineers committee on involute gears rendered at the last spring meeting was disappointing, but the fact that the data of tooth shapes produced by the so-called "involute" gear cutters made by the various cutter manufacturers are held a close secret caused an indefinite report by the committee to be almost a foregone conclusion.

The fact that true involute curves are not produced by commercial cutters of the rotary type was not generally known until a very few years ago, and the knowledge is by no means widespread now. Gears cut by true involute cutters of the rotary type, made in sets of eight to cover all numbers of gear teeth from a twelve-tooth pinion to a rack, will not run together satisfactorily. In order to make the rotary cutter a commercial proposition it was necessary to limit the number of cutters required for a given pitch, but to do this, theoretical considerations had to be sacrificed in order to secure satisfactory interchangeability. Hence, the involute cutter is involute in name only. The real tooth shapes are empirical and were reached by experimentation.

The data of "standard" cutter shapes comprising the radii of the curves, positions of centers, points of intersection, and so forth, have been offered to MACHINERY for publication twice within a few years, but could not be accepted because they were submitted without authority. The contributors were not authorized to publish the matter by the concerns that had developed the shapes at heavy cost. But this scrupulous policy of MACHINERY has not been a bar to the dissemination of the data. Probably none of the rotary gear cutter makers need make their cutters by copying B. & S. cutters if they have been willing to "pay the price."

The situation is unfortunate in several respects. A premium has been placed on the dishonesty of trusted employes, the mechanical public has been misled and true interchangeability of gears cut with the cutters made by different manufacturers has not been realized. We believe that mechanical progress would have been fostered if the policy of secrecy as to the exact shapes produced had not been so rigidly adhered to. The correctness of the theory of involute gearing has been seriously questioned by mechanical men because of a misunderstanding of the situation. That the theory is correct, however, has been proved by the success of the generated involute teeth on spur, spiral and bevel gears.

In the interests of mechanical progress we suggest that the well-known "involute" gear cutter makers publish the data of tooth shapes used and thus bring about an agreement which will make for true interchangeability of milled tooth gearing and eliminate a mystery that is hardly creditable to American manufacturing policy.

RECORD OF PRESSED FITS

The paper presented before the American Society of Mechanical Engineers contributing the record of over two hundred pressed fits is of interest and value to machinists. No feature of machine shop practice, within narrow limits, of course, has been attended with more uncertainty than the over-size allowances to be made on shafts and crank-pins assembled with hubs by pressure. The length and thickness of the hub and the material affect the over-size allowance to be made. Many mechanics who never saw a micrometer were able to make pressed fits with no guide but "judgment" which, of course, was the result of experience, but most of them made excessive allowances compared with those recorded by Mr. MacGill. The result was often overstrained hubs that cracked in service.

Little is gained in tightness of fit by exceeding the elastic limit of the solid metal composing the hub, and serious damage will result if the overstrain is carried far. Rough turning and boring, however, permit of considerable apparent variation in practice. The ridges of metal on the parts are crushed in pressing together, and in crushing require much more pressure to assemble than to press apart. This is the test. The pressed fit which shows the least difference between the pressure required to assemble and to force apart, other things being equal, is the best.

* * *

"SAFETY ALWAYS"

The National Tube Co. is distributing a safety calendar which should serve a useful purpose in promoting the principles of safety in the operation of shops, mills, factories and in the ordinary affairs of life. No one needs to be told of the importance now attached to safety considerations nor how rapid the growth of the sentiment has been. Every general manager, superintendent and other responsible officer of concerns in states where compensation laws have been enacted is familiar with the new aspect of the safety movement and should feel that he is now his brother's keeper. The calendar mentioned bears twelve mottos of special application in steel mills, and of general application in manufacturing plants. Following are examples:

> Every danger sign posted in the mill means that the danger pointed out is real. Men must ascertain what is on these signs around places where they work and give heed to the warnings. The red ball on a sign means danger.
>
> It is better to be careful a thousand times than to be injured once. Get the safety habit. If you see a man acting carelessly tell him about it, and don't be afraid of hurting his feelings by doing so.
>
> Neglect of slight injuries often results in blood poisoning and serious trouble. The company has provided an emergency hospital, where employes injured in the mill can receive the best of attention. Don't neglect small injuries.
>
> Your eyes are valuable to you. Wear goggles when working where chips or sparks may fly. They may be awkward at first, but you will soon get used to them and then you wouldn't work without them.
>
> A dirty mill means accidents. Do not leave waste material or refuse lying around. Places are provided for keeping it. Do your part toward keeping the mill clean.

The mottos "Safety Always" and "Safety First" have become industrial slogans which must have some influence on the methods of older men and much on those of the younger ones. In the course of twenty years there will be an entirely changed attitude on the part of workmen generally in regard to accidents and accident prevention. A preventable accident will then be looked upon as little less than a crime on the part of the one responsible, and the intelligent employers of labor will have contributed greatly to the spread of the idea by enforcing rules for safe conduct of their employes similar to the foregoing.

WORK-HOLDING DEVICES AND TOOLS

The articles by Albert A. Dowd now running on work-holding devices, tools and tool-guides, for lathes and boring mills are unusual if not unique. So far as we know, nothing comparable with them has been published before. The importance of the subject is indicated by the large number and variety of means provided for holding work and performing circular machining processes.

The first and principal accessories for holding work for turning were, and still are, pointed centers. These and a driver constitute a perfect means for holding parts for cylindrical or taper turning or grinding. But they can be applied only when the work is of a shape that permits it to be mounted securely on conical points fitting into it. A narrow, thin ring cannot be held thus, and the primitive means provided was either a mandrel or a faceplate. The mandrel has its limitations as has also the faceplate. The latter fitted with bolts, clamps, straps and finally with movable jaws actuated by screws, became a chuck.

The lathe center, mandrel, faceplate or chuck appear in some shape or other in all forms of work-holders; but the variety of designs possible and necessary for efficient mounting and driving work in modern manufacturing plants is almost endless. To work out efficient designs independently requires wide experience and good judgment on the part of the tool designer.

It is not too much to say that no factor of production is more important than the mandrels and chucks provided for machines. The best machine tool must be inefficient if not provided with these in the variety and form required for the work to be done on it. Although so important, they have been neglected in many plants that outwardly present the appearance of being well equipped. A machine is only the mechanism for applying power to a tool for cutting or shaping. It is useless unless the tool and the holders for the work are provided. Thus three elements are necessary—the machine, the cutting or shaping tool and the work-holding device.

* * *

NEW MACHINERY AND TOOLS

Every period of business depression is marked by activity in the development of improved means of production. The reasons are not far to seek. First, there is an insistent demand for machines, tools and methods which will produce more cheaply. Manufacturers strive harder in dull times to produce goods at lower prices than when the demand for their products is heavy. Second, the builders of machinery have more time to improve their products and they take the opportunity to simplify and improve methods of production and to introduce new practices that cannot be given the necessary attention when the shop is running at top notch production.

The January number of MACHINERY contained twenty-eight pages of descriptions of thirty-two improved products in the machine shop and closely related fields. This showing is gratifying. It not only indicates that American machine tool builders possess great enterprise, but that they fully appreciate the advantages of showing their new products in a journal that maintains a liberal policy in regard to the publication of matters of news to the mechanical world. That this liberal policy means much to American machine tool manufacturers is becoming generally appreciated. In no case is exclusive publication required or even suggested. On the other hand, the editorial policy has always been to encourage simultaneous publication in all the mechanical journals. The new developments made by manufacturers in a given field are matters of news interest to the readers of the journals in that field. Manufacturers who support the technical press by their advertising patronage merit this recognition of new developments which they bring forth from time to time. The policy of exclusive publication of new developments in one journal only is selfish and even dangerous to the welfare of the industry both as regards readers and advertisers. It gives that journal a false standing and would permit monopoly in technical journalism to be established if carried to its logical conclusion.

FILING YOUR OWN PATENT*

BY FORD W. HARRIS†

It is an economical man who tries to cut his own hair, but it is probable that any of us marooned on a desert island and given a pair of shears would take an occasional "whack" at it. Similarly, an inventor ought not to be his own patent lawyer, but there are occasions, when stern necessity drives, on which any inventor is justified in trying it. This condition is often due to the fact that the inventor is unable to find the $65 demanded by a reputable attorney for securing a patent but can find the $15 fee charged by the government.

Before outlining just how an inventor goes about prosecuting his own case, it might be well to say a word or two about patent attorneys. It is a notorious fact that there are a great many incompetent patent lawyers. It is also a well-known fact that the average patent is valueless. The two conditions go together, being cause and effect. Some patents—in fact, most patents—are valueless because there is no real invention behind them. They are mere adaptations or improvements upon which no patent should have been allowed. The line between mechanical skill and invention is so indefinite, however, that our patent office has no choice but to grant a patent upon an application that discloses a novel structure or results and which can by any stretch of the imagination be considered an invention. Such a patent, however, has generally very limited claims and is of little value to anyone. The "shyster" lawyer is generally responsible for the existence of such a patent, as he has led the inventor to think he has a meritorious invention when he is morally certain that the invention is valueless. It is probable that some legislation looking to a tightening of the lines and excluding such trivial patents would drive many of the poorer patent lawyers out of business and save the inventors of the country a great deal of expense and many a disappointment. It is also probable that anything that would decrease the number and increase the professional honesty of patent lawyers as a class would have the same effect. Both of these reforms are urgently needed and no doubt will come.

Many patents are valueless, not because the inventor did not have a meritorious invention, but because he allowed a poor lawyer to give away his rights. There is nothing more pathetic than a good invention poorly protected. The inventor has disclosed his invention to the public, he has fully explained and illustrated it as required by law, and he has obtained in exchange a claim or collection of claims which is easily avoided or which will be declared invalid by the first court called upon to pass on it. This is almost always due to the laziness or incompetence of the attorney who handled the case. The patent office is generally fair, but it will not give an inventor any more than he asks for, and if his attorney is satisfied with poor claims, that is what he will get. It is, of course, sometimes possible to surrender such a poor patent and take a re-issue that adequately protects the invention; but the proceeding is difficult, involves additional expense, and must be done promptly. It is probable that raising the standard among the patent office examiners and the cultivation of a fairer viewpoint among them might assist in this matter, but the real remedy is fewer and better attorneys. Our patent system is the foundation upon which a great deal of our industrial prosperity rests, and the American people should make an earnest effort to correct the manifest abuses and graft that have sprung up in the patent soliciting business.

Any man having a real invention should exercise great care in committing it to the tender mercies of the average patent lawyer. The good lawyers are not hard to find. They generally have built up a reputation over a long period of years and are known to prominent attorneys, bankers and business men. Only such men should be employed on real inventions, and they charge little if any more than the

† Address: 1029 Higgins Bldg., Los Angeles, Cal.

shysters. It often happens, however, that an inventor does not have the money to employ such a man and must abandon his invention or make a start at prosecuting it himself. Or it may happen that he has some experience in patent cases and does not value his invention highly enough to warrant employing an attorney. He can deal directly with the patent office, and though the old saying that "the man who doctors himself has a fool for a patient" is somewhat applicable, nevertheless it is probable that the average mechanic or business man could prosecute a case before the patent office with as good or better results than the shyster lawyer. In any case the following hints can do no inventor any harm, even if he has a lawyer.

In the first place, it should be recognized that the United States Patent Office gives an inventor a lot of latitude. It will send him, free of charge, a copy of the Rules of Practice governing the general conduct of its business and the inventor's relations to it. This book looks formidable, but really only the first twenty-eight pages and some of the forms interest an inventor on an ordinary application. If you cannot prosecute an application on this information you will find that the difficulties you meet with are unusual ones. In addition, every library has Walker, Robinson or Hopkins on Patents, and a few evenings spent in reading the opening chapters will give you an insight into patent theory that is well worth while.

Having mastered the general theory you can prepare your application. The first thing is the drawings. The Rules of Practice are very specific as to size, etc., and should be followed closely. Here again, the general spirit of fairness to an inventor is shown. The patent office will accept for examination any sort of a drawing that is plain, and will examine and act upon any application that contains such a drawing. Before the patent issues and is printed, however, drawings of the style specified in the Rules of Practice must be furnished by the inventor or he must pay the patent office for making them. But he can prosecute his patent to final allowance or rejection on drawings that are decidedly not in accordance with the rules.

Having made the drawings, the inventor must write his specification. A sample drawing faces page 68 of the Rules of Practice and the specification for it is given on pages 70, 71 and 72. Pages 12, 13 and 14 explain this specification and the general structure thereof, and it is not hard to prepare a reasonably good one. The petition and oath are given as Form 1 to 10 and Forms 18 and 19; they are plain and can be copied and filled in directly from the Rules of Practice. The inventor should be careful to fully show and clearly describe his invention, as new matter can not ordinarily be added to either the body of the specification or the drawing after it is once filed.

The specification ordinarily ends with one or more claims which to the ordinary mortal look like a mere jumble of words. They are a general, concise and exact description of the invention. In all the books on patents and patent law, there has been very little written about the form of claims that will assist an ordinary man in writing them. They are the patent, and it is in writing and changing them to make them allowable that the attorney earns his fee. Years ago, when the writer was an inventor and had never attempted to handle cases, he conceived a great awe for claims. They appeared to be wonderful examples of verbal gymnastics. After having prosecuted many cases for himself and others, the conviction grows upon him that they are mostly a trick. They are simply fundamental ideas wrapped up in verbiage. Some men apparently never learn to write them, others take to it naturally. The best advice I can give a prospective prosecutor is to go to the nearest public library and get a late copy of the Official Gazette of the United States Patent Office. Look through the single views and appended claims therein and pick out five or six patents that have a number of claims that you can understand. Preferably, pick those that are very short, for the fewer the words the better the claim. Send five cents in coin or money order for each patent to the Commissioner of Patents, Washington, specifying the number, date and name of the inventor of each, and you will get a complete copy of the drawings, specification and claims. Study the form and the way the claims are expressed.

If you have read Walker carefully you will know that you cannot claim a mode of operation, but only the means by which the mode of operation is carried out. You cannot use as an element in your claim "a shaft moving up and down," but you may say "a shaft, means for moving said shaft up and down," etc. Writing claims is a trick and the main thing to remember is that the more different things a claim may be imagined as describing the better it is. Avoid being definite. Say "means for fastening said pulley to said shaft," instead of saying "a tapered key." One way you may limit yourself to a simple tapered key and the other way you cover any means that may be used to fasten the parts together; for example, a set-screw or a tapered pin. Believe one who has tried it with good success that claims are not as hard to write as they look. The main thing is to claim enough. Ask broadly for everything in sight and say it as many ways as you can. A dozen claims are not too many.

Now wrap up your drawings, petition, oath, specification, claims and filing fee of $15 and send it to the Commissioner of Patents. Take your drawings to a blueprinter and get copies or the patent office will make them for you for 15 cents each. Then sit down and wait for from one to nine months for the patent office to act. The examiner may reject all your claims; he may object to your drawings as informal and tell you that before the patent is printed you must have others made; but he must give you reasons and he will tell you how to fix them. And when he does act, you have one year in which to answer him. And if you materially amend your claims by a letter to him you have another year after he answers you to answer him. And so long as you put in broad claims and stand by them, your rights cannot suffer. Patents may be kept pending for years in this way. The patent office is full of them. You have a year to answer the examiner every time and so long as you keep claiming the earth you cannot lose. But before you let the patent issue and as soon as you possibly can, get a good lawyer in on your patent and let him fix it up for you. Just consider how your hair would look if you cut it yourself and how you would miss an ear if your shears slipped.

* * *

Native copper is found extensively in the Lake Superior region, and with the exception of a few mines that produce arsenical copper, the "lake copper" is of remarkable purity. It is seldom found on the market at the present time, as most of it is contracted for by the makers of wire, sheet copper, etc. Most of the copper production of the United States does not come from "native copper" but from the ores of Montana and Arizona, which consist of copper and sulphur, or copper, iron and sulphur. These ores are usually roasted to remove a portion of the sulphur, arsenic and other volatile impurities. They are then smelted with coke in a vertical furnace, producing a matte or compound of sulphur, copper, and iron that may contain thirty per cent copper. This matte may be given a higher copper content in various ways, or it may be run into a Bessemer converter, the iron and sulphur burned off and the resulting coarse or crude copper, which may be 99 per cent pure, cast into anode plates and electrolytically refined. The resulting electrolytic copper is often superior in purity to lake copper. The less pure grades of electrolytic copper are known as "casting copper" and are sold for making brass castings and for uses where a high conductivity is not required.—*Mechanical World.*

* * *

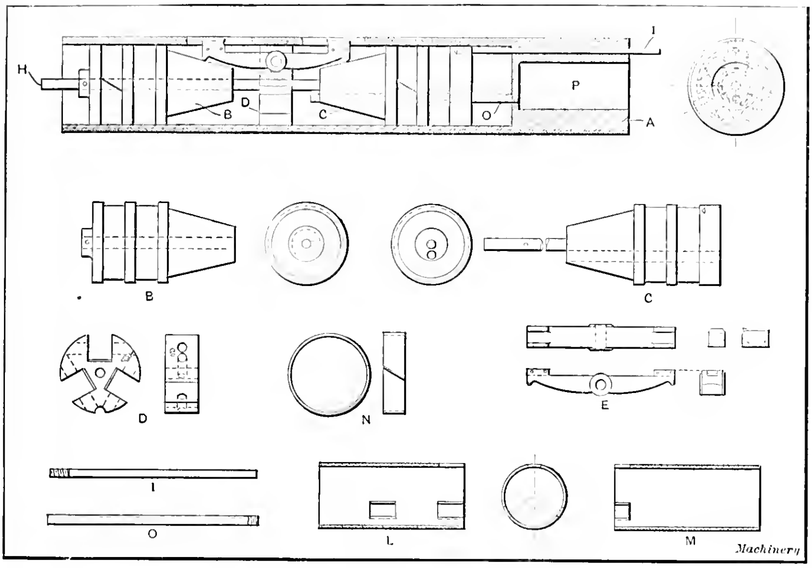
Machine tool builders suffer in some cases from the effects of jealousy or false pride which prevents them using the machine tools of competitors for work on which they are manifestly superior. If a special design of machine will do a certain class of work better and cheaper than the ordinary standard machine tools, the manufacturer—whatever his product may be—should be of a sufficiently liberal mind to adopt and use it in his shop. Of course, there may be honest disbelief in the value of a given machine for its express purpose, but in nine cases out of ten the disbelief is simply prejudice that will not be overcome.

RIFLING HEAD FOR RIFLING RECOIL VALVES AND GUNS

BY RUDOLPH R. GUENTHER*

The improved form of rifling head illustrated herewith has been used very successfully by a large eastern corporation for rifling recoil valves and guns. The outside diameter of the rifling head is about 0.002 or 0.003 inch less than the finished bore of the gun barrel, or recoil valve, and, as it is fed through the finished bore, three spiral grooves are cut, the finished depth of the grooves being 0.189 inch. The rifling head is connected at *P* to the bar of the rifling machine, and it is held in place by a steel pin. The machine used for this class of work is especially designed for the purpose, and measures about 60 feet in length. The bar to which the rifling head is attached has a travel of about 20 feet and is operated by means of a long worm screw which runs in a tail-head to which the rifling bar is attached.

The gun barrel or recoil valve to be rifled is held by means of a headstock and tailstock, which are geared so as to revolve the work at the proper ratio in order to generate the helical rifling grooves. The rifling head is equipped with a double set of tools, so that it cuts both the forward and return strokes. At each end of the machine there is a feeding mechanism which automatically withdraws the three cutters which have just completed a stroke, and moves the other set of three cutters outward for the return stroke. Each of these feeding mechanisms is composed of a worm, worm-wheel and ratchet wheel, to which a stop is attached; this stop engages the rifling head and is caused to move outward a certain distance for each stroke of the head, the movement depending upon the depth of the cut to be taken.



Rifling Head for rifling Recoil Valves and Guns

The construction of this rifling head is shown by the assembled and detailed views of the illustration. The casing *A* is made from a solid steel forging in order to secure a true bore and a perfect working fit. On the outside of this steel casing there are two sleeves *L* and *M*. These sleeves are made of bronze and forced on but are also held by small set-screws. Inside the steel casing *A*, two expansion heads *B* and *C* are located. Expansion head *C* has an extension rod which passes through a hole in the head *B* and the latter is attached to it by a small pin, thus locking the two expansion heads together.

The cutters are held in cutter-holders *E* which are pivoted in the center to a pivot bearing *D* which is slotted at three places 120 degrees apart, as shown by the detailed view. This pivot bearing is held in position by set-screws, and the outer ends of the cutter-holders are supported by conical surfaces on the expansion heads. Expansion head *C* has a hole directly under the central rod, which is provided for pipe *O*, through which oil is supplied to the center of the rifling head for washing out the chips at the end of each stroke and for keeping the cutters well lubricated. The oil also flows through a small recess cut in the bottom of pivot bearing *D*, into the space adjacent to head *B*.

Head *C* is provided with a rod *I* which is engaged by the stop of the feeding mechanism previously referred to, when the head is at the right end of its stroke. Similarly, end *H* of the extension rod engages the corresponding stop at the opposite end of the machine. In this way the expansion heads are moved either to the right or left, thus expanding one set of cutters outward and withdrawing the opposite set. Each head is equipped with cast-iron expansion rings *N*, which, by reason of the friction between the ring and casing, cause the rifling head to stay in the position in which it is set by the feed stops at the end of each stroke. The feeding mechanism is designed so as to feed the cutters outward at the beginning of each stroke not more than 0.0035; in other words, successive cuts of 0.0035 are taken until the grooves are machined to within about 0.0045 or 0.005 inch of the finished depth. The mechanism is then adjusted to throw out the cutters only 0.0015 inch, in order to prevent the tools from gouging into the grooves on the finishing cuts.

The rocker arms or cutter holders are made of forged steel and the outer ends beneath the cutters are shaped concave to fit the cones of the expansion heads. These conical ends of the heads were hardened and then ground and polished to insure a true working surface. The bearing ends of the cutter holders were also hardened to insure a perfect working fit and to reduce wear to a minimum. This improved rifling head has made it possible to rifle the bore of a gun barrel or recoil valve in about 56 per cent of the time required with the old-style head. With the latter, which was only equipped with one set of cutters, the time for rifling a recoil valve was about 55 hours, whereas with the improved head the same operation is performed in about 30 hours.

EXPERIMENT WITH FALLING BODIES IN A DEEP MINE SHAFT

The Michigan College of Mines, Houghton, Mich., has made some interesting tests of falling bodies in a deep vertical shaft of a copper mine at Calumet, Mich. Within a radius of a mile from Calumet are three of the deepest shafts in the world, one of them being 5300 feet deep. One of the experiments consisted in dropping a smooth metal ball two inches diameter from the center of the shaft and trying to catch it in a box of clay placed 4200 feet beneath. Another ball was dropped from the southwest corner of the shaft. The balls were dropped by burning the threads by which they were suspended so that they started to fall directly downward. The shaft is nine by thirty feet cross-section. The first of the balls was suspended four feet from the side of the shaft and the second from a point nine feet from the opposite corner. Neither of the balls reached the box of clay; one of them was never found and the other, presumably the one started from the center, was found by a workman lodged in the timbers on the east side of the shaft 800 feet from the surface.

Bodies dropped into the shaft invariably lodge somewhere in the east wall. This action takes place because the earth is rotating on its axis from west to east. At Calumet a particle at the surface is moving to the east at the rate of about 1000 feet a second; but a particle 5000 feet down the shaft,

having the same angular velocity as the particle on the surface, is moving eastward at a rate of four inches less than 1000 feet per second. The ball suspended at the top of the shaft had a thousand-feet-a-second velocity; it was not only moving eastward at that rate when it started to fall but continued moving eastward all the way down the shaft. Meanwhile it dropped to the bottom at a rate which would have taken 17½ seconds for the fall if there had been no air resistance to encounter. During the 17½ seconds, the particle at the surface and the ball falling at the same rate would have traveled 17½ times four inches or nearly six feet further eastward than the particle at the bottom of the shaft. The ball started from the center of the shaft, therefore, struck the east wall long before it reached the bottom. As a matter of fact, the resistance of the air at the high speed the ball acquired soon after starting, was sufficient to prevent any further acceleration and consequently the ball was much longer than 17½ seconds in falling. In fact, only 800 feet of fall was required for the ball to make the four feet from the center of the shaft to the east wall and the other ball must have lodged at some point not much further down.

If the walls of the shaft were smooth and free from obstructions, no doubt a falling body would rebound from side to side of the shaft and finally reach bottom, but the many timbers in the lining of the shaft and the levels all the way down furnish places where a body is sure to lodge, and so if a load of ore were to be spilled into the shaft near the top most of it would later be found clinging to the shaft or stranded on the levels east of the shaft.

ROLLER AND SILENT CHAINS

At a recent meeting of the Society of Automobile Engineers, John R. Cautley presented a paper on roller and silent chains. A few general hints and practical suggestions contained in this paper are given in the following:

Many engineers have a distinct misconception as to all forms of driving chains. No roller or silent chain can be compared directly with belting. A driving chain is a piece of fine and highly accurate mechanism and should be treated as such. It will stand an amazing amount of abuse, but if properly installed and cared for it has an efficiency throughout its life which is hard to equal. Two basic principles in the design of a "standard" roller chain are: first, maximum wearing surface for the minimum of weight consistent with reasonable strength; second, such a proportion between roller diameter and sprocket tooth gap as will allow the maximum of wear on both with proper gearing.

Never use a tightening device on the back of a silent chain. An idler sprocket may be used, but it must start with at least three teeth in engagement. This is owing to the difference in mesh when the chain runs as a rack and when it runs over sprockets. If the chain runs over three wheels for any purpose, adjustment must be provided. Accuracy of chain and sprockets and mounting is just as necessary with both silent and roller chains as with gears, but this is easier to obtain with chains.

Means for adjustment is advisable for both kinds of chain and is often imperative. Suitable dust-proof cases improve the running of chains. Silent chains have drawn the attention of automobile engineers to the advantages of chain drive, but they should not overlook the modern and highly accurate roller chain which has many uses. An odd number of teeth is advisable for the small sprocket. This is not "a hunting tooth" but has the same effect with regard to the chain, as it prevents the same combination of links coming into mesh each time. Avoid an odd number of links where possible, as offset links, no matter how well made, are inherently weak. Small sprockets should be made of steel and should preferably be hardened, though this practice is not universal. For many purposes, sprockets of over forty-two teeth may be made of cast iron. Even with poor installation, chains hold up to their remarkably high initial efficiency until practically worn out.

Friction wears out machinery, and worry—not work—uses up men

MAKING SHRAPNEL CASES ON THE CLEVELAND AUTOMATIC

An unusual example of automatic machine work is that of producing the shrapnel case shown in Fig. 1. This case is made from a bar of 3 1/16-inch chrome-nickel steel stock. The steel has a tensile strength varying from 125,000 to 135,000 pounds per square inch, and is extremely tough. The work

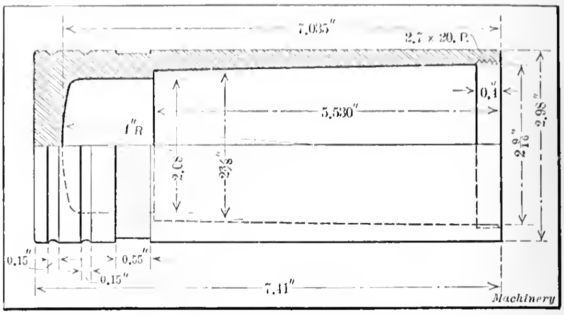

Fig. 1. Shrapnel Case made from Chrome-Nickel Steel having High Tensile Strength on a Cleveland Automatic Screw Machine, made by Cleveland Automatic Machine Company, Cleveland

is accomplished on a 3¼-inch Cleveland automatic, and the tooling equipment, as shown in Figs. 2, 3 and 4, is interesting. While the general operation of the Cleveland automatic is well understood by many mechanics, the production of this piece illustrates a number of points in the operation of this machine which are not so well known. Therefore it is

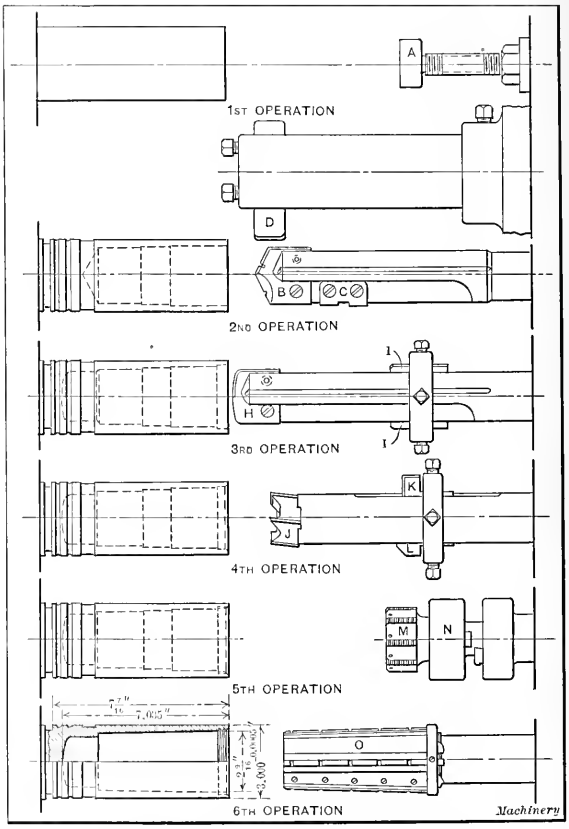

Fig. 2. Order of Operations on the Shrapnel Case

advisable to explain in detail just how this interesting job is handled.

The first operation, as the job was originally laid out, was to feed the stock out to the stop *A*, shown in Fig. 3, which is held on the cross-slide and operated by a lever on the base of the machine. This method, since the photograph shown in Fig. 3 was taken, has been improved upon and the time

cut from twenty-seven and one-half minutes to twenty-five minutes (see Fig. 2 for improved method). The second operation is to rough-drill the large hole with an inserted bit *B*, step the hole for the taper reamer with cutter *C* and rough-turn the external diameter with cutter *D* held in a special turning attachment. This attachment envelops the shanks of all six tools in the turret in order to obtain support. The cutters in the attachment shown in Fig. 3 work in advance of the under-cutting forming tool *E* shown in Fig.

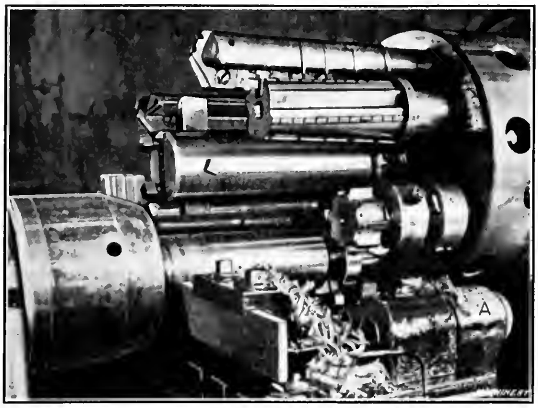

Fig. 3. Cleveland 3¼-inch Automatic Screw Machine set up for making a Shrapnel Case in Twenty-five Minutes

4, which is held on the rear cross-slide. The time required for the completion of the operations outlined is thirteen minutes.

In the third operation drill *H* finishes the powder pocket, and two cutters *I* counterbore for the tap—time required three minutes. The fourth operation consists in finishing the diaphragm seat with the counterbore *J*, finishing the face end with inserted cutter *K* and breaking the corner to facilitate tapping with inserted cutter *L*, the time required being forty-five seconds. In the fifth operation the thread is cut with a tap *M* held in the tap-holder *N* in forty-five seconds. Then the turret is indexed and for the sixth operation the hole is taper-reamed with reamer *O* provided with four inserted "Novo" steel blades, in ninety seconds. The last and seventh operation consists in knurling the band with a knurl *P* (see Fig. 4) mounted on the front cross-slide, and cutting the shell off with a cut-off blade *Q* retained in a holder on the rear cross-slide time six minutes. The total time required to produce this shrapnel case by the improved methods illustrated by the diagram in Fig. 2 is twenty-five minutes.

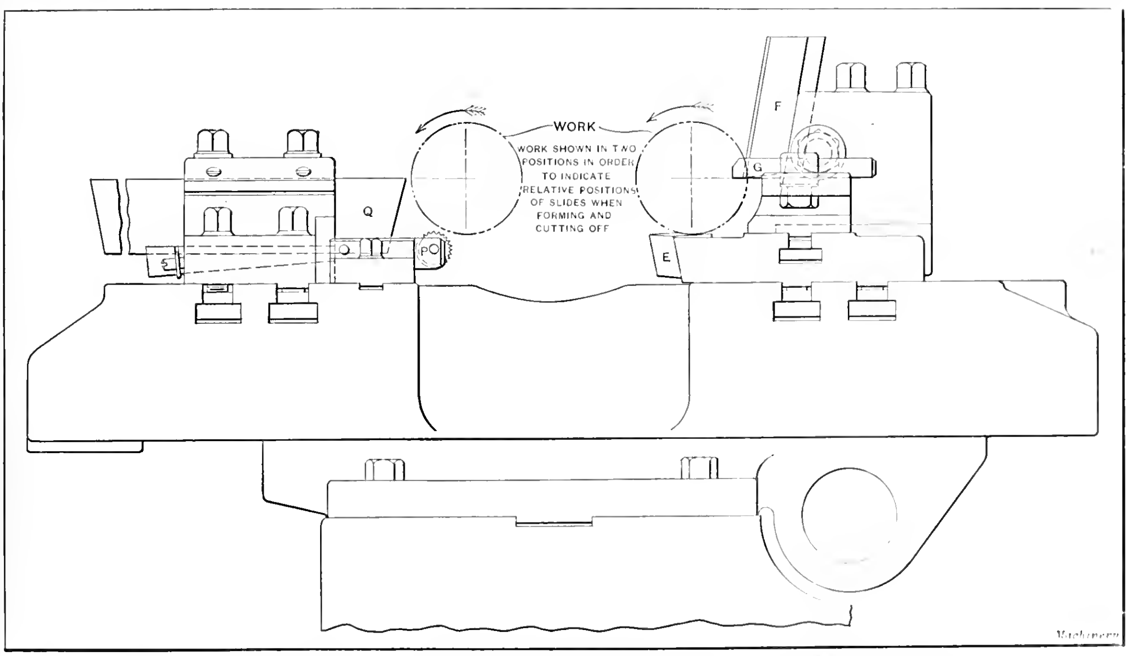

Fig. 4. Showing Tools held on the Front and Rear Cross-slides for performing the Knurling, Forming and Cutting-off Operations on the Shrapnel Case

There are several points of unusual interest in the production of this shrapnel case. One is the large amount of stock to be removed to form the hole; the second is the long taper-reaming operation difficult work to accomplish satisfactorily on an automatic screw machine—and the third is the long outside forming operation which must be held to a limit of 0.0005 inch on the diameter. In order to accomplish this last operation successfully, the external diameter of the piece is first turned with a cutter held in a separate turning attachment, leaving only 0.010 inch on the diameter to be removed by a wide under-cutting or shaving tool *E* held very rigidly on the rear cross-slide. Not only must the case be exact as regards diameter, but it must not vary from one end to the other nor at any point throughout its length. The large shaving tool held rigidly in the manner illustrated in Fig. 4 accomplishes this result satisfactorily.

The material from which the case is made is so tough that some difficulty was met with in selecting a tool steel that would stand up for a reasonable length of time under cut. The drills and counterbores are tipped with "Novo" cutters and all the forming tools, including the cut-off tool, are also made from the same steel. The only cutting tool in the entire tooling equipment not made of this steel is the tap. The bar is rotated at sixty-four revolutions per minute, giving a surface speed for the external cutting tools of approximately fifty-one surface feet per minute. The low cost of production of this shrapnel case is remarkable. Although the material is difficult to work, the labor cost for each piece is only 0.041 cent—almost negligible as compared with the cost when made by hand-operated machine methods. D. T. H.

* * *

The Russian torpedo-destroyer *Novik*, on the official trial run, reached a mean speed of 37 knots and a maximum speed of 37.3 knots. Several days afterward the vessel underwent the continuous six hours trial provided by contract. The speed of 36 knots prescribed for this trial was not only reached, but exceeded considerably, a mean speed of 36.2 knots throughout the six hours, and a mean speed of 36.8 knots during the last three hours being obtained. The *Novik* is a turbine-propelled vessel of 1280 tons displacement, and the boilers are fired with liquid fuel.

LUBRICATING SYSTEMS FOR CUTTING TOOLS—2

METHODS OF DRAWING LUBRICANT—DESIGNS OF DRAINAGE PANS AND TANKS—SEPARATION OF CHIPS AND LUBRICANT

BY JOSEPH G. HORNER*

The cutting tools which require a supply of lubricant through their hollow bodies include drills, reamers, counterbores, boring tools, and, less frequently, taps. Threading dies

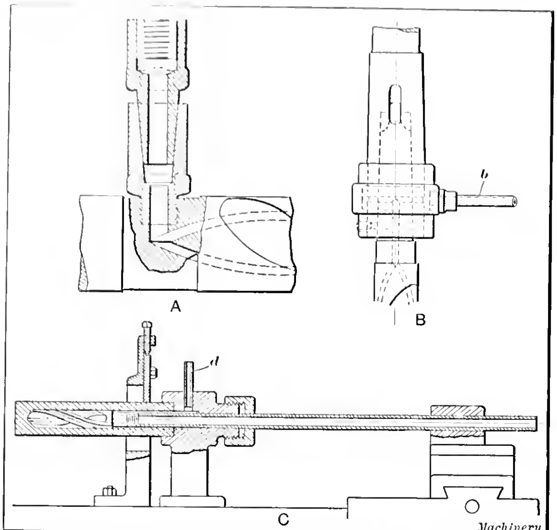

Fig. 11. A, Connection to Oil Passages of Stationary Drill; B, Connection to Oil Passages of Rotating Drill; C, Method of lubricating Hollow Drill for Deep Hole Work

are also fed by a pipe which floods their interior, or the threading machine may have a hollow spindle through which the oil is pumped. Long drills or their separate holders, not held

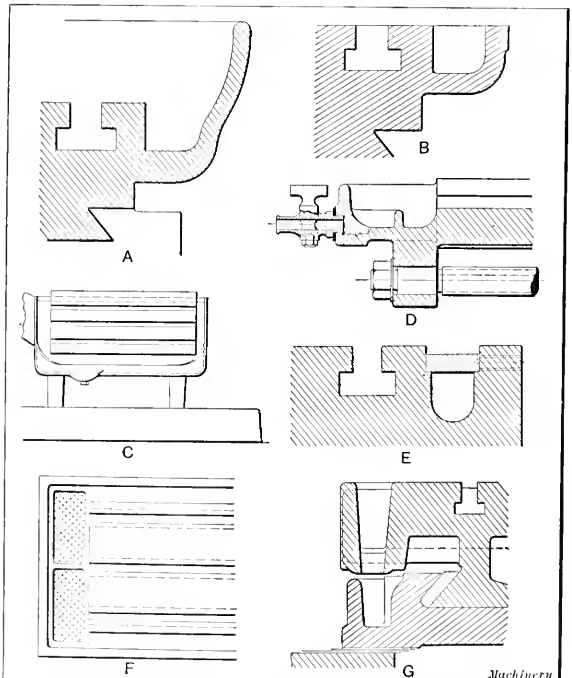

Fig. 12. Various Forms of Drainage Channels for Machine Tables

in a turret, usually have the supply pipe screwed in at the end and the oil goes to the cutting end by way of open grooves or grooves covered with strips soldered over; sometimes holes are drilled in the solid metal to the cutting point, or pipes are laid in recesses along the body of the tool. If the oil is not taken through the end of the drill it may be supplied as shown at *A*, Fig. 11. This method is suitable for any class of drilling machine or turret lathe in which the drill does not rotate. Connection to a flexible tube enables the drill to feed along to any desired extent.

A modification in the form of a loose collar, as at *B*, is necessary to permit a drill to revolve. The collar is held from revolving by the supply pipe *b*. The oil is sometimes fed by gravity but it should preferably be pumped through; it passes to the passages which communicate with the holes or tubes of the drill. A cup-shaped collar is sometimes used, the oil being poured in from the top. In all these tools, the chips find their way out of the hole by the flutes or spaces of the tool, but in the hollow drills used for deep holes, they have a special outlet. The oil is fed by way of the body grooves, and the cuttings escape through the flutes, the hollow shank and an extension tube (see sectional view *C*, Fig. 11). A stuffing-box surrounds the tube and the oil is pumped through pipe *d*, and goes along the outside of the tube and past the shallow flutes on the lands of the drill. The oil then forces the chips

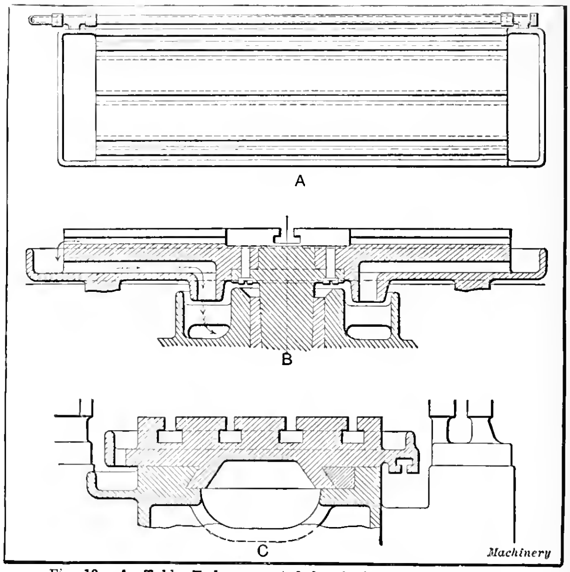

Fig. 13. A, Table Ends connected by Drain Pipe; B, Drainage leading to Annular Channel beneath; C, Drainage Channel for Reciprocating Table

back through the main flutes and out through the shank and the tube. The hole must be first drilled to a depth equal to the body length of the drill, before the latter can be used with

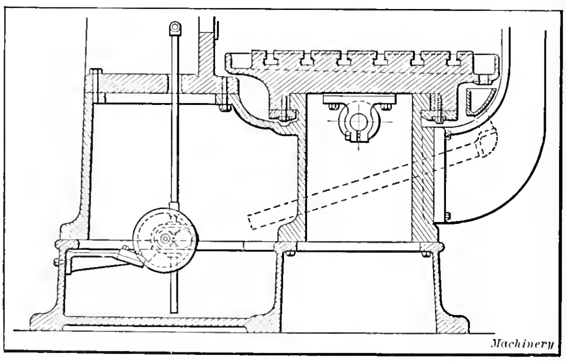

Fig. 14. Drain from Table into Tank in Base of Machine

oil, this preliminary operation being done with a short starting drill.

Methods of Recovering Used Lubricant

The methods of catching, draining and returning the oil are simple on some of the smaller machines, but more compli-

* Address: 45 Sydney Bldgs., Bath, England.

cated on the larger ones, particularly on types which use lubricant very freely. The provision for lubricant often affects the design of the frame and many of the smaller details. The simplest catching device is a can hung underneath a table, this being emptied into the drip-can overhead at intervals. This is quite satisfactory when the quantity of lubricant used is very small, but like the drip-can, it fails to meet requirements when a flow of any magnitude is required, and a proper tank must be employed. The three principal means of receiving waste lubricant are, by a suspended tank, a tank on the floor or bolted to the machine base, or by using the hollow base of the machine to form a tank. The pans which surround the bases of so many machines come under the second category. The suspended tank is objectionable only on account of its limited capacity; the second class can be made of any desired dimensions; the tank in the base is a means of profitably utilizing the interior space, thus making it unnecessary to provide a separate receptacle.

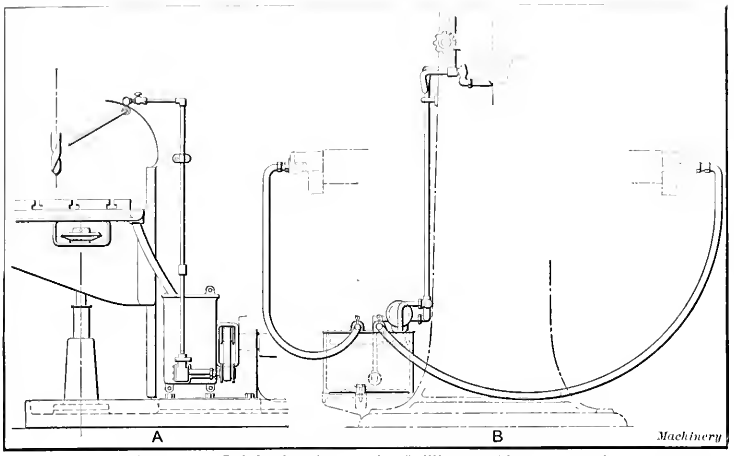

Fig. 15. A, Lubricating System for Drilling Machine; B, Supply and Return System of Vertical Milling Machine

The simplest method of dealing with the question of waste lubricant will be to follow the lubricant in its course, from the point where it leaves the work. It is also necessary to take into consideration the provisions for dealing with chips, since these affect the matter vitally.

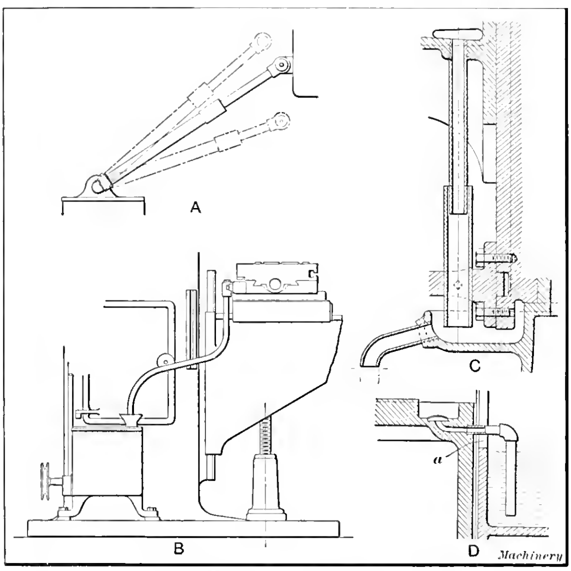

Fig. 16. Drainage Connections to permit Vertical Adjustment of Work Table

All work which is machined is held either on or over a table, or it may project beyond the bed or slide. In the first case, the table receives the waste oil, in the second, the oil either falls directly into a trough or is caught and diverted in various ways. Tables, when not intended for use with oil, simply have slots or tee-slots, and there is no rim or other provision to prevent a lubricant from falling onto the floor. The addition of a turned-up rim prevents the lubricant from escaping, excepting by the way of a spout or a hole, whence it drains into a can hung under the spout or tap, or falls through a rigid or flexible pipe, or by way of rims on subsidiary slides, to a tank below. The height of the rim is limited, in the majority of cases, by the level of the table, the rim being just below the table, but there are some exceptions. When it is known that the size of work or of jigs or fixtures will never exceed the bounds of the tee-slotted surface, then it is possible to raise the rim as shown at *A* in Fig. 12. This high rim is desirable when splashing is likely to occur. It is the practice now, with a great many milling machine manufacturers, to machine the oil rim flush with the table top as at *B*, in order that it may be utilized as a support and form part of the table surface. Large fixtures which hang over the working surface can thus be held, and dividing heads can also be set further apart than on a table with the rim set below. If a table having a vertical face, in addition to the horizontal top face, has to be drained, the oil rim is cast as shown at *C*, which is the table of a radial drill. The channel follows around the table and has a small well at the bottom, into which the waste collects and is drawn off by a tap or pipe.

Draining the Lubricant to the Supply Tank

The end of the table is the place most commonly selected for drawing off the lubricant, because it is more convenient to apply or attach a can, or to connect a pipe. The sectional view *D*, Fig. 12, shows the end of a milling machine table,

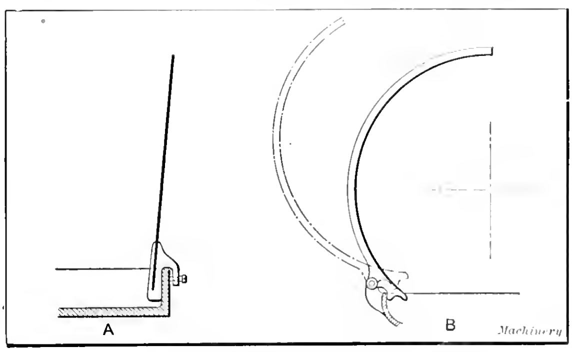

Fig. 17. Detachable and Pivoted Splash Guards or Plates

with a draw-off tap and an enclosure adjacent to the hole to prevent chips from blocking up the tap. Another device to prevent choking, which impedes the proper flow of the lubricant, is to fit guard strips to the channels, as at *E*, so that they cannot be quickly clogged with chips and thus cause table flooding. The filling up of the end pockets with chips is avoided on some tables by the use of removable strainer plates,

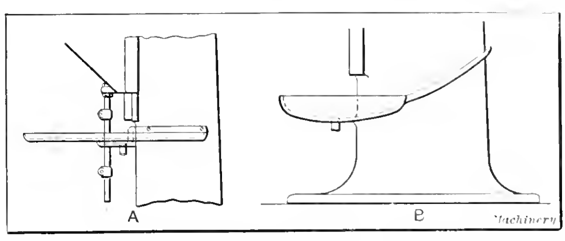

Fig. 18. A, Lubricant Tray attached to Column; B, Lubricant Tray cast integral with Column

as at *F*, which shows a plan view. These plates are set at about one-half the channel depth so that there is a clear space beneath for the liquid. In the milling machines made by

Messrs. D. & J. Tullis Ltd. of Clydebank (Scotland), the end pockets are connected by a pipe (A, Fig. 13), instead of having a deep channel on each side of the tee-slotted surface, comparatively shallow grooves being milled in the top to conduct the waste to the pockets.

When a square or a circular table has to make complete revolutions, the waste is preferably drained through the center into a tank or a hollow bed, the alternative to this being chutes leading to the main tank have to be used. If a table or slide has a limited range of travel in relation to some part below it, the part below can, in certain instances, be utilized as an intermediate drain. The section G, Fig. 12, of a milling machine table and slide, is an illustration. When, as in large plano-miller tables, there is no other moving part, arrangements have to be made to receive the oil at any longitudinal position. This is done by casting or bolting a trough

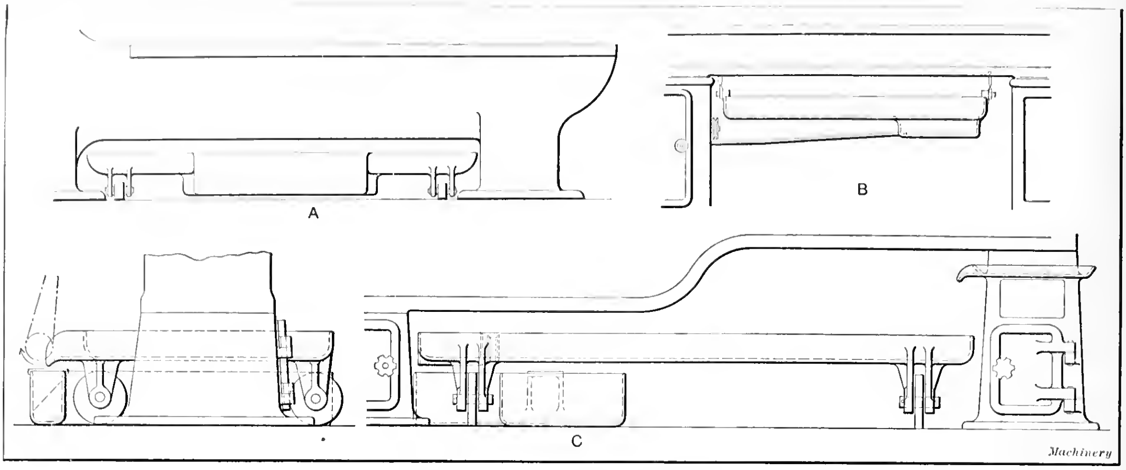

Fig. 19. Different Designs of Drainage Pans

to surround the table with a fixed pan into which the oil drips and is drained therefrom through a channel into a receptacle below. In the central drainage system, the precise course of the oil ducts depends on the manner in which the table is mounted. If there is no central spindle, but merely a hollow boss, the oil can flow down through this, but if a solid spindle occupies the center, the drainage takes place through passages situated some distance out, as at *B*, Fig. 13, to the side of the bed, just below the overhanging drain hole or spout of the table, and locating the drain hole in such a position that it will never run past the lower trough. The oil drains from the latter into a tank or hollow bed. A typical arrangement is shown at *C*, Fig. 13, and also in Fig. 14 (from a Walcott rack cutter), which includes the drain pipe from the trough into the hollow base and the pump and suction pipe.

Flexible tubing is employed very largely for drainage pur-

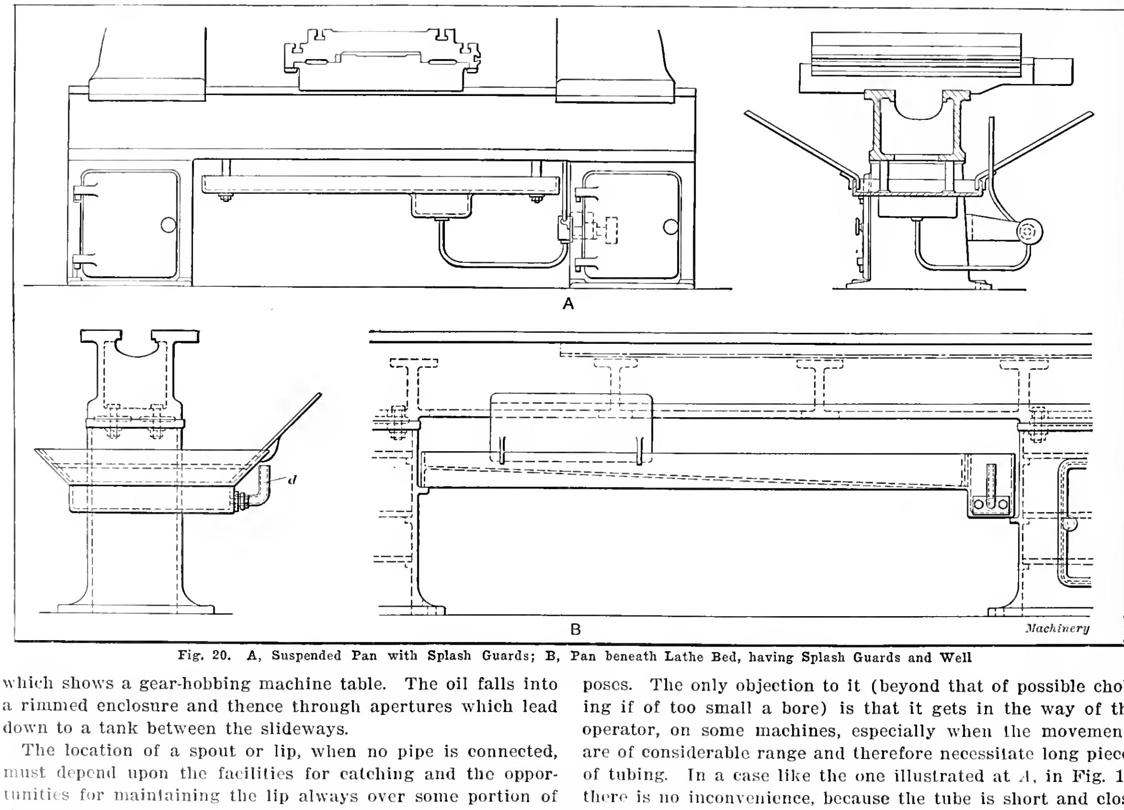

Fig. 20. A, Suspended Pan with Splash Guards; B, Pan beneath Lathe Bed, having Splash Guards and Well

which shows a gear-hobbing machine table. The oil falls into a rimmed enclosure and thence through apertures which lead down to a tank between the slideways.

The location of a spout or lip, when no pipe is connected, must depend upon the facilities for catching and the opportunities for maintaining the lip always over some portion of the pan or other receptacle. Frequently, it is impracticable to insure the latter condition, and then piping, or special poses. The only objection to it (beyond that of possible choking if of too small a bore) is that it gets in the way of the operator, on some machines, especially when the movements are of considerable range and therefore necessitate long pieces of tubing. In a case like the one illustrated at *A*, in Fig. 15, there is no inconvenience, because the tube is short and close to the frame, but at *B*, which shows an Alfred Herbert, Ltd., vertical milling machine the tubes are of necessity

long and somewhat cumbersome. Some of this firm's horizontal machines have a telescopic arrangement of piping extending from the cross-slide on the knee to the tank alongside the frame (as shown at *A*, Fig. 16), which accommodates itself to the vertical and horizontal positions of the slide, and takes the place of a flexible connection. The lower view *B* shows how a flexible drain tube is applied under similar circumstances, this example being from French practice. A slide with vertical movements can be drained by pipes, as represented at *C*. These pipes are telescoping and the lower one conducts the oil to a pan from which an outlet leads to the tank. Section *D* illustrates the drainage into the hollow frame of a drilling machine. There is a slot *a* of sufficient length to permit the pipe to travel up to the limit of the table adjustment.

Guards and Splash-plates

Two other details which are required for many types of machines are the guards and splash-plates which prevent the oil from flying beyond the limits of the machine or drainage pan. These devices are necessary chiefly for work rotating rapidly and comprise curved plates or castings around chucks

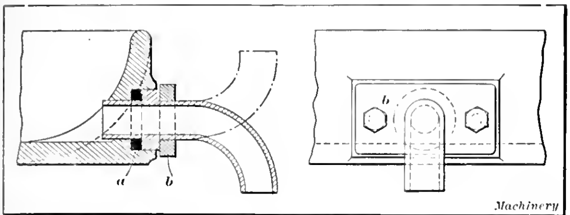

Fig. 21. Combined Drainage Pipe and Tap

and parts of spindles as well as around rotating work, and flat or curved plates held opposite the spindles or work, at some distance, so as to deflect the waste down into the pan. Sometimes drills are also encircled by sheet guards to catch the oil thrown off by the curling chips. All these types of guards are usually removable to facilitate the work of the operator, and are either clipped to convenient places or hinged to swing back. A clip for holding a flat guard is shown at *A*,

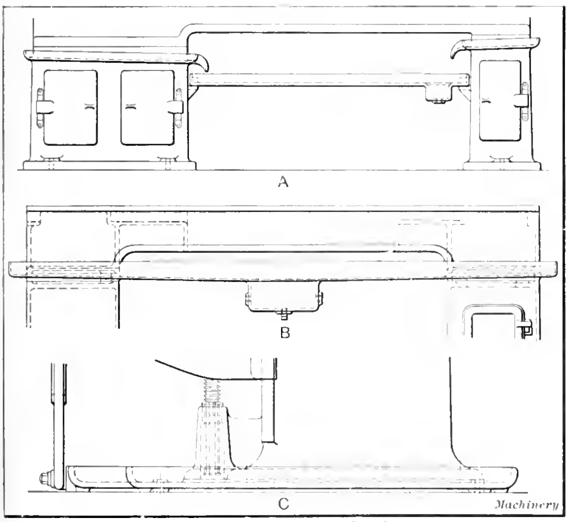

Fig. 22. Other Drainage Pan Developments

Fig. 17. This is also a convenient device for holding curved pieces to fit around the angles of a pan or base, instead of riveting the clips permanently to the splash-plate. At *B* is represented a hinged guard for protecting the whole of an automatic screw machine head, two of these being used. They can be swung down below the pan for inspecting the head. Hinged guards are also fitted around the tables of boring and turning mills, when lubricant must be used and the speed of rotation is rather high.

Drainage Pans for Cutting Lubricant

The nature and capacity of the drainage channels and drip-pans on any machine, depend both on the quantity of lubricant which is likely to be employed and the course which it takes after leaving the tools and work. Lubricant which does not escape from the bounds of a table and is caught immediately by a pipe, or other means, does not, of course, require channels or pans for collecting it; but if there is extensive splashing, catching-lips, trays, or regular pans become essential, until, in the final development, the whole machine stands in a large pan having deep sides. With a minimum of splash-

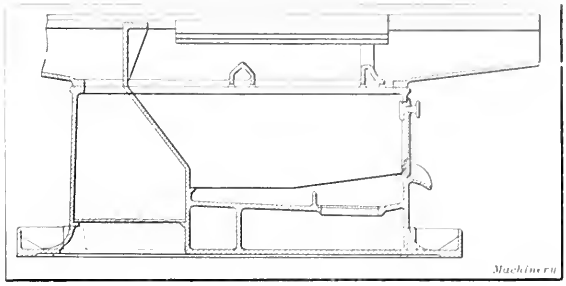

Fig. 23. Hollow Base of Turret Lathe used for receiving Chips and Lubricant—Tool Cupboard at Left

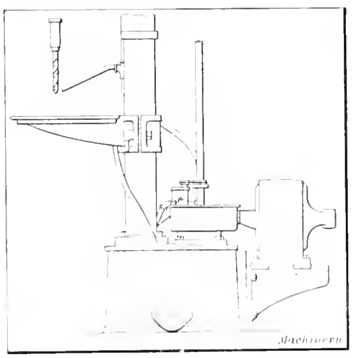
ing or dripping, which causes a small amount of oil or suds to trickle down the frame of a machine, a simple tray screwed on (as at *A*, Fig. 18) is sufficient, or the column may be completely encircled with a channel, as at *B*, the depth being increased at the front to hold a moderate quantity of oil.

A portable pan is often attached to a portion of a machine beneath the area of operation to receive the chips and lubricant, the latter draining through a pipe and away. Portable



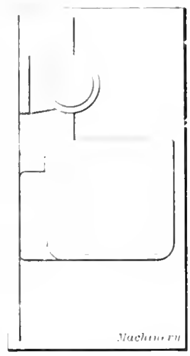


Fig. 24. Base of Drilling Machine used for Lubricant Tank
Fig. 25. Tank suspended on Lugs to permit Easy Removal for Cleaning

trays are also used on some boring and milling machines; these are placed under particular locations where lubricant drips down, and a flexible pipe connects the tray to the tank. A few examples of different arrangements of pans are given in succeeding illustrations. The detail *A*, Fig. 19, shows a portable pan with a well combined; illustration *C* shows another portable pan which has a separate tank that is fixed

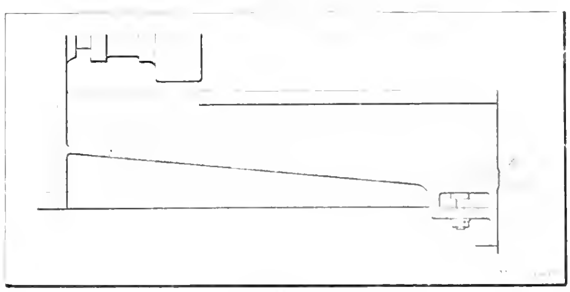

Fig. 26. Threading Machine with Tank Bed

and carries the pump. The portable pan has a lip, as shown in the end view, to drain into the tank beneath. The right-hand cabinet leg has a channel surrounding it which drains into the portable pan. For dealing with large quantities of chips, the pan on wheels is preferable to the fixed pan from which the chips have to be removed and transferred to some

other receptacle for disposal. At *B*, Fig. 19, is shown a fixed pan that is suspended beneath the machine. This practice is common in Germany because it enables pans to be added only when required, leaving the machine otherwise suitable for op-

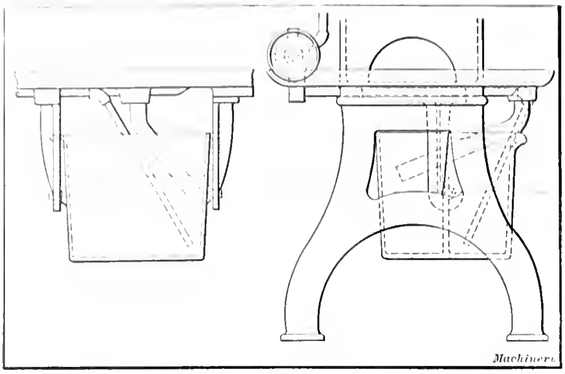

Fig. 27. Lubricant Tank suspended on Hooks for Tilting

eration without cutting lubricant. Another suspended pan (on a Greenwood & Batley special milling machine) is shown at *A*, in Fig. 20. This pan is hung on four bolts and has plates to catch the drip from the overhanging table. A pan with splash-plate attached is shown at *B*. This pan is supported on lugs cast on the cabinet legs and has a well and drainage

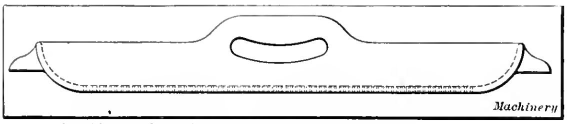

Fig. 28. Perforated Tray for separating Chips from Lubricant

pipe *d*. The method of fitting a pipe of this kind is shown in Fig. 21. It has a packing ring *a* which is clamped by the shoulder of the bent pipe; the latter is held in by the gland plate *b*. In the position indicated, the pipe drains off the contents of the pan, but when turned vertically, as shown by the dotted lines, it retains the lubricant in the pan, forming a simple tap or drainage cock.

A further development is shown at *A*, Fig. 22, the drainage system including channels around each leg, so that no oil can escape, excepting into the pan; in a more complete system, the whole bed stands in a pan interposed between it and the legs, as at *B*. This is common practice with some classes of small milling and other machines which rest upon a floor stand, and with the smaller automatic screw machines. The larger ones either have a turned-up foot all around the base, or the whole machine stands in a large tray which is partly filled with lubricant, the depth of the tray ranging from a few inches to a foot or more. Milling machines standing in a separate tray, as at *C*, do not require such a large oil capacity as "automatics," especially of the multi-spindle type. The latter often have a hollow cabinet leg which contains an extra oil supply. Supplementary sloping chutes overhang the edges of the trays of some automatics to receive drippings from projecting turret slides and spindle ends.

The practice of receiving all the chips and lubricant entirely within the bed is noticeable in the Pittler (German) turret lathes (Fig. 23). The interior has a plate and grid to catch and drain the chips and there is a door at the end for their removal. The vessel to contain the chips is placed under the drainage lip by the door. The remaining portion of the machine frame, to the left, forms a tool cupboard. This utilization of the interior of the machine base to hold the oil, in order to avoid the provision of an outside tank, is a practice becoming increasingly popular. The bases of drilling machines (see Fig. 24), milling machines, gear-cutters, etc., often form excellent tanks for the reception of cutting lubricant. The chief objection with some designs is the difficulty of cleaning the tank. If the chips cannot enter the hollow body, this objection is negligible, but if they are free to fall in with the oil (as in Fig. 26), the chips become a nuisance. For this reason, special facilities are afforded for cleaning the tanks from which pumps draw their supply, in

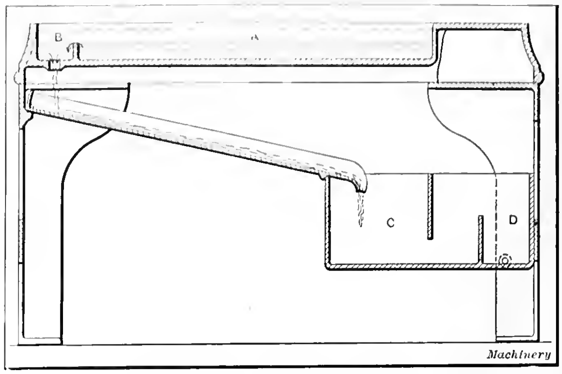

Fig. 29. Lubricant Tank with Partitions for separating Fine Chips from Lubricant

cases where the chips are fine and difficult to keep back. A tank, instead of being bolted down, may be hooked over a pin standing up from a lug (Fig. 25), without interfering with the pipes, or it may be tilted on lugs (Fig. 27). The tanks for Lincoln millers are often suspended in this way.

Separation of Chips and Lubricant

The separation of chips presents little difficulty, when they are large and cannot possibly pass through a small opening which admits the lubricant; but when they are fine, like the small chips from threading machines, etc., and particularly

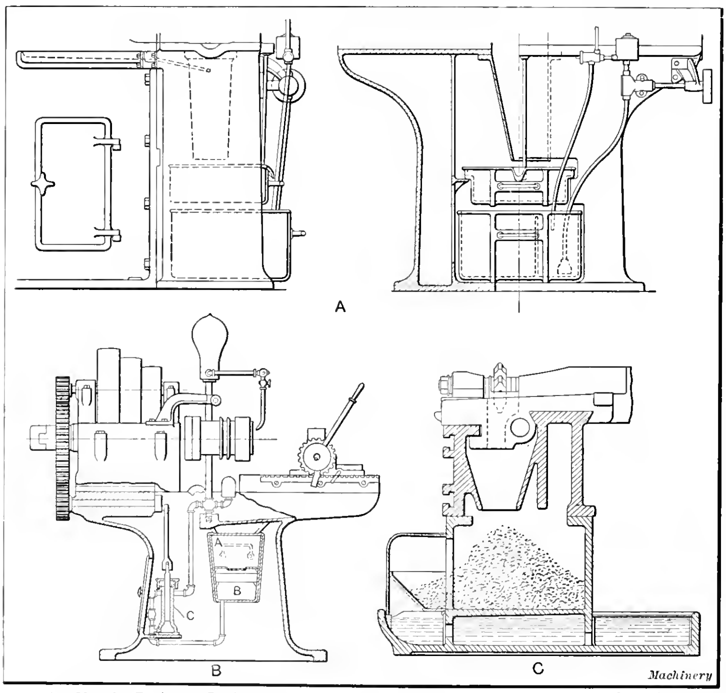

Fig. 30. A, Drainage Tank placed above Main Supply Tank; B, Common Lubricating Arrangement for Threading Machinery; C, Gear-cutting Machine with Provision for storing Oil in Base

those from hacksaws or cold saws, the greatest care has to be taken to prevent their entering the pump. This is done in two ways: By using strainers, and by fitting divisions or weirs so that two or three have to be passed before the liquid

reaches the pump chamber. An example is shown in Fig. 29, which illustrates the frame of a hacksaw machine built by Messrs. C. Wicksteed & Co., Ltd. of Kettering (England). Soap-water is used as a lubricant; this is first received in the recess *A* in the bed, and is drained at the front end *B*, which is farthest away from the falling swarth or chips as they are carried back by the blade on its return stroke. A sloping trough then conveys the lubricant to the tank *C*, which has two divisions, as shown. Light swarth which floats on top, cannot pass over the first division, and the clear liquid goes underneath to the pump chamber *D*.

If chips are produced in moderate quantities, it is well to have a separate perforated tray resting on the main pan, and empty this as required. One form is shown in Fig. 28. This tray should be deeper when larger quantities of material are handled, and is placed over the main tank, as shown at *A*, Fig. 30. It is drawn out when full, for getting rid of the chips. For threading machines, the usual arrangement is represented at *B*. This view shows the chip box *A*, with strainer and the settling tank *B*, with a division which prevents any sediment that might pass through the strainer from entering pump *C*. The latter is of the plunger type, and there is an air-vessel on the delivery pipe to insure a more constant flow of lubricant. In some designs, the interior, where the pump is located, forms an oil reservoir of larger capacity than the tank *B*.

Oil is contained only in the foot or base of some machines, corresponding in this respect to automatic screw machines, and the interior of the frame or the bed is used only to receive the chips. The sectional view *C* illustrates a large Brown & Sharpe automatic gear-cutting machine having this arrangement. The base stores the oil (from 25 to 30 gallons) and the chips fall from the cutter-slide to the position indicated, accumulating at the front eventually, and being removed through the opening for treatment in the oil separator.

ABOLISHING THE "CAN"

BY J. CROW TAYLOR*

It will be a surprise to some to hear that Germany, the country famous for beer and temperate drinking, is now showing a tendency, and a pretty general one at that, to discourage the use of beer by factory employes during working hours. There is what would be called in this country a pretty general disposition among German factory owners to abolish the "can."

As an example of how some handle this matter in Germany a consular report cites the methods used at the works of Ludwig Loewe & Co. of Berlin, where 3000 men are employed. Here they prohibit the beer can during working hours and offer in its place a drink of tea. The company has the tea prepared, puts it into pint bottles and sells it to the men for approximately three-quarter cent per bottle. Arrangements are made so that the tea may be had at any time any of the men desire it. Special trucks are used for distribution and boys wheel the tea about through the works, where bottles can be bought at any time by employes by a system of coupon tickets.

This tendency at present in Germany is in keeping with the attitude of factory owners in the United States. For a good many years now there has been a pretty general disposition to eliminate the use of beer during working hours. Many American mills and factories have long since put the ban on the beer can. Meantime Germany and the German element in this country has clung to it and pled the privilege of temperate drinking in extenuation. Temperate drinking is undoubtedly a great improvement on drunkenness, but it seems we are arriving at an age now which is not merely to be temperate but is to be prohibition so far as strong drink and even the milder drink of beer is concerned during working hours. It may be necessary to substitute tea and coffee in some instances, but as a general proposition it will likely be found eventually that water is a mighty good thing to drink during working hours, and that it will make for the good of the men as well as the employers and reduce accidents as well as increase efficiency.

A RECORD OF PRESSED FITS*

BY C. F. MACGILL†

Articles on forced or pressed fits have been published in various technical journals of the country during the past ten or twelve years (one by Stanley H. Moore appearing in the transactions of the Society), but in only one of the papers noticed is there any reference to the diameter and length of the hub into which the shaft is forced or the material of which the hub is made—three very important elements in a forced fit. The great difference in allowances recommended, and in the pressures shown in the articles referred to, led me to have an exact record kept of each forced fit, from which were later calculated the tension stress, radial pressure and the coefficient of friction. The accompanying tables are the result.

In my experience, covering about twenty years in charge of shops where forced fits were made, I found that it was not necessary to increase the allowance with the diameter of the shaft, as the increased surface area of the fit added sufficient friction to bring the pressure up to the required tonnage, and that an allowance of from 0.002 inch to 0.004 inch on steel shafts pressed into steel hubs, and an allowance of from 0.003 inch to 0.005 inch on steel shafts pressed into cast-iron hubs of ordinary hardness, gave good results. I have yet to learn of one of these shafts coming loose.

There is no doubt in my mind that allowances greater than 0.006 inch on steel shafts pressed into cast-iron hubs, not only do not serve any useful purpose, but tend to set up strains that are injurious to the casting. One large plant with which I am familiar, issues an allowance table for pressed fits, the allowance gradually increasing with the shaft diameter. This is not followed in their shaft department, but instead a flat allowance of 0.003 inch is used without regard to the diameter of the shaft.

The allowances given by Mr. Moore, in his paper already referred to, are very much too great, while those given by Mr. Riddell in his discussion of the paper, are too low for sizes under 12 inches. According to Mr. Moore's formula $A = (2D + 0.5) \div 1000$. The allowance for an 8-inch shaft would be $(8 \times 2 + 0.5) \div 1000 = 0.0165$ inch, and on a 12-inch shaft $A = 0.0245$ inch. By referring to the accompanying tables of actual fits, it will be seen that an allowance of 0.002 inch on 8-inch shafts pressed into steel hubs, showed pressures of from 60 to 110 tons, and an allowance of 0.004 inch on a 12-inch shaft pressed into a cast-iron hub, showed 130 tons; hence it does not seem that greater allowances are either necessary or advisable.

The records in these tables cover 204 fits of diameters varying in size from 3.5 inches to 20 inches; sufficient in range and number to demonstrate the correctness and value of the practice followed. All of these measurements and gage readings were taken by the same inspector, and as he was a thoroughly reliable man, I am satisfied that they are correct. The records are all of fits made on electric generators and motors. The tables give the diameter of the shaft; the diameter of the bore; the length of the seat; the diameter of the hub; the material of which the hub is made; the allowance (the difference between the diameter of the shaft and the diameter of the bore of the hub into which the shaft is pressed); the pressure in tons required to force the shaft in; the maximum tension stress in the bore, in pounds per square inch; the radial pressure on the surface of the shaft, in pounds per square inch; and the coefficient of friction. The figures are given as a record of actual experience on sizes between the diameters shown. They are not claimed to represent correct practice beyond these dimensions.

The values in the last three columns were figured from formulas developed by Prof. A. Morley and published in *Engineering*, August 11, 1911. In these formulas

R_1 = outer radius of hub;

R_2 = inner radius of hub = radius of shaft after fitting;

$A = R_1 - R_2$ = thickness of hub wall;

$D = 2R_2$ = diameter of shaft;

p_2 = radial compressive stress in pounds per square inch at radius R_2;

* Paper presented before the American Society of Mechanical Engineers, December, 1913.

† Superintendent, Busch Sulzer Bros., Diesel Engine Co., Second and Utah Sts., St. Louis, Mo.

PFAUTER PATENTS ON GEAR HOBBING MACHINES IN GERMANY

The German Pfauter patent No. 112,082 class 49a on spiral gear hobbing machine expired September 1, 1912. The patent for this invention by Mr. Pfauter was taken out by the Chemnitzer Strickmaschinenfabrik of Chemnitz in 1897 and expired at the end of fifteen years. As the patents have expired, anyone can build hobbing machines in Germany on the Pfauter system. When Pfauter applied for patents on his hobbing machine he made application for both spur and spiral gear machines but after making a thorough examination, the patent office discovered that the hobbing method as applied to cutting spiral gears only could be protected, inasmuch as the hobbing principle of cutting spur gears had been known for thirty or forty years. Up to September 1, 1912, only two makers were permitted to manufacture hobbing machines for cutting spiral gears, these being Mr. Pfauter, whose entire product was taken over by the Schuchardt & Schütte Co., and Biernatzki & Co., who had acquired the patent rights from the Chemnitzer Strickmaschinenfabrik.

LAMINATED SPUR GEARS

A new method of making spur gears to secure accuracy and silent operation which is being developed commercially by Laminated Gears, Ltd., Sedgley Road, Owlerton, Sheffield, England, was described in *Page's Engineering Weekly.* This new gear, which is the invention of Arthur E. Terry, consists of a number of thin disks in which teeth have been formed by dies. These disks, which may be of brass, mild steel, high-tensile steel, etc., are placed side by side and clamped together by rivets. In assembling the gear, successive disks are displaced a distance equal to one-half the circular pitch, so that the teeth are staggered as shown in Fig 1. These disks

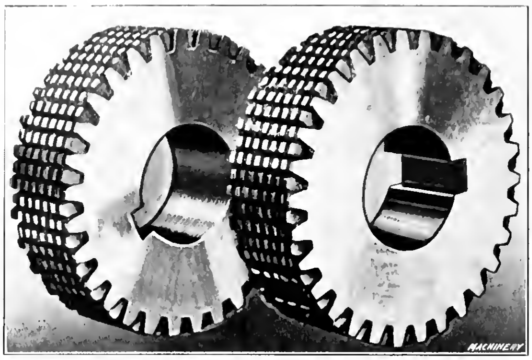

Fig. 1. Laminated Gears formed of Toothed Disks riveted together

are located on the tooth notching machine, by the bore and keyway, so that each disk has exactly the same pitch diameter. Between the plates of an assembled gear are metal washers varying from 0.001 to 0.012 inch thick, in accordance with requirements. These washers provide a slight clearance for the meshing teeth. The laminated gears are said to produce very little noise in operation, owing to the fact that the impact of the meshing teeth is halved, thus lessening the noise produced; moreover, as the gear is formed by a number of laminations, it cannot vibrate as a whole, and if one of these gears is suspended and struck by a hammer,

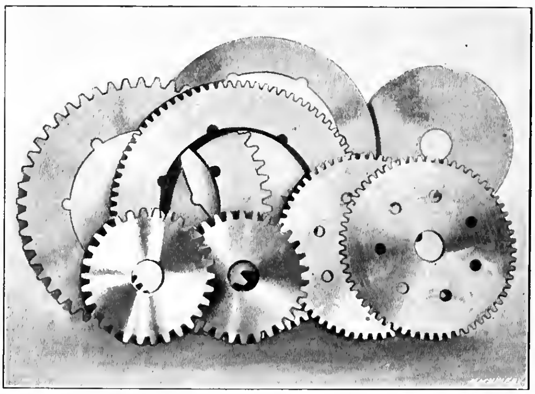

Fig. 2. Stampings and Blanks for Laminated Gears

the sound produced is about the same as would be obtained by striking a disk of lead; hence, the vibrations which produce a ringing sound in the case of a solid gear are entirely eliminated, owing to the laminated construction. It is claimed that when laminated gears are hardened there is no danger of distortion, because in the hardening processes the plates can be packed on a mandrel so as to form a long pinion with the teeth in line. When the plates thus assembled are casehardened, they will only be hard on the working faces of the teeth, and, consequently, the distortion of the plates will be slight; furthermore, when they are assembled, what little distortion there may be in each individual plate will be neutralized.

No one was ever lost on a straight road.

COMPARATIVE TESTS OF THREE TYPES OF LINESHAFT BEARINGS*

RELATIVE POWER CONSUMPTION AND COEFFICIENTS OF FRICTION FOR BALL, ROLLER AND BABBITT BEARINGS

These tests were made in order to ascertain definitely the relative and absolute amounts of power required to drive a specially constructed lineshaft carrying given loads at certain known speeds of revolution, when supported successively by three different types of shaft bearings, and to determine coefficients of friction for each type. The three types tested were ring-oiled babbitt bearings, roller bearings and ball bearings. Twenty bearings of each type were used in order that representative results might be obtained.

The design of the apparatus was made with the assistance of the manufacturers of the bearings to whom preliminary drawings were submitted, and during the four years of the tests representatives of these firms have visited the laboratory for the purpose of giving whatever advice and assistance was possible. The preliminary work, covering the first two years, showed the necessity of considering the temperature of the oil film in the babbitt and roller bearings, and it was only after careful study of the temperature question with regard to all three types that satisfactory results were finally obtained.

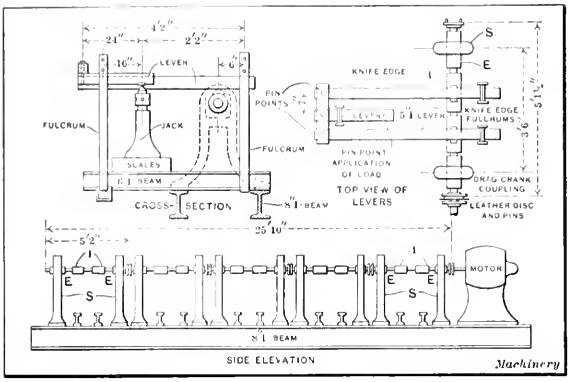

Fig. 1. Diagram of Apparatus for testing Lineshaft Bearings

Description of Testing Apparatus

The apparatus consists of 25 feet 10 inches of lineshafting in five equal sections, mounted in hangers *S* (see Fig. 1) which are inverted and used as floor stands. The hangers are bolted to two 8-inch I-beams which are leveled upon the floor. The shafts are of cold-rolled steel, 2 7/16 inches in diameter. Each section is 5 feet 2 inches long; the adjacent sections are coupled together by means of a flexible leather disk or two straps connecting the two flange couplings. The flexible couplings prevent transmitting any part of the load applied on one shaft, to either adjoining section, and also prevent binding between shafts and bearings due to possible lack of alignment.

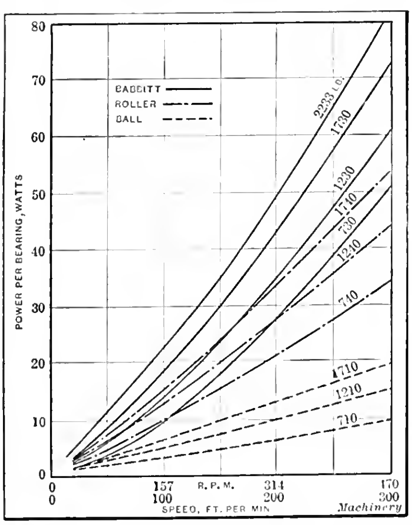

Fig. 2. Comparison of Power consumed by Friction in Babbitt, Roller and Ball Bearings at Various Speeds, with Loads per Bearing as indicated—Temperature of Bearing 100 Degrees F.

A direct-current Fort Wayne motor is directly connected to one end of the shafting by means of a flexible coupling. The motor is of the interpole type with the interpoles removed, making it a shunt motor. Its rating with the interpoles is 7½ horsepower, 28 amperes, 400/1600 revolution per minute, four pole, 230 volts. The power required to run the motor alone at all speeds, without load, was accurately ascertained, as well as the power required to run the motor and shafts together, at all loads and speeds. The relative amounts of power required to overcome the friction of the various types of bearings were therefore accurately determined.

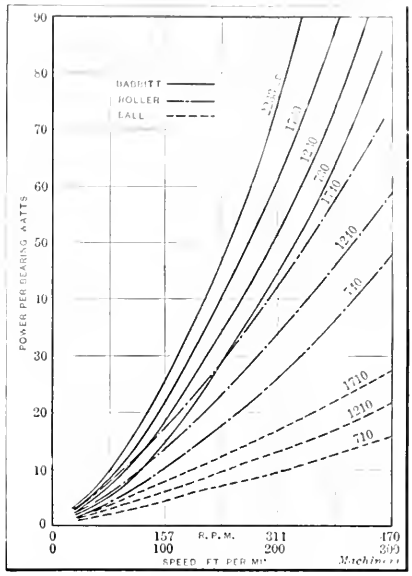

Fig. 3. Comparison of Power consumed by Friction in Babbitt, Roller and Ball Bearings—Temperature of Bearing 77 Degrees F.

The load was applied through levers having hardened knife edges and pin points as fulcrums. Across the top of the 8-inch I-beams and at right angles to them, are bolted short 6-inch I-beams to which the fulcrums are attached. Standard 1000-pound scales are set upon the 6-inch I-beams. A double system of leverage is used in order to get sufficient load upon the bearings with as short a length of lever as possible.

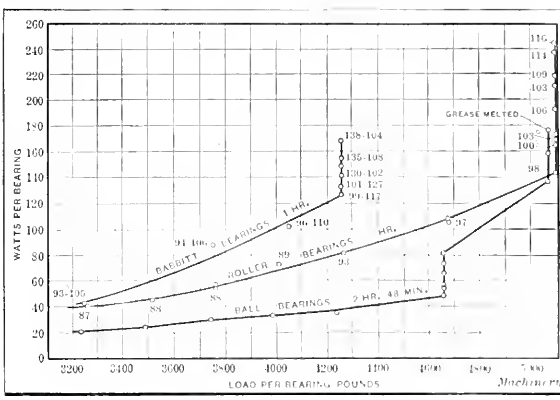

Fig. 4. Lubricant Breakdown Tests for Babbitt, Roller and Ball Bearings

This double system of levers also serves to steady the apparatus and prevent excessive vibration. A pressure ratio of 8.33 at each bearing to one at the scale was obtained. This was checked by an independent method of weighing the actual load resulting at the bearings, from a given load on the scales. The loads were applied to the shaft by two bearings between each pair of hangers. These bearings are identical with those in the hangers, and are supplied with knife edges which engage a V-shaped groove in the 5-inch I-beam levers. The bearings and hangers for each section are symmetrically placed with respect to the middle of the sec-

* Abstract of paper by Carl C. Thomas, E. R. Maurer and L. E. A. Kelso, presented before the American Society of Mechanical Engineers, December, 1913.

tion; therefore, equal loads on the intermediate bearings *I* produce equal pressures on the end bearings *E*. The reason for using twenty bearings was that the amount of power necessary for a single bearing was so small as to be difficult of measurement; moreover any single bearing might not truly represent results that would be obtained from that type of bearing in general.

The Bearings Tested

The three kinds of bearings tested were: the Hess-Bright ball bearing manufactured by the Hess-Bright Mfg. Co.; the ring-oiled bearing manufactured by the Dodge Mfg. Co., lined with babbitt metal made from their formula; and the Hyatt roller bearing manufactured by the Hyatt Roller Bearing Co. All bearings were for the same size shaft and the same pieces of shafting were used for all the tests, except that two sections bent during the tests were replaced. The babbitt bearings are 9 21/32 inches long and hence their projected area is 22.36 square inches.. These bearings were oiled by the well-known ring-oiler device, there being two rings in each bearing. Each roller bearing contains six right-hand and six left-hand rollers, 0.780 inch in diameter; six are 9 9/16 inches long and six are 9 3/16 inches long. The bearings are of the type in which a cage is used for holding one-half the rollers. Each ball bearing contains a single set of balls 9/16 inch in diameter. The diameter of the inner race across the ball groove is 3.4729 inches.

Mercury thermometers (two in each babbitt and roller bearing, and one in each ball bearing) were used for measuring the temperature of the oil or bearing. In order to avoid the endwise thrust of the shaft, when supported by the roller bearings, it was necessary to interpose two ball thrust collars. Before this was done, excessive vibration of the motor and of the apparatus resulted from the tendency of the shaft to move endwise. This was particularly troublesome at high loads and speeds.

Procedure when Making Tests

The power was measured by the ammeter voltmeter method. A second ammeter was used as a check on the first; and a watt-meter (arranged for direct and reverse readings) as a further check. The general order of taking data was as follows: Clean the commutator; adjust motor to speed; take all power readings; read all thermometers; adjust speed again and repeat power measurements. This gave the power both before and after the temperature was taken, the mean of which would give the mean power for the mean temperature very closely. In addition, the readings acted as a check on each other.

The manner of making a test or run was essentially as follows: Each night the plant was run from three to twelve hours under the load and speed to be used during the run of the following day, but without observation. The purpose of the preliminary night run was to allow the shaft and bearings to adjust themselves to the conditions of the run. Then on the following day the shaft was run from three to six hours and frequent observations of power and temperature were made during the run. The first few observations were made as often as practicable (about five minutes apart); the others, generally at fifteen-minute intervals, but toward the end of the run when the temperature was rising slowly observations were made at intervals generally of thirty minutes or more.

TABLE I. RELATIVE AMOUNTS OF POWER CONSUMED IN FRICTION

Bearings	100 Feet per Minute		300 Feet per Minute	
	77 Deg. F.	100 Deg. F	77 Deg. F.	100 Deg. F.
Ball	1	1	1	1
Roller	2.2	2.5	2.7	3
Babbitt	3	3.6	4.5	4

Machinery

The speeds used in the tests were between 150 and 450 revolutions per minute, corresponding, respectively, to about 100 and 300 feet per minute peripheral speed. Most of the loads used were between 700 and 1800 pounds per bearing, corresponding, respectively, to about 30 and 80 pounds per square inch for the babbitt bearings. All statements of results therefore are subject to the above limitations as to speed and loads. Two lubricants were used in all the tests: Atlantic red engine oil in the babbitt and roller bearings, and No. 2 Keystone grease in the ball bearings.

Relative Power Consumption

Figs. 2 and 3 show a comparison of the power consumed by friction in the babbitt, roller and ball bearings for bearing temperatures of 100 degrees and 77 degrees F., respectively. Each curve gives the power required per bearing of the kind indicated, to run the shaft under the load and speed given. The power required for the babbitt bearings is higher than for the other bearings, except perhaps at low loads and speed, and the power for roller bearings is higher than for ball bearings. The excess of power for babbitt over rollers, and rollers over balls, increases with increase of speed for all loads. Table I shows the relative amounts of power consumed in friction by the three kinds of bearings at the speeds and temperatures indicated; the relative numbers are based, in each case, on the average power for the three loads: 710, 1210, and 1710 pounds for balls; 740, 1240, and 1740 for rollers; and 730, 1230 and 1730 for babbitt.

TABLE II. COMPARISON OF COEFFICIENTS OF FRICTION

Type of Bearing	Coefficient of Friction					
	Load, 727 Pounds		Load, 1227 Pounds		Load, 1727 Pounds	
	77 Deg	100 Deg.	77 Deg.	100 Deg.	77 Deg.	100 Deg.
Ball	0.0025	0.0019	0.0022	0.0018	0.0020	0.0016
Roller	0.0069	0.0055	0.0055	0.0047	0.0049	0.0042
Babbitt	0.0112	0.0075	0.0082	0.0058	0.0070	0.0051

Machinery

The coefficients of friction for the three types of bearings, when subjected to average loads of 727, 1227 and 1727 pounds, respectively, and temperatures of 77 and 100 degrees F., are given in Table II. The peripheral speed was 150 feet per minute.

Lubricant Breakdown Tests

In order to observe the performance of the bearings under extraordinarily heavy loads, "breakdown tests" were run on each type of bearing with only one section of shafting on which were four bearings. This small number of bearings was used because it was impracticable to keep close watch of a larger number and avoid trouble during the excessively severe conditions. The maximum load was 600 pounds on the scales, or about 5000 pounds per bearing. The results are shown in Fig. 4. A speed of 200 revolutions per minute was chosen because it represents about the average lineshaft speed in practice. These tests began at about 3200 pounds per bearing. Failure occurred at about 4250 pounds per bearing in the case of the babbitt, 4650 pounds in the case of the ball bearings, and about 5100 pounds in the case of the roller bearings.

The quality and amount of lubricant used undoubtedly have an important effect upon the load that will cause a given bearing to fail. The bearings did not in any case fail structurally, as the power was cut off soon after distress was manifested, but the failure was simply that of the lubricant. Breaking down of the lubricant resulted in an immediate increase of the power required to maintain the original speed of rotation of the shaft in the bearings. In each case probably only one of the four bearings used in the breakdown tests showed distress at any one time. In the case of ball bearings, distress was manifested by disintegration of the grease which "melted" and ran out of the bearing. This was accompanied by the immediate increase in power requirement, as shown in Fig. 4. The temperatures given (99 degrees, 117 degrees, etc.) indicate the averages for the four bearings being tested. Similar behavior on the part of the babbitt and the roller bearings indicated that at least one of the four under test was suffering from an approach to "metal-to-metal" contact. The bearings were not injured by these endurance tests, and all were used in subsequent tests at the more usual speeds and pressures.

CENTRALIZED CONTROL SYSTEM FOR PANAMA CANAL LOCKS

ELECTRICAL CONTROL-BOARD WITH INDICATORS TO SHOW POSITIONS OF GATES, VALVES, ETC., AND MECHANICAL INTERLOCKING SYSTEM

In an article on the Panama Canal published in the April, 1913, number of MACHINERY, a general description of the electrical control system for operating the locks was given, and the ingenious mechanical interlocking system to prevent all dangerous combinations in the relative positions of gates, valves, etc., was also referred to. These control and interlocking systems constitute one of the most interesting features of the canal for the mechanical and electrical engineer, and now that they have been installed in the locks, we are able to present a more complete description. In order to clearly understand this control system, one must be familiar with the general arrangement of the locks, which were described in detail in the article referred to, published in the April number.

An electrically operated centralized control system was necessary owing to the size of the locks. For instance, the flight of locks at Gatun has a total length of approximately 6200 feet, and the principal operating machines are distributed over a distance of about 4000 feet, so that any form of mechanical transmission for controlling these machines would be almost impossible. The control-boards are installed in houses located on the middle lock walls at points which afford the best view of the locks. The position of the gates or other apparatus is shown by indicators on the control-board so that the operator does not need to actually see the various parts which he controls. The control-boards are, to some extent, miniatures of the locks themselves, and, with the exception of that machinery which only needs an "open" or "closed" indication, the indicating devices will act in synchronism with the movement of the lock machinery to which they are connected. One of these control-boards is shown in Fig. 1. It is a flat-top bench-board type, 32 inches high and 54 inches wide. The total length of these boards varies for different locks as follows: Gatun, 64 feet; Pedro Miguel, 36 feet; Miraflores, 52 feet. On top of the control-board, the side and center walls of the locks are represented by cast-iron plates and the water in the locks by blue Vermont marble slabs. The control switch handles are mounted above the surface of the board, as well as the various indicating devices.

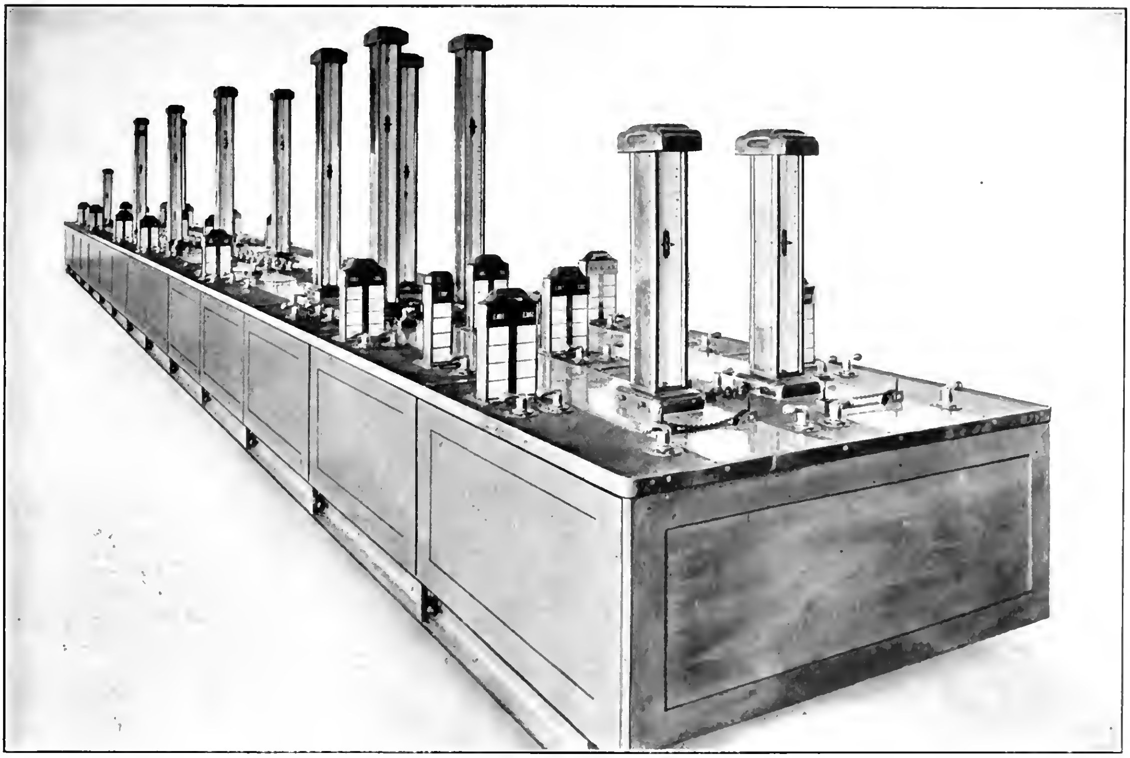

Fig. 1. Lock Control-board for Miraflores Locks of Panama Canal—The Water Levels in Different Chambers and Positions of Gates, Valves and Fender Chains are shown by the Indicators seen on Control-board

Operation of Control-board Indicators

A synchronous indicator for showing the movement of a lock member, has a transmitter located at and operated by the mechanism in the lock wall, and a receiver operating an indicator at the switchboard in the control house. Both transmitter and receiver have a stationary and a rotating part. The movement of the lock machinery and the connected transmitter rotor produces a field in the transmitter stator polarized in the direction of the rotor axis, which induces voltage in the stator coils. This voltage is transmitted by a three-phase connection to the receiver stator coils and duplicates in them, but in the reverse direction, the conditions of polarity and voltage in the transmitter. The rotor of the receiver being energized by the external source in the same direction as that of the transmitter, is reacted upon by the polarized receiver stator until the magnetic axes coincide and the rotors of both transmitter and receiver are in the same relative positions. Any difference in the position of the transmitter and receiver rotors causes a difference of potential between the stator windings, with a consequent flow of current, and resultant torque, which again moves the receiver rotor to the same relative position as that of the transmitter rotor. The receiver rotor follows closely and smoothly the movement of the transmitter rotor, and, consequently, imparts to the control-board indicator a movement identical with the movement of the lock machine, although on a reduced scale. A brief description of the different synchronous indicators follows:

Indicators for Lock Gates, Fender Chains and Valves

In the case of the lock gates, the vertical operating shaft is connected to a shaft which operates the transmitter machine. The latter shaft is threaded and carries a nut on which is mounted a rack. The rack engages a gear on the rotor shaft, and this turns the rotor as the gates operate. The mitering gate indicator (See Fig. 2) comprises a pair of aluminum leaves, shaped to correspond to a plan view of the gates. These leaves travel horizontally just above the top

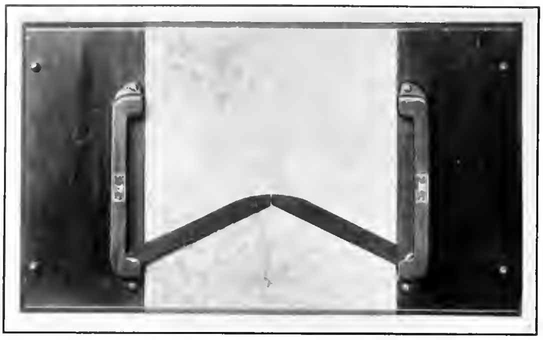

Fig. 2. Indicator used on Control-boards to show Positions of Lock Gates—The Indicator Leaves move in Synchronism with Lock Gates

of the board, the hinged ends being connected to shafts extending down through the board, where they are geared to the receivers by means of bevel gears.

For the chain fender, the position indicator transmitter is driven by the shaft operating the limit switch that controls the stroke of the piston for operating the chain. The indication on the board is given by a small aluminum chain, which, like the large chain, is raised and lowered, each end operating independently. Two of these chains may be seen near the right-hand end of the control-board in Fig. 1. The ends of the miniature chains are fastened to semaphore arms which are connected to segmental gears meshing with the driving gears on the receiver machines. As the receiver rotors turn, the chain is either lifted or lowered, the position of the large chain from the bottom of the lock being indicated by the angle of the semaphore arms.

As the gate valves which control the flow of water into the main feed culverts are in pairs to reduce the size of each valve, their position indicator machines are also in pairs. The transmitter rotor is driven by a shaft and gearing similar to that described for the lock gates. Each indicator is similar to a small elevator, a car being used to indicate the position of the gate valve. Both the front and back of the shaft is fitted with opaque glass marked with black lines for the one-quarter, one-half and three-quarter positions. A small aluminum cage moves up and down in each compartment. A drum for operating the cord which raises and lowers the cage is located underneath the control-board and is operated by the receiver through a suitable train of gears. To make the indications visible from points up and down the control-board, the elevator shaft under each car is always illuminated and the portion above is dark. These indicators are located on the cast-iron plates of the control-board, which, as previously mentioned, represent the side walls of the lock. (See Fig. 1.)

Water Level Indicators

The specifications for the water level indication required an accuracy of 1/20 foot in actual water level. In the transmitters and receivers for the machines described previously, the rotors turn less than 180 degrees with an inherent lag of 1½ per cent between transmitter and receiver rotors in this distance, which, obviously, prevents this arrangement from being employed to give the water level indication. The required accuracy was obtained by two sets of transmitters and receivers. One set is connected to a "fine" index in which the rotors make ten complete revolutions, and the other set is connected to a "coarse" index operating less than 180 degrees. The fine index is a hollow column carrying a pointer. The length of the column is such that when an aluminum ball representing the coarse index (which can be depended upon for coarse indication) is within the limits of the column, the reading of the fine index is correct within the limits specified. The scales are illuminated by lamps at the base and top of the indicator. These indicators, which may be seen in Fig. 1, are the tall column-shaped members mounted on the marble slabs. To operate the water level indicators there are wells 36 inches square in the lock walls, which communicate with the lock by a small opening at the bottom of the well. These wells contain steel box floats, 30 inches square by 9 inches deep. A non-slipping phosphor-bronze belt transmits the movement of the float to a sheave fitted with pins on the transmitter mechanism, the pins registering with holes punched in the belt.

The positions of the miter forcing machines (for locking the closed gates and forcing them together to make a good joint) are not indicated by synchronous indicators, but the open and closed positions are shown by red and green lights and a mechanical indicator on the control-board.

Mechanical Interlocking System

In order to make it necessary for the operator to manipulate the control-switch handles always in the proper order, corresponding to a predetermined sequence of operations of the lock machinery, and to prevent the operator in control of one channel from interfering with the machinery under the jurisdiction of the operator controlling the other channel, the control switches are provided with mechanical interlocks.

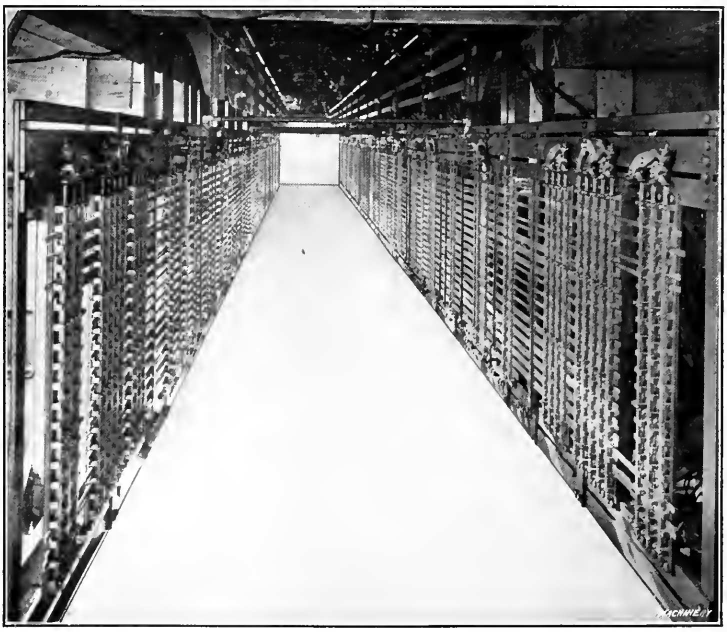

Fig. 3. Mechanical Interlocking Bars located beneath Control-board to prevent Dangerous Combinations in Relative Positions of Gates, Valves, etc.

The interlocks, which are shown in Fig. 3, are in two vertical racks under each edge of the board and some distance below, so that they may be inspected and oiled from a floor which is about seven feet below the floor on which the switchboard operator stands. Vertical shafts operated by connecting-rods from the control switch shafts extend downward past the electrical parts, for the operation of the interlocks. The interlock system is essentially a bell-crank mechanism, connecting the shaft of the control switch through a movable horizontal bar, to a vertical operating shaft which can or can-

not move, according to the relative positions of the interlocking bars and dogs. The interlocking system depends mainly on the action of engaging bevel dogs located on the horizontal and vertical bars, the movement of a horizontal bar tending to lift a vertical bar by bevels on the dogs. A horizontal bar cannot be moved without raising a vertical bar; thus, if at any time a dog on a horizontal bar rests against the upper end of a dog on a vertical bar, no movement of the horizontal bar where the dog engages with the vertical bar can take place, and the control handle connected to that particular horizontal bar is locked.

Interlocks prevent the chain fender from being lowered until adjacent lock gates have been opened, and also prevent the gates from being opened until the chain is in the raised position. In this way it is insured that the chain fender will always be in the up position to protect the gate when the gate is closed. After the lock gates are closed the miter forcing machine which locks the ends of the gates cannot be operated until the gates are closed.

The gate valves for the side wall culverts, next above or below a lock gate, must be closed while the miter forcing machine is open. As the miter forcing machine cannot be closed until the gates are closed, this means that the valves either above or below the gate must remain closed until the gate itself is closed, thus preventing the operator from creating a current of water around the gates while they are open, or are being opened or closed. This interlock is not included on the middle wall valves for the reason that they will be used with the locks on either side and must be free for that purpose.

The gate valves are not only installed in pairs, but each pair is in duplicate. One pair of duplicates is left open as a guard, or reserve pair, and the other is used for operating, so that in case of an obstruction in the culvert or accident to the machinery, the duplicate pair can be used. Either pair of gate valves may be opened first, at the choice of the operator, an interlock becoming effective when the first valve of the second pair of duplicates is opened. The control of these valves is interlocked so that if the valves are opened at one particular point, the valves a lock length upstream or downstream cannot be opened. Thus the operator is limited to equalizing the water between locks and cannot allow water to flow from the upper lock past the middle lock into the lower lock, which operation, if permitted, might flood the lower lock walls and the machinery chambers in them.

The cylindrical valves (which control the flow of water to the lateral feed culverts) are interlocked so that if those on one side are opened the ones on the other side are locked closed, and the opening of one switch on a side will lock the opposite ten. This prevents careless cross filling between locks, which operation might be combined with the regular method and produce flooding. However, there may be times when it is desirable to employ cross filling to economize in the use of water from Lake Gatun, in the cry season. For this reason this interlock is made removable by the use of a Yale lock and key. The key will be placed in the hands of the chief operator. In the use of the middle wall culvert, the cylindrical valves on one side or the other must be opened before the main gate valves can be opened, and the latter must be closed first. This interlock is applied in order to require the operator to control the flow of water by means of the gate valves rather than by the cylindrical valves.

In most cases the locks are divided into two unequal parts by intermediate lock gates. This arrangement makes it necessary to divide the ten cylindrical valves into two groups of seven and three, respectively, for the long and short lengths. A lever is provided for these interlocks and may be set as indicated by a nameplate on the lever to "three," "seven," or "ten," respectively; then the corresponding valves are subject to that interlock, and the others of the group of ten are locked closed if three or seven only are to be used. The failure of the operator to make his selection properly in advance will simply cause him the trouble of going back and doing so, as the remaining valves are locked closed. This arrangement permits handling small vessels without causing waste of water due to operating such vessels in the large chambers. If a short vessel were being passed downstream it would first enter the chamber having three cylindrical valves. The group selective lever would then be placed on the "three" position which would permit the opening of three valves above the intermediate gate, but would lock closed the other seven valves above it. After the vessel has been passed below the gate, the handle may be reversed releasing the lever and locking three switches. In case a large vessel is to be locked through, the interlocks on the intermediate gates can be made ineffective by the operation of a Yale lock which uncouples a clutch and disconnects the central switch from the operating mechanism.

To obviate the possibility of flooding the locks when valves are in a certain position, diagonal interlocking is introduced between the gate valves of the side wall and those of the middle wall a lock length away. This interlocking between valves diagonally across a lock when the cylindrical valves are open is needed to prevent the flow of water from, say, the upper lock by way of a side wall culvert to the middle lock, thence by way of the middle wall culvert to the lower lock, thus allowing an operator through carelessness to flood the lower lock walls. If the cylindrical valves of a certain lock are closed, the interlock is not needed on the gate valves of that lock; and since such interlock would interfere with the proper use of the valves of its twin lock on the other side of the middle wall, this interlock is automatically removed when all ten cylindrical valves are closed on the particular lock in question, and is automatically applied again if one or more of the ten cylindrical valves is opened. Furthermore, the valves of the side wall immediately at the gate which is being moved, will be open to equalize the water level, and diagonal interlocking will prevent the opening of the middle wall valves a lock length above or below the gate being moved. Each of the four valves of such a group has independent control, their control switches being so interlocked that either pair may be opened and left open as guard valves, the interlocks becoming effective when the operator tries to open the first valve of the second pair. In addition to these pairs of valves in parallel, each pair is duplicated at each change of level from one lock to the next.

All of the lock machinery motors, control panels, centralized control-boards, power station generating apparatus, switchboards, transmission line substation equipments, etc., were manufactured by the General Electric Co. The specifications for the entire generating, lock-controlling and distribution system for operating the Panama Canal were prepared under the supervision of Mr. Edward Schildhauer, electrical and mechanical engineer, Isthmian Canal Commission, assisted by a staff of able electrical engineers.

* * *

A remarkable exhibition of engine endurance was recently made by the Moline Automobile Co. in New York City under the auspices of the Automobile Club of America. A Moline-Knight four-cylinder motor was put on the testing block late in December and run continuously for two weeks—336 hours—without adjustment of the motor, carbureter, spark plugs or magneto at 1100 revolutions per minute. It developed thirty-eight horsepower and ran at a rate that would have carried it 14,700 miles on the level at forty-five miles an hour. It would have steadily climbed an eight per cent grade 10,000 miles long at twenty-seven miles an hour, or a mountain 800 miles high. At the end of the run the speed was increased to 1682 revolutions per minute for one hour, developing 53.6 horsepower. The engine was then taken apart and exhibited at the Auto Show. The parts showed very little evidence of wear. The test demonstrated that a properly proportioned motor well lubricated should have a long life and that it is the most dependable part of the modern motor car.

A petition has been presented to the German Reichstag, signed by some two hundred and fifty commercial and industrial organizations, asking their government to take steps toward the introduction of a universal international two-cent letter postage, and to endeavor to have this adopted by the International Postal Congress in Madrid next year.

CUTTING POWER OF LATHE TURNING TOOLS*†

INFLUENCE OF SPEED, DEPTH OF CUT, FEED, SHAPE, AND PHYSICAL PROPERTIES OF METAL

The question of the definite measure of the output of work or removal of material of which lathe tools are capable, is one about which there is very little information readily available, and it it was for the purpose of determining the performance of cutting tools over a fairly wide range of working conditions and of deducing therefrom some practical results that the experiments described in the following were made. The object of the tests was to determine to what extent the output of both high-speed and ordinary carbon-steel tools is affected by such elements as cutting speed, depth of cut, feed of tool, shape of tool nose and physical properties of the metal upon which the cutting tool is acting. The question of the association of a high speed and a light cut *versus* a low speed and heavy cut received particular consideration in order to find the relation between these two factors and the maximum output.

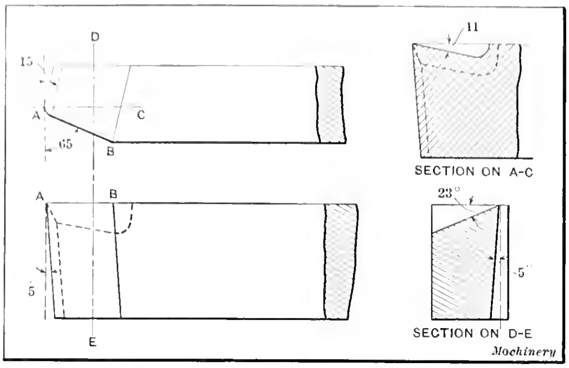

Fig. 1. Standard Shape of Tool used for Tests

Owing to the extensive use of turning tools of high-speed steel at the present time, especially when the cutting speed is an important consideration, the results of the tests made with carbon-steel tools have been omitted in this abstract.

Tools used for Tests—Test-bars

The high-speed steel tools tested were made from ¾- by ½-inch bars and were about 8 inches long. The shape of the tool used for the first series of tests is shown in Fig. 1. The tools were of high-grade steel and the ends were shaped entirely by grinding in a universal tool grinder. They were then hardened according to the directions of the maker. These tools were of the same shape and size as those used for the carbon-steel tool tests so that the results in each case could be compared.

TEST-BARS FOR HIGH-SPEED STEEL TOOL TESTS

Physical Properties

Letter of Identification	Breaking Load in Tons per Square Inch	Elongation, Per Cent	Compressive Load in Tons per Square Inch
A	27.2	28.4	81.2
B	33.5	21.7	90.0
C	50.5	12.0	126.4

Chemical Composition

Letter of Identification	Carbon	Silicon	Manganese	Sulphur	Phosphorus	Grade of Steel
A	0.29	0.100	0.42	0.037	0.028	Mild
B	0.39	0.075	0.50	0.030	0.038	Medium
C	0.60	0.249	0.83	0.053	0.030	Hard

Machinery

The tests were made on a large electrically driven experimental tool-testing lathe installed in the machine tool laboratory of the University of Sheffield. The test-bars were three in number and of different chemical compositions and physical properties, as shown by the accompanying table.

Their approximate original dimensions were: Length, 9 feet 6 inches; diameter, 1 foot 8 inches. The meaning of the identification letters is as follows: A, mild steel; B, medium steel, and C, hard steel.

With the high-speed steel tools it was found possible to obtain a definite point at which the tool failed to cut; this is the point at which the cutting edge collapses, and instead of continuing to cut causes the surface of the bar to become polished. The exact instant at which each tool broke down or began to produce this polished surface was observed and from this the durability of the tool was determined. (The method adopted for carbon-steel tools involved a microscopic examination of the cutting edge to determine the amount of bluntness or wear, this being found the only possible way of establishing a standard for measuring the working life of the tool.)

Standard for Duration of Test

One hour was selected as a convenient value for the standard life of the tools used in these tests, although in machine shops high-speed tools usually run a much longer period than this before resharpening, and the curves of performance seem to suggest that this practice has a reasonable basis, since the cutting speed which corresponds to a life of sixty minutes is, in practically every case, only about 5 or 10 per cent greater than that which will allow a tool to last for three or four hours.

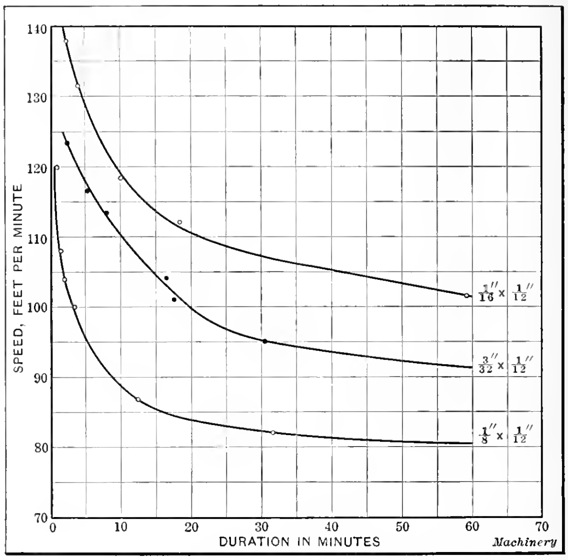

Fig. 2. Cutting Speed and Duration Tests for Varying Areas of Cut—High-speed Tools cutting Mild Steel

The failure of a high-speed turning tool working under normal conditions is, in most cases, brought about by the fusing of the nose due to the heat generated as the result of friction. The friction is due to the rubbing of the chip on the upper lip of the tool as it passes off from the work. This rubbing action frequently causes a pit or hollow to be worn out of the upper face or lip of the tool just in front of the cutting edge. There is also friction due to the cutting action of the tool as it traverses the work in a line parallel to the axis. When the tool is worked under conditions which are not excessively severe, the heat generated at the nose of the tool is conducted away as fast as it is generated, and thus the nose is not subjected to overheating; but if the cutting speed

* Abstract of paper presented before the Institution of Mechanical Engineers, at Manchester and London, by Prof. William Ripper and G. W. Burley of the University of Sheffield.

† See also the series "On the Art of Cutting Metals," published in MACHINERY from January to August, 1907, inclusive.

and area of cut are such as to generate heat faster than the tool can conduct it away, fusing and breakdown at the nose takes place. Moreover, as the work proceeds, the tool accumulates heat from the nose backward, and the rate of flow or conduction of the heat away from the nose correspondingly decreases, with an increasing tendency to accumulation of heat at the nose.

The data taken during the tests include the circumferential or cutting speed, the depth of cut, the feed per revolution, the power-input to the motor on light load at the cutting speed selected, the time of starting the cut, the power-input to the motor during the actual cutting, and the time at which the tool failed. The tools were tested for the following areas of cut on each bar. Depth of cut, 1/16, 3/32 and ⅛ inch; feed per revolution for each depth of cut, 1/30, 1/20, 1/12 and 1/8 inch, respectively.

Relation between Cutting Speed and Durability of Tool

Altogether, about two hundred tests were made, the duration of each test varying from one minute to 70 minutes.

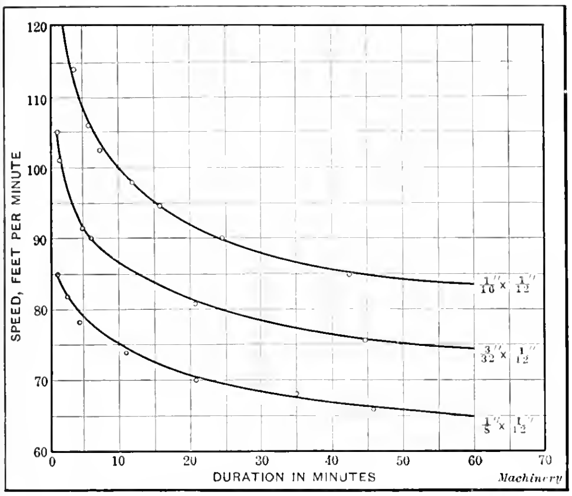

Fig. 3. Cutting Speed and Duration Tests for Varying Areas of Cut—High-Speed Tools cutting Medium Steel

For each area of cut or combination of depth of cut and feed per revolution, data for a cutting-speed-duration curve were obtained and the curves shown in Figs. 2, 3 and 4 were plotted. Fig. 2 is for mild steel (Bar A); Fig. 3 for medium steel (Bar B); and Fig. 4 for hard steel (Bar C). The curves are for a feed of 1/12 inch per revolution of the test-

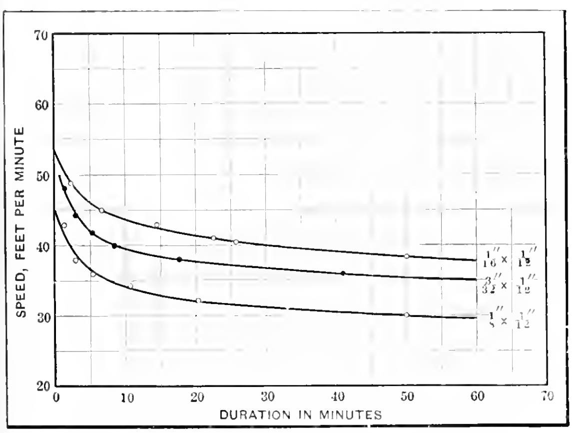

Fig. 4. Cutting Speed and Duration Tests for Varying Areas of Cut—High-speed Tools cutting Hard Steel

bar, the depth of cut, in each case, being given at the end of the curve. These curves show the effects of the hardness of the bar and area of the cut on the cutting speed, and the relation between the cutting speed and the life of the tool up to the point of failure. They further indicate that at high cutting speeds the durability of the cutting edge is very short, but that, as the rate of cutting is reduced to a speed which gives a durability of 40 or 50 minutes, the tool then continues to cut for a more or less indefinite period as indicated by the change of the curves toward the horizontal. If this speed,

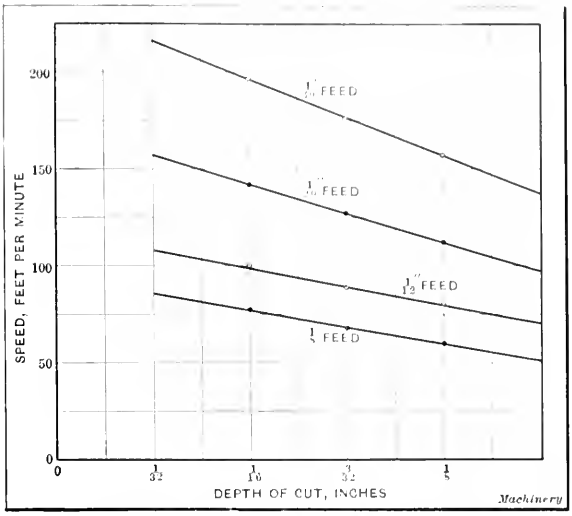

Fig. 5. Relation between Cutting Speed and Depth of Cut for Varying Feeds—Standard Life of Tool, Sixty Minutes

however, is exceeded by from 10 to 15 per cent, the life of the tool is rapidly shortened. The average relation between the cutting speed *S* and the life of the tool *M*, in minutes, for any given area of cut between durations of 10 and 60 minutes, is represented approximately by the formula:

$$SM^{\frac{1}{12}} = \text{constant.}$$

The value of the constant depends upon the quality of the steel being turned and upon the area of the cut. The relation between these two quantities, as determined by Mr. F. W. Taylor, for high-speed turning tools is

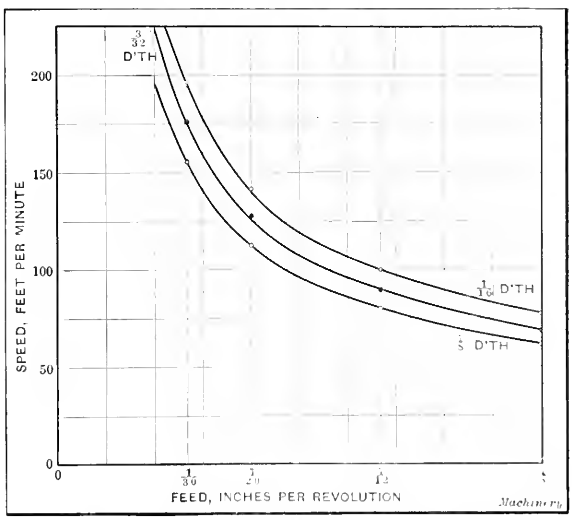

Fig. 6. Relation between Cutting Speed and Feed for Varying Depths of Cut—Standard Life of Tool, Sixty Minutes

$$SM^{\frac{1}{8}} = \text{constant.}$$

Relation between Cutting Speed and Area of Cut

For each test-bar, the relation between the cutting speed and the associated area of cut for a standard life of 60 minutes was determined, the data in regard to the cutting speed being drawn from the curves of which Figs. 2, 3 and 4 are representative. Contrary to the experience and views of Dr. Nicolson, and in agreement with those of Mr. F. W. Taylor, it was found that the cutting speed did not depend only upon the area of cut, independently of its component factors, but that it also depended upon the depth of cut and

feed per revolution, in two different ways, as shown by the curves Figs. 5 and 6. Fig. 5 shows the relation between the cutting speed, for the standard tool life, and the depth of cut for the various speeds adopted; whereas Fig. 6 shows the relation between the cutting speed and the feed per revolution for varying depths of cut, the curves referring to test bar A in each case.

By referring to Fig. 5, it will be seen that a cut 1/8 inch deep, with 1/20 inch feed, is taken at a greater cutting speed than a cut 1/16 inch deep with 1/10 inch feed, which is of equal area but less efficient as to output. A similar deduction can be made from Fig. 6, where it will be seen that a cut 1/8 inch deep with 1/24 inch feed is taken with a cutting speed of 125 feet per minute, whereas for a cut 1/16 inch deep with 1/12 inch feed the speed is 100 feet per minute. Some explanation of this is indicated by the illustrations *A* and *B* in Fig. 7. In each of these views a tool having a nose of standard shape is represented taking a cut, the area of which is the same in each case. At *A* the depth is one-half that at *B*, but the feed per revolution is twice as great. It will be noticed that the length of the cutting edge which is in contact with the work at *A* is considerably less than at *B;* hence, in the latter case there is a much larger cooling area back of the cutting edge to conduct the heat away as it is generated. Therefore, other things being equal, the rise in temperature of the cutting edge, in the second case, will not be so rapid as in the first; hence, a higher cutting speed can be employed with the tool having a longer cutting edge in contact with the work.

Output of Turning Tools

The standard output of a turning tool is defined in these tests as the number of cubic inches which the tool will remove during the standard life of 60 minutes. The maximum output or removal of metal is associated with the lowest cutting speed with which, for a standard life of 60 minutes, the heaviest depth-feed combination is associated; the greater influence is, of course, on the side of the depth. Thus, with a depth of cut of 1/8 inch and a feed of 1/20 inch per revolution, the volume of metal removed in 60 minutes is 504 cubic inches, whereas, with a 1/16-inch cut and 1/10-inch feed the output is 405 cubic inches per hour. This shows a gain of about 25 per cent in favor of the deeper cut with a reduced cutting feed. This law applies generally to all the bars and speed-depth-feed combinations; hence it may be stated that for the maximum tool output, the area of cut is

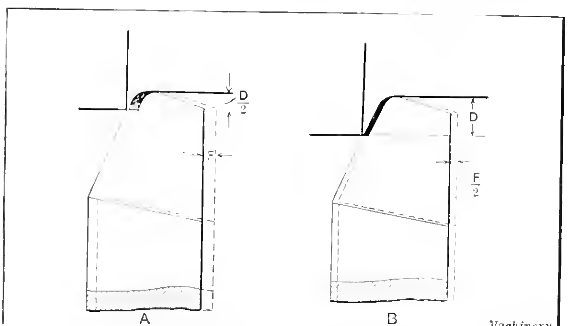

Fig. 7. Diagram showing Effect of Depth of Cut and Feed on Length of Cutting Edge in contact with Work

a maximum which the tool will stand without fracture, with the depth of cut a large factor and the associated speed correspondingly low.

To determine the effect of a change in the relation between the cutting edge of the tool and the axis of the test-bar, tools having shapes as indicated by the dotted and full lines in Fig. 8 were used. The same conditions as to the test were adopted in each case. It was found that for a given depth of cut the cutting speed was directly proportional to the length of the cutting edge of the tool in contact with the work; that is, a proportionately greater output with a tool having a longer cutting edge was obtained. In all other respects the angles of the tools were the same.

For an area of cut 1/8 inch by 1/12 inch, the cutting speed which would allow a tool to last one hour was found to be 78 feet per minute for high-speed steel, and 8 feet per minute for plain carbon steel, on a bar having a tensile strength of about 25 tons per square inch; that is, the high-speed tool removed ten times as much metal as the plain carbon tool in a given time.

Relation of Motor Power to Output

To determine the relation existing between the area of cut, the speed and the actual horsepower required, tests were made on different bars with various depths of cut and feeds and their associated cutting speeds. The power consumption was obtained by taking voltmeter and ammeter readings when the cut was in and also when it was not in, the speed being the same in each case. The net horsepower or power required for the actual cutting was calculated from the difference between the two readings. The results showed that the actual net horsepower required to remove a given number of cubic inches per hour is a constant for each quality of steel machined. In other words, the output per horsepower-hour is practically a constant quantity; that is, for a given output per hour nothing is gained in net power consumption by altering the ratio of the area of cut to the speed of cutting, the net horsepower being approximately directly proportional to the output only.

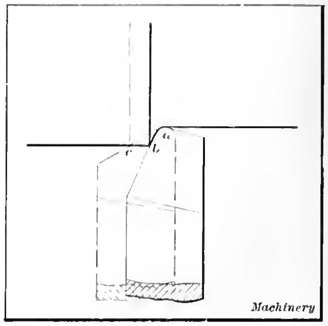

Fig. 8. The Tests showed that a Tool with a Short Cutting Edge a-b in contact with the Work cannot be used with as High a Cutting Speed as a Tool having a Longer Edge as at a-c

A SUGGESTION SCHEME

About two years ago the Automatic Electric Co., manufacturer of automatic telephone apparatus, Chicago, Ill., adopted a suggestion plan for its employes which has worked out satisfactorily. A suggestion form is supplied upon which all foremen are required to report at least once a week. They may send in one or a dozen of these forms, but one is the minimum, and it must either give a suggestion or the words "No suggestion to make this week." When a suggestion is received, the factory superintendent notes it and refers it to an engineer, who makes an investigation. The engineer obtains opinions from the employes affected and reports as to the changes in equipment necessary to put the plan into operation, giving an estimate of the saving that would result. With these data, the suggestion is returned to the factory superintendent for approval or rejection. A notice is then sent to the maker of the suggestion, advising him of the action taken and informing him of the reasons if his suggestion has been rejected.

During the past six months a modification of the plan has been tried, whereby a special subject for suggestions during certain periods is announced. The employes are informed that while suggestions on any subject will be appreciated, special attention is invited to the one named. The following subjects have been dealt with in this way. 1. Safety First. 2. Water, Light, Power and Gas. 3. Bonus Work. 4. Care of Materials. 5. Inspection. 6. Material and Finish. 7. Scheduling Work, Chasing, Requisitioning and Transferring Stock.

Substantial benefits have been realized from the suggestion plan, for while the company's plant was planned and systematized by efficiency experts of recognized ability, it has been found that the "man on the job" is often able to improve the details of the general system, thus materially adding to the efficiency of the methods employed and eliminating many causes of waste and expense. The plan has the additional value of giving employes a keener interest in their work and providing a useful channel for the criticisms always offered by workmen.

GAGING WATCH ESCAPEMENTS*

A COMPLETE SET OF GAGES FOR WORK OF UNUSUAL REFINEMENT

BY DOUGLAS T. HAMILTON†

The detached lever escapement is considered by horologists to be one of the most difficult parts of a watch movement to manufacture, because of the important function it fills in the proper timing of a watch. It transforms the rotary motion of the train of wheels into the vibratory movement of the balance, and at the same time acts as a brake to prevent the watch mechanism from "running away," retarding the motion of the wheels, and imparting the correct movement to the hands on the dial. To design an escapement properly requires not only considerable experience in this work, but also a clear understanding of the functions that this important part of a watch has to fill. The conditions are never ideal, so a compromise must always be made in order to obtain an escapement which fills the most important requirements.

As the functions and requirements of a watch escapement were described in an article on "Watch Movement Manufacture—1" which appeared in the May, 1912, number of MACHINERY, it will not be necessary to enlarge on them here, the chief aim of this article being to illustrate and describe the manner in which theoretical requirements obtained by calculation are brought down to a practical working basis. This is the problem with which horologists always experience difficulty. Drawings are first made on a scale of fifty to one, and all dimensions are obtained mathematically where possible. Reducing and producing a watch escapement with the accuracy defined by a mathematical calculation is not an easy matter.

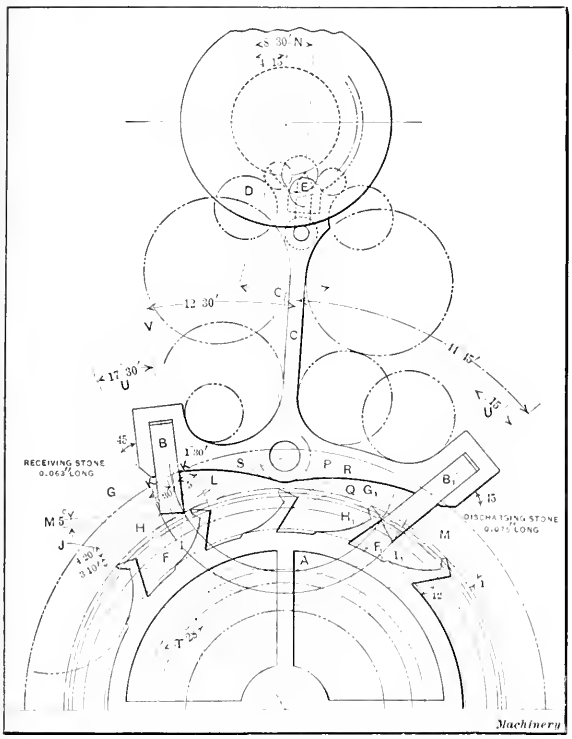

Fig. 1. Diagram illustrating Method of analyzing a Detached Lever Watch Escapement

The first step in producing a watch escapement, as mentioned, is to lay it out on paper on an enlarged scale of fifty to one, and then by means of certain parts outlined on tracing cloth, to study the movements in the manner that they take place in the watch. The proper manufacture of an escapement does not end here, and in fact the most difficult work—producing the various parts correctly—is still to follow. Several schemes are adopted in different watch making plants to check up the machining operations in order to determine whether they have been properly executed or not.

The Projector Method

One method which is used to a considerable extent is to employ a projector (an instrument designed on the principle of the magic lantern) to project and enlarge the escapement in order to determine if the machining operations have been correctly done. The escapement to be projected is placed on a pane of glass set in the frame of the projector where it is held flat against the surface of the glass by a spring. The projector is then placed in a dark room in such a relation to a screen as to obtain an enlargement of the escapement of ten diameters. The screen used generally consists of a sheet of drawing paper and the outine of the projected escapement is traced with a pencil. This sheet is then removed and the various functions, angles, etc., of the escapement are measured on this enlarged scale. The drawing paper may be replaced by a photographic plate and a photograph taken, but this process requires considerable time and is very seldom used except in horological schools, when a large number of copies are to be distributed to the pupils to study. Manufacturers, as a rule, simply make a drawing of the projection.

Fig. 2. Gage for measuring Different Angles on the Escape-wheel Teeth

The Microscope with Illuminated Chamber

The second method consists of a microscope with an illuminated chamber, mounted in such a manner as to give an enlargement of ten diameters and provided with a prism and a mirror, enabling the object to be set outside the microscope in order that its projection may be traced. The microscope is furnished with a screw, the barrel of which is provided with 100 divisions and enables measurements to be obtained to one thousandth millimeter. The lever escapement thus enlarged ten times with the aid of the microscope is then analyzed. The calibrated screw is used to check up the dimensions.

Method of Gaging Escapements Employed by the South Bend Watch Co.

The third method, and the one to be described here, is that used by the South Bend Watch Co., South Bend, Ind. This method consists in using gages which are very accurately made for measuring the various functions and members of a watch escapement. While the two methods previously described would seem to be scientific in their exactness, there is always a question in the mind of the mechanic as to the practicability of this procedure in work of an interchangeable character. There is little, if anything, to be gained by using methods of measurement which are much more accurate and worked down to greater degree of refinement than it is possible to obtain when manufacturing the parts on a commercial basis. For instance, by means of the microscope and illuminating chamber it is possible to obtain dimensions to within one thousandth millimeter. To duplicate this ac-

* For information on watch making previously published in MACHINERY, see "Watch Movement Manufacture" in the May and June, 1912, numbers, and articles there referred to.
† Associate Editor of MACHINERY.

curacy on thousands of parts produced with cutters in a mechanically operated machine is practically an impossibility. One piece could probably be made, but the slightest wear on the cutters would mean that this refinement would be lost. Gages can be made of sufficient accuracy to check up any variations in the work that may occur due to the wear of cutters or improper setting. Furthermore, the gages are at all times at hand to test the parts and determine just as soon as a slight error creeps in. If gages were not furnished it would be necessary to test the parts at short intervals as previously described, which would not only be impracticable but would not fill the requirements of the case.

In order to make the following description of the gages clear, reference should be made to Fig. 1 in which the various members of a detached lever escapement that require consideration are clearly outlined. These various members are indicated by letters, the functions and names of which are as follows: *A*, escape-wheel; *B*, receiving pallet stone; B_1, discharging pallet stone; *C*, fork; *D*, roller; *E*, impulse pin; *F*, impulse face of receiving stone; F_1, impulse face of discharging stone; *G*, locking face of receiving stone; G_1, locking face of discharging stone; *H*, locking corner of receiving stone; H_1, locking corner of discharging stone; *I*, releasing corner of receiving stone; I_1, releasing corner of discharging stone; *J*, lift of pallet; *K*, circular impulse; *L*, drop; *M*, lock; *N*, arc of impulse fork; *O*, arc of impulse of roller; *P*, impulse face of escape wheel tooth; *Q*, locking face of escape wheel tooth; *R*, locking corner of escape-wheel tooth; *S*, releasing corner of escape-wheel tooth; *T*, locking angle of escape-wheel tooth; and *U*, draft angle of pallet stone.

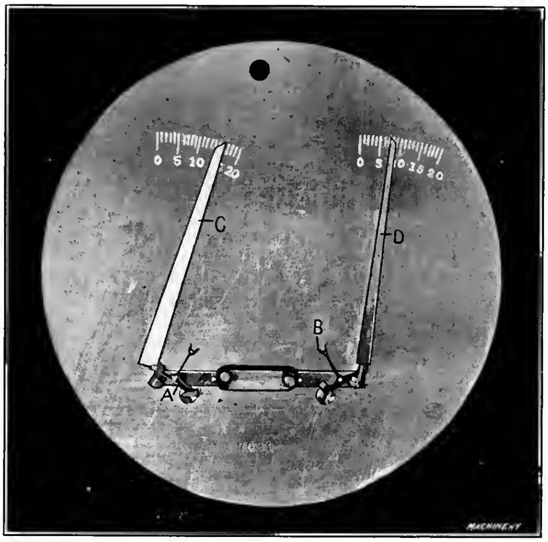

Fig. 3. Gage for measuring Position of the Forks, Pallet Stones, etc., of Detached Lever Escapement

Each one of these conditions and functions of the detached lever escapement must be checked up after machining in order to determine if the requirements secured by graphic methods and mathematical calculations have been obtained. The first gage which is used is shown in Fig. 2; the object of this is to measure the different angles on the escape-wheel teeth. It measures the angle that the impulse face *P* of the escape-wheel tooth makes with a tangent to the periphery of the escape-wheel at the releasing corner *S*; it measures the angle that the locking face *Q* of the escape-wheel tooth makes with a radial line drawn from the center of the wheel to the locking corner *R*, and it also measures the periphery diameter of the escape-wheel teeth. Straightedges *B* and *C* are used to measure the angles of the escape-wheel teeth and are set by plugs placed in the centers of the recesses, the radii of these plugs being the sines of the angles to be measured. When it is stated that one ten-thousandth inch of variation can be clearly indicated on a gage provided with knife-edge straightedges similar to that furnished on this gage, it will be evident that this method of gaging is practically as exact a method as it is possible to obtain; at least, it is close enough to check up any errors in machining which would affect the efficient working of the escapement.

The circular gage shown in Fig. 3 in which two forks *A* and *B* are located on pins is used with the aid of straightedges *C* and *D* to measure the draft angle *U* of the pallet stone, and also the angle that the impulse face of the stone makes with a line *V* passing through its center. (See Fig. 1.) This gage also measures the distance from the center of the pallet to the locking corners *H* and H_1 and the releasing corners *I* and I_1 of the pallet stones. It will be seen in this particular case that the draft angle of the receiving stone measures 15¾ degrees, and the draft angle of the discharging stone 7¼ degrees.

The third circular gage shown in Fig. 4, upon which the completed escapement is held, is used for the following measurements; Impulse face *F* and F_1 of pallet stones; the drop *L*; the lock *M*; the arc of impulse *N* of the fork; the arc of impulse *O* of the roller; the recoil of the escape-wheel in unlocking the slide or run of the escape-wheel; and the side shake of the impulse pin in the fork slot. These circular impulses of both wheel teeth and stones are taken as angular measurements from the center of the escape-wheel. The three needles, the correct positions of which are indicated on this gage, give readings as follows: The circular impulse of the

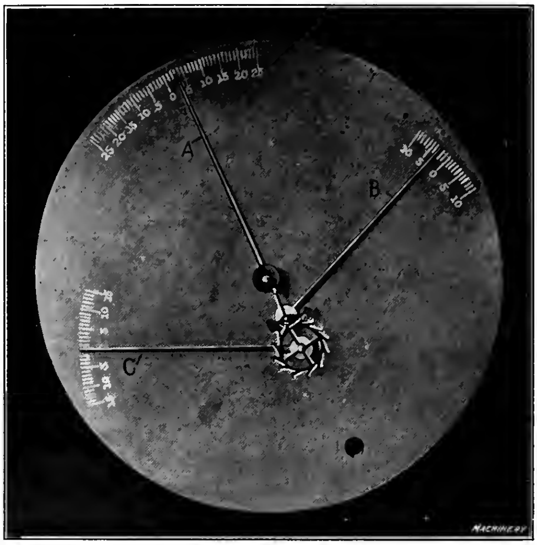

Fig. 4. Gage for measuring a Complete Assembled Escapement

pallet stone is 5½ degrees; the circular impulse of the wheel tooth 5 degrees; the drop ½ degree; and the lock 1 degree. The positions of the needles *A*, *B* and *C*, as shown in Fig. 4, have a meaning only when compared with their positions before the action of the escapement took place. The office of these needles, therefore, is to measure the angular distance at the beginning and at the end of each action.

By the use of these three gages all the functions of the detached lever escapement that it is desirable to know may be measured. An escapement can be taken from a watch and measured at every particular point. Furthermore, these gages are not made until an escapement has been produced which works as efficiently as it is possible to make it; then the various parts of the escapement are removed and the gages made to them, ideal conditions being realized in this way. It is also possible by the use of these gages to construct a perfect working escapement from a very much enlarged drawing with the positive assurance that it will be an exact miniature. This latter method, looking at it from a mechanical standpoint, would appear to be much more practical and exact than those previously described.

Telegraph poles of glass are being used in Germany with success. Woven wire is imbedded in the molten glass to reinforce the pole.

PROFIT-SHARING PLAN OF FORD MOTOR CO.

Probably no wage change made by a manufacturing concern has ever attracted more widespread attention than the profit-sharing plan of the Ford Motor Co. of Detroit, Mich. Henry Ford, head of the company, announced January 5 that his company would give to the employes $10,000,000 of the profits of the 1914 business, the payments to be made semi-monthly and added to the pay checks.

The factory will be run continuously instead of only eighteen hours a day, giving employment to several thousand more men by employing three shifts of eight hours each, instead of only two nine-hour shifts, as heretofore. A minimum wage scale of $5 per day will be established. Even the floor sweepers are included. Before any man in any department of the company who does not seem to be doing good work shall be discharged an opportunity will be given to him to try to make good in every other department. No man shall be discharged except for proved unfaithfulness or irremediable inefficiency.

The company's financial statement of September 20, 1912, showed assets of $20,815,785.63 and surplus of $14,745,095.57. One year later it showed assets of $35,033,919.86 and surplus of $28,124,173.68. Dividends paid out during the year, it is understood, aggregated $10,000,000. The indicated profits for the year, therefore, were about $37,597,312. The company's capital stock, authorized and outstanding, is $2,000,000. There is no bond issue.

About ten per cent of the employes, boys and women, will not be affected by the profit sharing, but all will have the benefit of the $5 minimum wage. Those among them who are supporting families, however, will have a share similar to the men of more than twenty-two years of age. In all, about 26,000 employes will be affected. Fifteen thousand are now at work in the Detroit factories. Four thousand more will be added by the institution of the eight-hour shift. The other seven thousand employes are scattered all over the world, in the Ford branches. They will share the same as the Detroit employes.

"It is our belief," said James Couzens, treasurer of the company, "that social justice begins at home. We want those who have helped us to produce this great institution and are helping to maintain it to share our prosperity. We want them to have present profits and future prospects. Thrift and good service and sobriety, all will be enforced and recognized. Believing as we do that a division of our earnings between capital and labor is unequal, we have sought a plan of relief suitable for our business. We do not feel sure that it is the best, but we have felt impelled to make a start, and make it now. We do not agree with those employers who declare, as did a recent writer in a magazine in excusing himself for not practicing what he preached, that 'movement toward the bettering of society must be universal.' We think that one concern can make a start and create an example for other employers. That is our chief object."

"If we are obliged," said Mr. Ford, "to lay men off for want of sufficient work at any season, we purpose to so plan our year's work that the lay-off shall be in the harvest time, July, August and September, not in the winter. We hope in such case to induce our men to respond to the calls of the farmers for harvest hands, and not to lie idle and dissipate their savings. We shall make it our business to get in touch with the farmers and to induce our employes to answer calls for harvest help. No man will be discharged if we can help it, except for unfaithfulness or inefficiency. No foreman in the Ford Motor Co. has the power to discharge a man. He may send him out of his department if he does not make good. The man is then sent to our 'clearing house,' covering all the departments, and is tried repeatedly in other work, until we find the job he is suited for, provided he is honestly trying to render good service."

It is impossible for anyone to accurately predict what the ultimate effect of this remarkable profit-sharing plan will be on the industrial conditions of the United States. Let us hope that it marks the dawning of a brighter day when labor and capital will share more equally in the profits of industry, but that such a consummation will directly follow is very doubtful. Whatever follows, one fact stands out clearly: The Ford Motor Co. has stamped itself and its product indelibly upon the minds of all classes the country over.

* * *

BRIEF HISTORY OF THE MOTOR CAR

An interesting description of early types of motor cars, and the industry's development from the seventeenth century, has been written by Walter H. Whiteside, president of the Stevens-Duryea Co. An abstract of the article follows:

The first experiments with "horseless carriages" that met with any degree of success were made in the seventeenth century, when Johann Haustach of Nuremberg constructed a carriage propelled by springs. There was no steering device, but the car would travel in a straight line when wound up. During the same period vehicles to which sails were attached were used in Holland. In 1619 another spring-driven carriage referred to in the patent paper as a "cart without horses," was patented in England, and in 1644 a French patent was issued on a four-wheel carriage propelled by foot-power. In 1748 a carriage driven by clockwork was exhibited before Louis XV of France. Several others experimented with spring drives up to the year 1800, but with little success.

Steam was first used in a road carriage in Pekin, China, in the year 1630. History credits Father Verbiest, a missionary, with achieving this feat. This was followed in 1680 by Sir Isaac Newton's steam carriage. In 1769 a steam gun carriage was built in France. It had three wheels, was driven by a two-cylinder engine, and traveled three miles per hour when loaded with 2½ tons. In 1787, Oliver Evans of Maryland invented a steam road wagon, and Nathaniel Reed, in 1790, constructed a combined road wagon and boat at Pecousic, Mass. These two men were the first ones to build steam carriages in this country that would successfully propel themselves. The first steam carriage in which the crankshaft was geared to the driving wheel was invented by Richard Trevithick in England in 1802. In 1831 a steam-driven carriage was operated between Cheltenham and Gloucester, England. This carriage could run twelve miles an hour, but the service was discontinued after four months, owing to public opposition. Walter Hancock established a steam omnibus line in 1829. His was the first chain transmission vehicle invented. In 1836 five of these carriages were operated between Paddington and Stratford, and, in twelve weeks, 12,760 passengers were carried. This line was practically forced out of business by the English government, because of a toll law with taxes so high that none could afford to run cars. This law arrested further development of the horseless carriage until its repeal in 1846.

In France in 1880 a steam carriage was built which, as late as 1895, ran 745 miles in 90 hours. In 1886 the first gasoline engines were used on road vehicles. These were the invention of Carl Benz and Gottlieb Daimler of Germany. In 1889 a two-cylinder engine was invented by Daimler; Messrs. Panhard and Levassor of Paris immediately acquired the patents and built around the engine the first gasoline motor car. The Panhard car was quickly followed by the Renault Freres and the Benz. To J. Frank Duryea belongs the distinction of being the first American to turn out a successful motor-driven vehicle. The first car was completed at Springfield, Mass., in 1891, and was equipped with a one-cylinder motor. In 1894 a vehicle propelled by a two-cylinder engine was built.

In view of the present magnitude of the automobile industry, it hardly seems possible that the first automobile factory in the United States was started only twenty-two years ago, this being the factory established by J. Frank Duryea at Springfield, Mass. Today there are over 500 factories with an estimated annual output of 350,000 cars.

* * *

The turbines which will drive the new mammoth Cunarder *Aquitania* will have a total weight of 1400 tons. There are over a million turbine blades in the rotors, the combined length of which is about 140 miles. The blades vary in length from 1½ to 20 inches.

A VISIT TO THE WINDSOR CLUB

It was real winter when I stepped from the train in Windsor, Vt., up among the Green Mountains. Ten inches of snow lay upon the ground and the thermometer was slowly climbing to the zero point from six degrees below. On the way over to the club-house, Mr. Gridley, the manager of the Windsor Machine Co., explained the why and wherefore of the company's plan. He said that when it was realized that the old plant was too small and that adjacent land was not available, the company had built the new plant at a more advantageous location near the railroad. The old building was left idle, and as a manufacturing plant of its size had no market in Windsor, the decision was made to turn it into a club-house for the employes and those of the town people who cared to use it. A very good reason for the establishment of the club-house, Mr. Gridley went on to say, was that good boarding houses in Windsor were scarce, and the prices asked for board were exorbitant. It thus became imperative, in order to keep good men at the works, to provide a satisfactory boarding place for them, so it was decided to establish this permanent club where such of the employes as desired could reside and get good accommodations at a reasonable price.

The first illustration shows the club buildings after they had been transformed from the old factory. The addition of a veranda and a front entrance greatly improved the appearance, and as soon as I had stepped in the front door I became aware of a real home atmosphere. The lobby walls and ceilings have been panelled with art-board, using the color scheme of red and white for the walls and brown for the ceiling. This treatment prevails throughout the building and it forms an ideal way of covering the unsightly walls of an old factory. An attractive feature of the lobby is the fireplace, in front of which a jolly group of the men was gathered.

Fig. 1. The Windsor Club—showing what can be done with an Old Factory Building

Passing out into the reading and writing room, I found a few of the men writing letters and others looking over copies of the current magazines. But before we could go farther, the call for dinner was announced and we entered the dining-room. This room, by the way, was formerly the lathe department of the old factory, but a new hard-wood floor, panelled walls and ceilings and modern lighting arrangements have given it an entirely different aspect. There are accommodations for seventy-five or eighty boarders; the bill-of-fare is good and low rates are charged. The ability of the chef was attested by the meal, and the sirloin steak served would have done credit to the best metropolitan hotel.

In fact, the dinner and the service were so good that I expressed a desire to look through the kitchen, so Mr. Gridley volunteered to take me out. Here are the latest types of cooking apparatus, steam kettles, hotel range, dish-washing machine, etc., and the bakery, which is adjacent, is also fully equipped. To supply ice for the eight- by twenty-foot refrigerator, an ice machine has been installed, and a glance into the ice-box showed how well the provisions are kept in condition for the dining-room.

From this point on, Mr. Cone, the factory manager, conducted me into the club-rooms proper. Mr. Cone has been especially interested in this feature of the project, and he explained as we were sitting in the arm chairs with which the main hall is furnished that the club features had as much to do with the success of the establishment as the hotel end of it. In this hall a dance is held once a week on which the interest of the entire town is centered. Besides, there are occasional concerts, and at the present time a lecture course is going on. The hall is attractively finished with white ceilings and walls and well lighted with electricity. More reading tables are provided here and except on dance nights the room has the appearance of a general recreation room. The superintendent of the club has his desk here and has a general oversight of all that goes on. A game of pool shortly after convinced me that the pool table equipment and accessories are first-class.

On the way out to bowl a few strings on the alleys, Mr. Cone showed me the modern laundry in which the needs of the hotel and club are cared for. The up-to-date washing machine and mangle comprise part of the equipment. Nearby are shower baths for the club members, which are greatly appreciated, especially during warm weather. When the company erected the new plant, a new power plant, heating and electric lighting equipment was installed. As the old apparatus was left in place in the old building, it was utilized. I found the bowling alleys, of which there are four, are of modern construction, regulation size and equipped with bottle, candle and duck pins. Rows of spectators' seats are provided at the rear and the alleys present an animated scene every evening. By providing features of this kind the management has assured that the leisure time of employes will be pleasantly and healthfully spent.

"The Windsor Machine Co.," said Mr. Cone, "gives employment to several hundred men, most of whom are skilled workmen who must naturally come from out of town." He stated that time after time they had secured good men whom they would have liked to retain but when those men found how poor the boarding accommodations of Windsor were, and how little was the chance for recreation, they soon left their jobs for others in larger cities. Since the institution of the club-house, the condition has changed and men are contented; in fact the club has proved to be a decided attraction for desirable men.

The fitting up of the club represents several thousand dollars expenditure, and though fourteen people are employed and it is open from six in the morning till eleven at night seven days in the week, it is practically self-supporting. The rates charged for board and room are remarkably low, considering the accommodations given. An excellent room with hot and cold water, including meals, costs $6.50 per week. The club also caters to the traveling public, automobile parties, etc., and for such the rate is $2.50 per day for board and room, and all guests are furnished with cards admitting them to the privileges of the club.

The dinner, inspection, bowling and chat made a pleasant evening all too short. I was conducted to a room on the second floor to spend the night. There are forty rooms and more are being constructed. They are all built in what was formerly the large second floor machine shop, and a new floor had to be laid, the walls sheathed and partitions put up. The connecting bath was a refreshing convenience that a traveler fully appreciates, and so comfortable was my bed that sound sleep was broken only when my next-door neighbor's alarm clock rang at 6:30. After a breakfast that well fortified one for the day's work, I bade adieu with reluctance to the Windsor Club, and returned to the grind of the great city.

COLD-HEADING—3

COLD-HEADING DIES AND TOOLS—POINTS IN THE TOOLMAKING—SETTING UP A COLD-HEADER

BY CHESTER L. LUCAS* AND E. W. DUSTON†

In the first two installments of this article published in the May and July, 1913, numbers of MACHINERY, the principles and different types of cold-heading machines were treated, together with the character of work for which each machine was adapted. In this number we will consider in detail the tools for solid- and open-die machines, including an outline of the operations connected with their making. As there are numerous little kinks and methods followed by individual heading die makers, it will only be possible to strike an average and outline the general processes of making the tool. As in other lines of toolmaking, no two workmen's ideas on a given set of tools will agree, although each may be right from his own point of view.

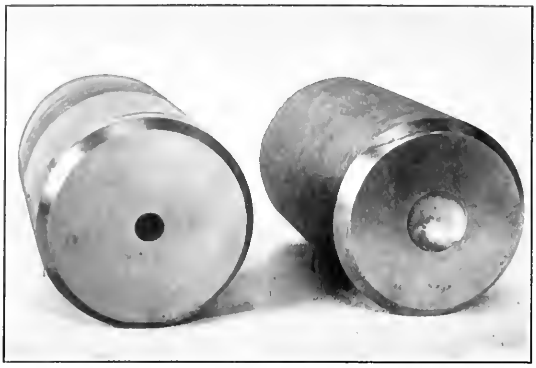

Fig. 28. A Pair of Solid Dies for the Cold-header

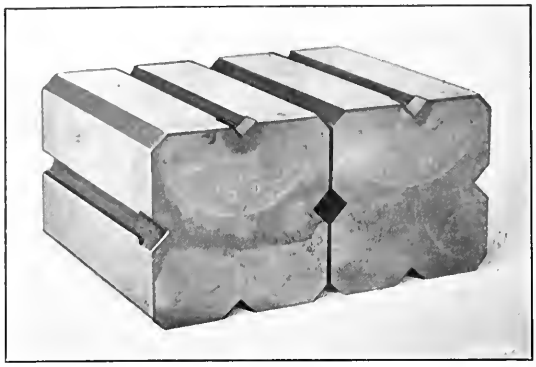

Fig. 29. A Pair of Open Dies for the Cold-header

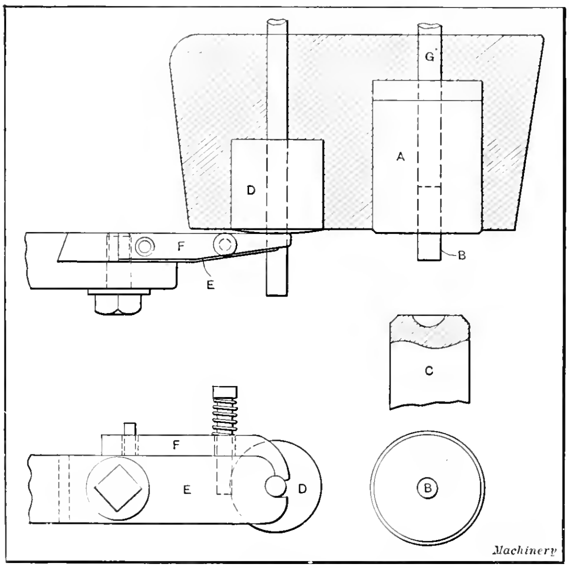

Fig. 30. Section of Cold-header showing Locations of Principal Tools

Tools for cold-heading machines may be roughly divided into two classes—those used in solid-die machines and those used in open-die machines. Whether the tools are for a single- or double-blow machine affects only one extra tool, namely, the upsetting or coning punch. In all other respects the tools are similar. The chief difference between the tools for the solid-die and open-die machines lies in the dies themselves, the punches being the same in both cases. Figs. 28 and 29 illustrate the difference between dies for the solid- and open-die machines. Fig. 28 shows a die and punch for a solid-die machine. These tools are very simple, being merely sections of round stock, the die being made with a hole to agree with the diameter of the wire, and the punch with a cavity of the correct shape for forming the head. In Fig. 29 a pair of open dies, without the punch, is illustrated. In this case the wire is held between the halves of the die, and the cutting off is done by the dies themselves, as was explained in the May installment. Therefore a pair of dies for the open-die machine must be of exactly the same length as the finished rivet under the head. The dies shown in Fig. 29 were made for forming a carriage bolt having a square shoulder under the head. By referring to Fig. 30, a set of tools for a solid-die machine may be seen in place. These consist, in the case of a single-blow machine, of the die *A*, in which the wire blank *B* is held for heading; the punch *C* which shapes the head and is actuated by the ram of the machine; the cut-off die or quill *D*, which is similar to the heading die, having a hole through its length through which the wire is fed against a feed-stop (not shown) the proper distance, and is then cut off by the cut-off blade *E*. The face of the cut-off die is crowned to help the cut-off blade do its work. Mounted on the cut-off blade is a carrier *F* that holds the blank to the cut-off blade so that it may be carried over to the heading die. A backing pin *G* fits in the hole in the heading die and regulates the length of the rivet under the head; it also serves as an ejector after the rivet has been finished. In Fig. 33 may be seen a set of heading tools,

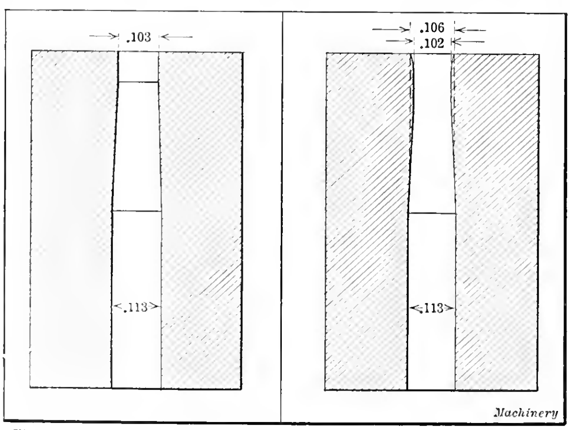

Fig. 31. Section of Solid Die showing Allowances left for Hardening Fig. 32. Section of Solid Die showing Usual Shrinkage in Hardening

with the exception of the cut-off quill. These particular tools were used in making a round-head screw that required two blows to form the head. The die is shown at *A*; the second-operation punch at *B*; the first-operation punch at *C*; the backing pin at *D*; and the cut-off blade without the carrier at *E*. At *F* may be seen the cut-off blank; at *G* the coned blank

* Associate Editor of MACHINERY.
† Chief draftsman, Blake & Johnson Co., Waterbury, Conn.

resulting from the first operation; and at *H* the finished round-head screw. If this same job were to be used in an open-die machine the cut-off blade and the backing pin and die would be eliminated and a pair of open dies substituted.

Making a Solid Die

At first glance, the solid die appears to be simply a round piece of stock with a hole extending through it to receive the wire. There are, nevertheless, many points to be considered in making this die, and without the knowledge of them the tools would never work satisfactorily. The heading dies, punches and cutting-off tools are made from a good grade of tool steel, annealed stock being preferred. The tools are sometimes made of low carbon steel and then carbonized, and at least one large user of heading machines follows this method exclusively, but unless the best of carbonizing and hardening facilities are available it would be inadvisable.

The length and diameter of a heading die are governed by the size of the machine in which the die is to be used. An idea of the proportion of the diameter to the length may be obtained by stating that for handling wire up to 1/8 inch

Fig. 33. A Set of Heading Tools and Work from a Double-blow Cold-header

diameter, a die of 7/8 inch diameter by 1 3/8 inch long agrees with good practice, and for handling 1/2 inch wire, the die may be 3 3/8 inches in diameter by 4 1/2 inches in length. These dimensions are not arbitrary, but are, of course, determined by the make and size of the machine in which they are to be used. In Fig. 35 is illustrated a little kink by means of which considerable die-steel may be saved. In this case a backing block is made to replace about one-third the length of the die. The dies themselves may thus be made

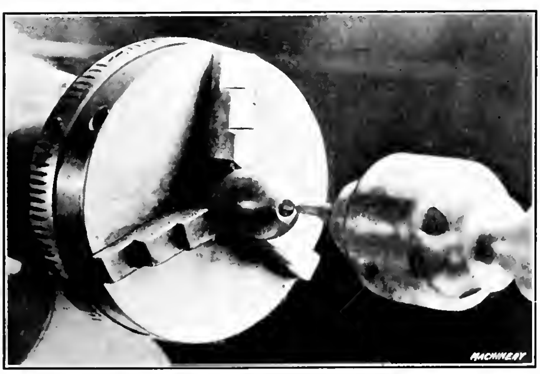

Fig. 34. Reaming out a Coning Punch

correspondingly short, and as this pillar block is used beneath each die, one-third of the steel of each heading die is saved.

Fig. 31 shows, in section, a typical heading die of the solid type, just made and ready for hardening. This die is given with actual dimensions so that the shrinkage allowances may be duly noted. The length of the die is 1 3/4 inch and the diameter 7/8 inch, and it is to be used for heading rivets from 0.105 inch wire. First, a hole a few thousandths under 0.105 inch diameter is drilled through the die. The die is then relieved from the back for a short distance with a No. 33 drill, enlarging this section to 0.113 inch. A tapered reamer which has a taper of about 0.003 inch to the inch is then used to ream out the unrelieved section very nearly to the face of the die. At this point the die is hardened and this operation causes the mouth of the die to "open," leaving it about as shown in Fig. 32. Using emery and oil, the die is then lapped out from the back until the hole measures 0.106 inch diameter, this being 0.001 inch over the diameter

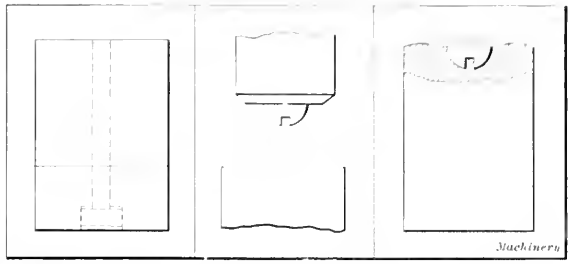

Fig. 35. A Kink for saving Die Stock Fig. 36. A "Hub" and a Punch Blank Fig. 37. Punch after hubbing

of the wire, allowing plenty of play for the working of the stock.

The hardening operation is comparatively simple, the requirements being to have the die, especially the section adjacent to the hole, very hard. A useful kink to be followed in securing the desired hardness is illustrated in Fig. 44. This consists of a funnel shaped bushing which is threaded so that it may be screwed onto the ordinary water faucet. The die is brought to the right heat and held under this conical bushing and the water turned on full force. When

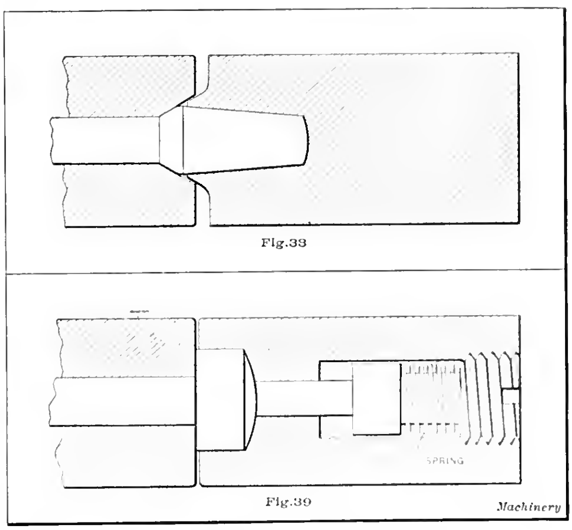

Fig. 38. Coning Punch relieved to force Wire into the Countersunk Head of the Die
Fig. 39. Spring-pin in Punch which facilitates Ejection

the water is turned on, the face of the die and the hole receive a sudden quenching, giving it the extreme hardness that is necessary.

The Punches

Before a punch can be correctly made for any rivet except a "flat-head" a counterbore is necessary to obtain the exact shape of the cavity. In the case of flat-head screws or rivets, the punch consists simply of a length of round steel having a perfectly flat face with chamfered edges. With round or fillistered head blanks, however, the finish punch must contain a cavity of the exact size and shape of the head. In making a punch like that shown in Fig. 33 for a round-head rivet, a reamer of the same semi-spherical shape is necessary. The reamer is turned up in the lathe, leaving a flat shoulder to limit the depth of the cut. The "half-type" reamer is employed, and is relieved only for a short distance behind the cutting edge so that a good bearing is secured while the

punch is being reamed, resulting in a smoothly finished cavity. In hardening these reamers they are drawn to a straw color. In the case of difficult shaped heads, it is often found advisable to hammer a piece of lead into the soft die so that measurements may be taken and checked up with the sample. Weight forms an important feature in determining the amount of metal which goes into the head. In setting up the machine, for instance, the toolmaker will often compare the weights of his rivet and the sample in order to see if the right amount of stock is being used. By cutting off the head close to the shoulder and weighing it, he can determine the amount of stock required, and by balancing the head with an equal weight of wire stock, he can readily determine the distance to which to set the wire feed.

In the case of double-blow machines, in which an upsetting or coning punch is used, there seems to be no definite rule that can be laid down for the shaping of the cavity in the coning punch. As before explained, the idea of the coning punch is to upset the metal and leave it in condition for the final distribution into the finished head. Generally speaking, this intermediate shape is that of a truncated cone, the base of which is very nearly the diameter of the finished head, and the length of which is about two-thirds the amount of wire advanced by the wire feed. The top of the wire is left approximately the same diameter as the blank and slightly rounded. If a very large amount of metal must be put into the head, the angle of the cavity in the coning punch is made as obtuse as possible. It is customary to relieve the coning punch about as shown at C in Fig. 33, the object being to remove all danger of interference with the cut-off blade, because the coning punch strikes the wire blank just as the cutting-off blade releases it; therefore it helps matters to have the cut-off blade relieved as well as the coning punch. When the coning punch is to be used in connection with a countersunk die for flat-head screws, it is relieved about as shown in Fig. 38. By so doing, the wire in the cone is supported and driven down into the countersunk section of the die, instead of being left out at the line of the die face. There are so many governing factors bearing upon the shapes of coning punches that it must be left largely to the judgment of the toolmaker. Punches for fillister head or other deep types of punches where the blanks would be likely to stick are often fitted with spring ejector pins as shown in Fig. 39. Ordinarily the die is the member in which sticking is most prevalent, but when the blank is short and the head is deep sticking will be encountered in the punch.

In the manufacture of very cheap screws, the slot in the head is often formed by the heading punch instead of being sawed. This means that the cavity in the heading punch must have a ridge of steel left standing to drive the metal down for the slot. To cut the cavity to this shape would be practically impossible; therefore the common practice is to

Fig. 40. Drilling out a Solid Die

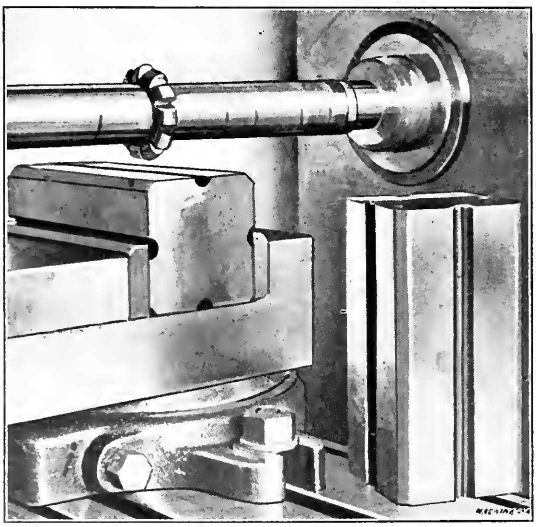

Fig. 43. Milling the Grooves in Open Dies

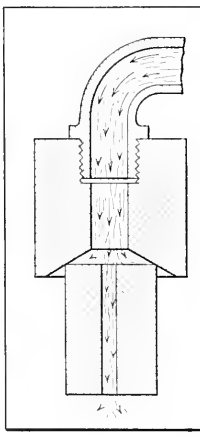

Fig. 44. A Method of hardening Solid Dies

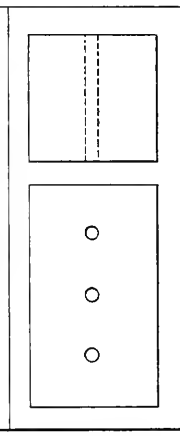

Fig. 45. Multiple Die of Square Type

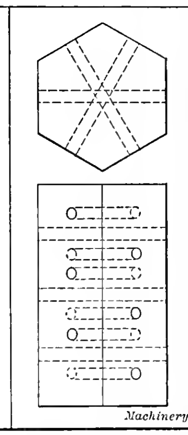

Fig. 46. Multiple Die of Hexagonal Type

hub the punch. The hub is made by turning up a blank of steel with a face of the same shape as the head of the screw to be produced. A slot is then milled or filed in the center of the head of the hub, after which it is hardened and drawn to a straw temper. Before being hubbed, the face of the heading punch is first convexed so as to leave the highest point at the center, thus providing enough stock to make a well formed cavity. The tendency is for the metal in the punch to sink away from the slot in the hub; therefore by leaving an excess amount of metal at this point, the slot is completely filled when the punch is hubbed. After being hubbed, the punch is faced off, of course, and the sides turned up for hardening. Fig. 36 represents the hub and the punch-blank before hubbing and Fig. 37 shows the hubbed punch before being faced off.

The Cut-off Tools

The cut-off die is simply a section of round stock having a hole extending through it slightly larger in diameter than that of the wire being worked. On small sizes of wire 0.001 inch is enough clearance. The face of this die is crowned slightly so that the cut-off blade which works in conjunction with it may act without binding on any other part of the die face. The cut-off blade is shown at *E* in Fig. 30, from which it will be seen that the end is filed out U-shaped, so as to partly enclose the wire, thus supporting it while the cutting-off operation is taking place. A spring-finger *F* is fitted to the cut-off blade that snaps over the wire when the cut-off blade advances to the cutting and holds the blank so that it can be carried to the heading die. There are different methods of applying the spring-finger or carrier, but a good way is illustrated in Fig. 30. Here the spring pressure is supplied from the spiral spring over the stud near the center, while the pin at the end operates in an enlarged hole in the finger serving merely as a guide to prevent the finger from swiveling. Both cut-off die and blade are hardened and drawn to a straw temper. There is little to be said about the backing pin which is shown at *D* in Fig. 33 except that as it receives the full force of the heading blow, it must be hardened and drawn to a very dark purple.

Tools for Open-die Machines

The only explanation required for tools for the open-die machines is the operations connected with the making of the die halves. These, which are illustrated in Fig. 29, are made by shaping up square sections of tool steel to fit the die-holding block of the header. The halves of the die are left large enough in size to allow for grinding, and down the center of each face is milled a half-round groove of a size slightly less than the diameter of the wire which is to be handled in the header. After the bulk of the stock has been milled out in this manner, as shown in Fig. 43, the halves are clamped in a special holder illustrated in Fig. 41 and a reamer of the proper size is run through the hole, taking half the stock from each die face. Set-screws are provided on the die-holding box to clamp the two halves together and take up end play while this operation is being performed. Each of the four pairs of faces is treated in this manner and, of course, they are marked so that they can be mated readily. The object of having all four faces grooved is simply to make use of the other three sides of the die; thus as soon as one pair of grooves has worn out of round, the dies are simply turned to bring a new pair of faces into use. As was explained in the May installment, the object of chamfering the corners of the die halves is to facilitate the opening of the dies by the spring-finger on the machine. Fig. 42 shows the manner in which the square section of a die for producing a carriage bolt is machined. This square section comes under the head of the bolt and, therefore, must be provided for in the dies. After reaming out the grooves in the die faces the square outline is marked on each of the faces of the die, and the lines scribed for the depth. A starting point is made by chipping a groove at the proper distance from the face of the die, and the rest of the stock is removed by a square shaper tool, thinned down at the face to permit of its starting in the chiseled groove. Each of the faces of the two die halves is similarly treated. As with the solid dies, the open dies are hardened and the faces and sides are ground before being put into use. It is very important that the faces of the dies be properly ground so that they will

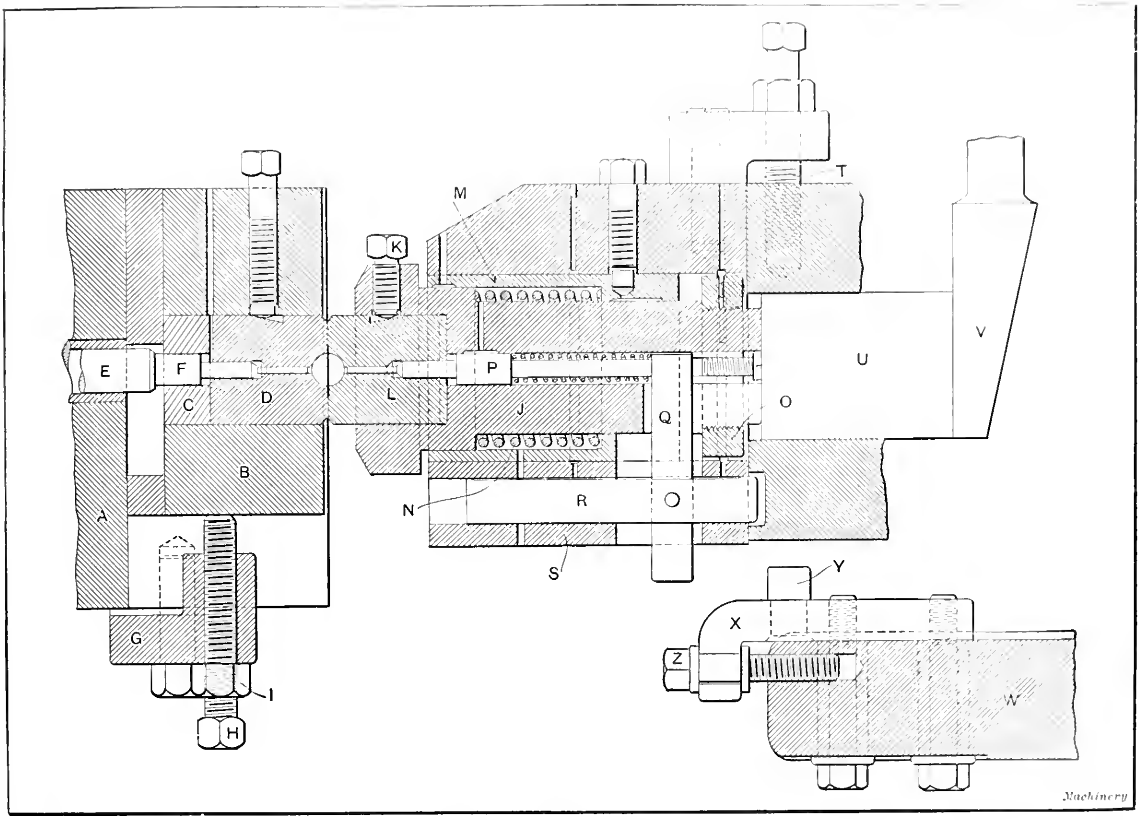

Fig. 47. Special Ball-header Tools

come close together and prevent the headed metal from bulging out in the form of fins on the sides of the work. In grinding the sides of the die halves, the stock taken off permits the faces to come together far enough to flatten the circular opening in which the wire is held. This provides the necessary clearance for gripping the wire.

Multiple solid dies are often made for the sake of economizing in steel. Examples of such dies are shown in Figs. 45 and 46. The die in Fig. 45 has three openings so that after one of them has been worn out of round, the die may be moved along in the special holder necessary to hold a square block and another hole put into use. If the work is such that the die can be made without clearance, the block can then be reversed and the opposite ends of the three holes used. Similarly, in Fig. 46 is a multiple die of hexagonal shape, providing eighteen working openings. As a general rule, however, multiple dies are not used, because of the trouble caused by special die-holders. The plan of reversing the die to use the opposite end of the hole has disadvantages on some work where the heading blows close the hole in so much that the necessary lapping out makes the method more troublesome than beneficial.

Setting up a Plain Job in the Header

In setting up a job in a solid-die header, the first step is to put in the cut-off die and adjust the cut-off blade. The blade is adjusted by snapping the finger over the wire, and while thus held it is clamped in position against the cut-off die. The die is next bolted into its seat and the backing pin adjusted to size the length of the rivet under the head. The finish punch, in the case of a double-blow machine, is then located in the punch-holder. The coning punch is next held in the punch-holder, and, if necessary, it is adjusted to bring its face into line with the finish punch. The finish punch should be set without backing or "shimming" of any kind, but if necessary the coning punch may be shimmed up to agree with it. The stroke is then adjusted so that the punch faces almost touch the die face. After this, the wire feed may be set and the machine is ready to be operated. On every job there is more or less adjusting of the feed, grip and ram movements to obtain the exact results.

In setting up the tools on an open-die machine there is, of course, no cut-off to be taken into consideration other than the proper setting of the die halves, as the cutting is done simultaneously with the movement of the dies. The operations of setting up the punches on the open-die machine are the same as on the solid-die machine.

Special Ball Heading Machinery

The E. J. Manville Machine Co. makes a special type of header adapted for forming ball blanks. The cold-header is an important adjunct to ball making. The principal feature is positive ejection for the ball blanks after heading, because ball headers operate at a very high rate of speed and positive ejection is absolutely necessary. A secondary advantage of this machine lies in its ability to handle positively the short ball blanks.

Fig. 47 shows a vertical longitudinal section taken through the working parts of one of these special ball headers. *A* is the frame or bed of the machine; *B* is the die-block of steel; *C* is a hardened tool-steel backing block for the die *D*; *E* is the backing or knock-out pin which backs up the smaller knock-out pin *F*; *G* is a cast-iron bracket screwed onto the under side of the bed to hold the adjusting screw *H* which raises or adjusts the die-block into the correct position for heading. A lock-nut *I* insures the adjustment. *J* is a tool-steel punch-holder having an enlarged head with a set-screw *K* for holding the punch *L*. The body of this holder is of smaller diameter than the head and is made a sliding fit in the bushing *M*. The holder is normally kept in its forward position under spring tension by means of the coil spring *N*. Two adjusting nuts *O* are on the back end of the holder. *P* is a small hardened tool-steel ejector pin, which is also kept under a spring tension, and is backed up by the bar *Q* that passes through the round rod *R* and is pinned in place. *S* is the punch-slide that carries the punch-holder and other parts shown and is adjusted by the screw *T*. The punch-holder is backed up by a solid block *U* that acts as a buffer as well as a filler between the holder and adjusting wedge *V*. *W* is a bar cast in the bed between the two sides carrying the adjustable bracket *X* that has the stop-pin *Y* and adjusting screw *Z*.

The action of the machine is as follows: The round bar or wire is fed in and cut off in the usual manner, and the cut-off blade carries the blank over to the heading die, but as there is no shank to be pushed into the die, as is the case with a longer blank or rivet, as soon as it is carried over, the gate or ram advances, and also the pin *F*. As pin *P* is under a spring tension the blank is very quickly seized between the two pins, and held in position until the gate has advanced far enough to hold and squeeze the blank into a ball.

After this the gate returns and when it has reached a certain position the bar or trigger *Q* strikes the pin *P* that acts as a knock-out, and ejects the ball if it clings to the punch; if it clings to the die the other ejector pin *F* ejects it.

It will be noticed that the pins *F* and *P* are not long enough to reach to the ball arc when under the heading pressure; this leaves slight projections on the two sides which can be removed easily, whereas if the pins were even slightly too long there would be flat spots left on the finished balls. The subject of cold-heading is almost inexhaustible, but these three articles have touched upon the most important principles and it is to be hoped that other articles will be contributed showing some specific cold-heading jobs and the tools and methods used in the production.

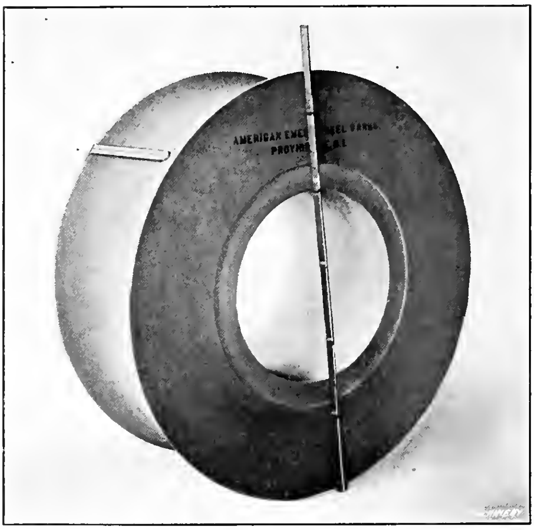
LARGE CORUNDUM WHEEL FOR NEEDLE GRINDING

The illustration shows a corundum wheel thirty-four inches diameter and thirteen and one-half inches face, made of corundum by the American Emery Wheel Works, Providence, R. I., for Worral Bros., Sheffield, England. The wheel, which was designed for an automatic textile needle grinding machine, was made by the vitrified process, and is believed by the company to be the largest (combined diameter and



Corundum Vitrified Wheel 34 inches Diameter and 13½ inches Face made for Needle Grinding

thickness) wheel ever made by the vitrified process. The net weight of the wheel is 640 pounds, and wheel makers and users familiar with vitrified wheel manufacture will appreciate the experience and extreme care necessary in handling and finishing such a massive wheel. The final temperature at which the company's vitrified wheels are fired is nearly 3000 degrees F.

* * *

As a part of its campaign to improve agricultural methods, the Pennsylvania R. R. is to distribute among the farmers along its lines 10,000 copies of a book describing the possible uses of concrete on the farm. The distribution of these books will be made through the office of the railroad's agriculturist.

LETTERS ON PRACTICAL SUBJECTS

We pay only for articles published exclusively in MACHINERY

DEVICE FOR TAPPING BUSHINGS WITH COARSE PITCH THREADS

A large number of brass bushings such as are used in motor car steering rods for controlling the spark timing and inlet and outlet of gas, were to be tapped. Machining these bushings in a lathe was found to be too expensive and not practicable, and as an accurate, quick method was required, a special hand apparatus was designed. This consists of a cast-iron base having three supports as shown in Fig. 1. The one to the left has a hollow shaft and a split collet by means of which the bushing to be tapped is held. The shaft has a dividing flange with three holes which are engaged by a spring-pin for indexing, in order to cut the three threads of the screw. The central support has a cast anti-friction metal nut and carries a large lead-screw of the same pitch as the hole to be tapped. This support has an adjustable cap for taking up wear. The lead-screw is also supported by a third bearing on the right and is fitted with a pilot wheel as shown. The opposite end of the lead-screw has a key and set-screw for holding special taps.

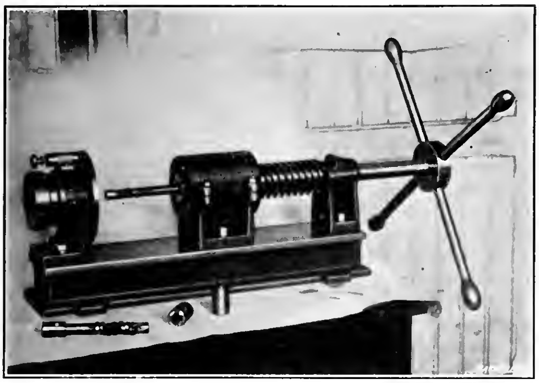


Fig. 1. Fixture for tapping Brass Bushings of Coarse Pitch

When the pilot wheel is turned, the lead-screw moves forward and feeds the tap through the bushing. These taps are an interesting part of the apparatus. Triple-threaded taps did not work satisfactorily as they broke frequently, owing to insufficient room for the dirt or chips. Single-thread taps such as are shown in Fig. 2, were then used, the three threads in the bushing being obtained by indexing the work. These taps gave excellent results, the bushings being tapped quickly and accurately with little wear of the tools.

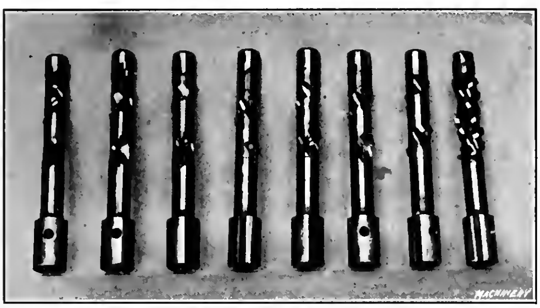

Fig. 2. Set of Eight Taps used in Fixture shown in Fig. 1

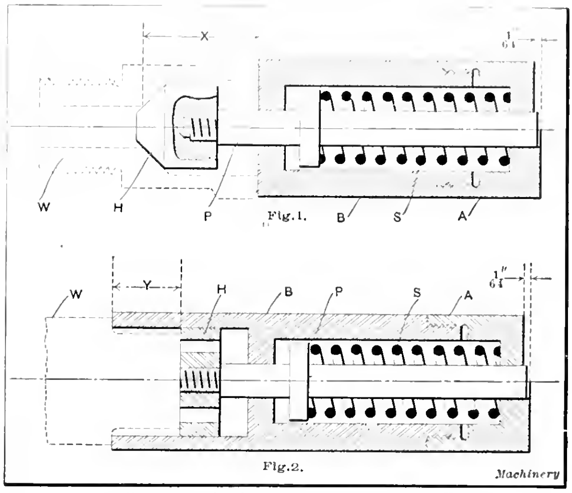
The operation of this fixture is as follows: After a roughing tap has been fed through the work, the lead-screw is drawn back; the dividing flange is then moved 1/3 turn and a second cut is taken with the same tap. The work is then indexed again and a third cut taken. The second tap of the set is next inserted and the same operation repeated for the three positions of the dividing flange, and so on for all the other eight taps of the set. The finishing tap has three threads and is used merely to correct slight imperfections left by the previous taps. Two of the finished bushings are shown in front of the fixture in Fig. 1. They are two inches long and $1\frac{1}{4}$ inch outside diameter. The engaging screw is 1 inch outside diameter and has a $1\frac{3}{8}$-inch triple thread of trapezoidal section. The output of this tapping device, when operated by a boy, is thirty pieces per day of ten hours. The lead-screw and taps were threaded in a Pratt & Whitney threading machine.

Turin, Italy. C. BOELLA

INSPECTION ROOM LIMIT GAGES

Two interesting limit gages are illustrated in Figs. 1 and 2. These gages are employed for inspecting parts that are produced at the rate of several thousand per day, and they are said to give perfect satisfaction. Both gages are built along identical lines. They consist essentially of a plunger *P*, plunger head *H*, plunger barrel *B*, spring *S* and barrel cap *A*. The outer face of the cap consists of two planes accurately ground within 1/64 inch of each other, this being the limit within which distances *X* and *Y* are permitted to vary The step or rise of 1/64 inch thus formed on the cap *A* extends across the center of the cap end.



Figs. 1 and 2. Simple Forms of Limit Gages

In Fig. 1 the important dimension is the depth *X* of the bevel seat from the outer edge of the piece *W*. In Fig. 2, *Y* is the important dimension. When *X* and *Y* are right, the outer end of the plunger projects as shown in Figs. 1 and 2. When *X* is too large or *Y* too small, the plunger end is completely inside the cap *A*. and when the reverse is the case the plunger projects beyond the shoulder formed on the face of the cap. The principal advantage of these gages is that work can be carried on with the help of either sight or touch, and thus one sense can be used to relieve the other—a feature that can be fully appreciated only by those who are continually employed in inspection work. These gages were designed by Mr. R. Vessey, superintendent of the Champion Ignition Co., Flint, Mich.

Flint, Mich. M. TERRY

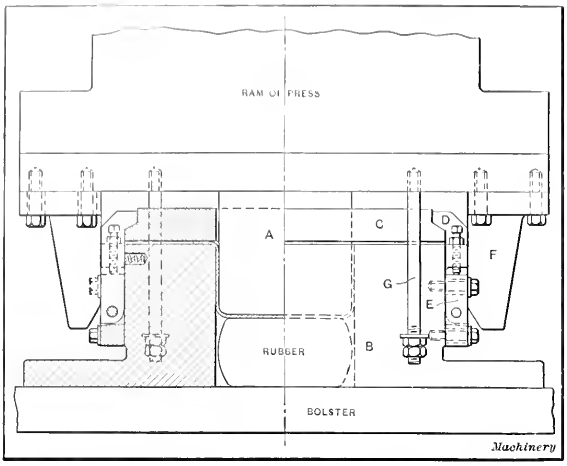
DRAWING IN A SINGLE-ACTING PRESS

We had an order for some steel cups such as would usually be made on a double-acting press. No double-acting press was available, but we did have a long-stroke single-acting press of sufficient capacity to do the job. The die was made as follows:

On the die *B* were bolted some U-shaped pieces *E* which carried the holding hooks *D*. These hooks *D* could be adjusted to any desired degree of tightness by setting down the pieces *E* with the set-screws provided and then clamping

them securely in place. The blank-holder C was suspended on four bolts G, and these bolts were adjusted to the proper length so that the blank-holder C was laid on the blank early in the stroke; then closing lugs F engage the holding hooks D and force them in on the beveled ledge of the blank-holder. The lugs F then slide along the back of hooks D during the remainder of the stroke.

On the up stroke the closing lugs leave the hooks D which are immediately thrown open by springs provided for this purpose, and then the blank-holder C is lifted up by the



Die for drawing Cups in a Long-stroke Single-acting Press

suspension bolts G. The formed piece is loosened in the die by the rubber block or, if necessary, a positive stripper can be provided.

At first we made the closing lugs F solid with the punch-holder, but after several were broken by dirt or other foreign substances getting under the blank, we made a new holder with the lugs bolted on, and now the bolts will usually allow the lugs to give enough to prevent breakage.

This die is more expensive than would be required for a double-acting press, but works nearly as well and enabled us to do the work with the equipment at hand.

W. Alton

HOLDING DEVICES FOR FIRST-OPERATION WORK

The chucking fixtures shown and described in the article on "Holding Devices for First-operation Work," by Albert A. Dowd, in Machinery for November, are very interesting examples of this kind of work, but they appear to me to be expensive, and for the most part would only be justified by

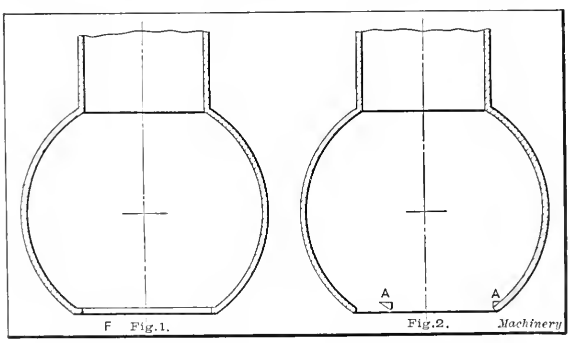


Fig. 1. Ball Joint having Internal Flange to provide Clamping Surface Fig. 2. Ball Joint with Clamping Lugs to be used if Internal Flange is not permissible

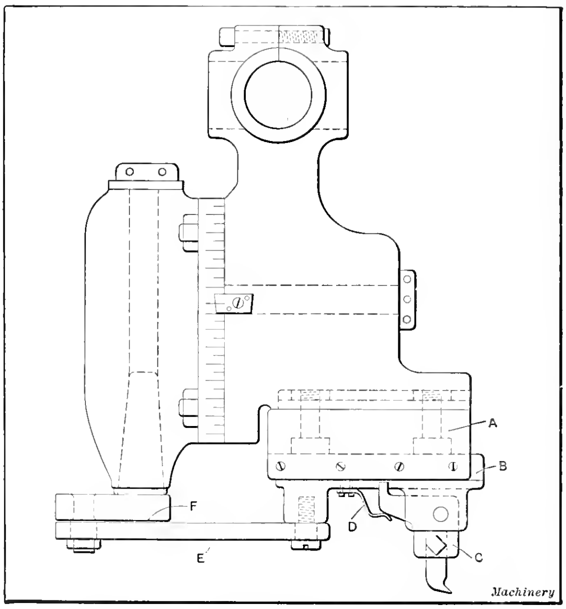
the production of large numbers of the parts for which they were designed. I shall, however, confine my discussion to the fixtures for ball and socket pipe joints shown in Figs. 3, 11 and 12 of the article referred to. Such pieces as this, especially when of large size, as shown in Figs. 11 and 12, are likely to be made in such small quantities that the fixtures should be of the cheapest if they are required at all.

The designer of any piece of machinery should not only be capable of designing mechanism that will perform the functions desired, but should so shape the various parts that they may be readily machined in ordinary machine tools with the least possible outlay for special equipment. In this case I think the designer has failed in just that respect. It would have been better to have made the patterns for both of these joints with an internal flange on the lower end of the ball, as shown in the accompanying illustration Fig. 1, the opening through the flange being the same size as the throat at the other end of the piece. The casting could then be held by a regular three-jawed chuck with the jaws inside, and the bull center could be used for an outboard support as shown in Fig. 3 of Mr. Dowd's article. With the pattern made in this way, either end of the piece could be machined first, and the core would make a smoother opening in the flanged end of the casting. If the face F, Fig. 1, is machined, and a cut taken through the opening, a finished surface is provided for locating the piece for future operations. If the flange in the opening is not permissible, three small lugs A, Fig. 2, could be cast inside the ball; then the first chucking becomes a simple matter of clamping by bolts and straps to the faceplate of either the lathe or boring mill. No special fixtures are required for either method of holding the work.

Springfield, Mass. F. H. Bullard

SLOTTING ATTACHMENT FOR VERTICAL MILLING ATTACHMENT

The illustration shows a slotting attachment which was designed by the writer for use on a Brown & Sharpe compound vertical spindle milling attachment. Those who are familiar with this type of vertical milling attachment know that there



Slotting Attachment for B. & S. Compound Vertical Spindle Milling Attachment

are two flat surfaces provided with T-slots to which the bracket is fastened which supports the attachment. These two surfaces are located at right angles to each other and only one surface is used to support the attachment, the provision of the two surfaces enabling it to be set up in different positions. The writer did not make use of the bracket in connection with the slotting attachment, although it could be used if desirable.

Referring to the illustration, it will be seen that the slotting attachment consists of a frame A which is bolted to the T-slots of the milling attachment. The slide B fits into the frame A and carries the tool-holder C, in which the tool is secured

by means of a set-screw at the side. Almost any form of shaper tool such as a lip, diamond-point or square-nose tool can be used in this holder. A spring *D* is provided at the back of the holder which allows the tool to drag on returning.

The slide is driven by means of a connecting rod *E* which transmits power from the crank *F*. This crank is mounted in the spindle of the milling attachment by means of a tapered shank, and the crank may be made of any length to give the desired stroke. This slotting attachment can be used in a number of ways and suitable tools can be made for slotting small keyways in gears or pulleys, for use on die work, etc.

Harrisburg, Pa. A. F. Lighthart

SPRING SUPPORTED CANTILEVER

In the December number of Machinery, "How and Why" section, an error occurs in the solution given by William L. Cathcart of a spring supported cantilever. The deflection as arrived at is correct, but the stress *S*, as given, is incorrect. The method pursued would give the maximum stress at the end of the beam, but no stress at all at the support, whereas the two stresses, of course, are exactly opposite to this. The bending moment in a section 15 inches from the support is evidently equal to 500 (20 — 15) = 2500 inch-pounds, this being the moment of all forces to the right of the section. It is not necessary to deal with the reactions at the support. In the solution given the reaction is given as 395 pounds, but to this should be added a couple which equals 500 × 20 — 105 × 10 = 8950 inch-pounds. This is a necessary condition if the forces are to be in equilibrium.

Hartford, Conn. A. E. Larsson

SCREW COMPENSATION FOR SHRINKAGE IN HARDENING

In the December number of Machinery "W. B. T." presents an interesting problem: He wishes to cut a screw to fit the threaded portion of a chuck jaw, the length of which and, consequently, the pitch of the thread, has been diminished by the contraction incident to hardening. In other words, he wishes to cut a thread of slightly less than standard pitch. What may be called the reverse of this problem is familiar to many of us; that is, cutting a thread slightly coarser than standard pitch, to compensate for the shrinkage in subsequent hardening of the threaded piece.

If, for example, a tap is to have 8 threads per inch and we know that the contraction of the steel necessitates cutting the thread 0.12502 inch pitch instead of 0.125 inch, the lathe is geared to cut 0.125 inch pitch and the taper attachment is set to an angle the cosine of which is $\frac{0.125}{0.12502}$. The tailstock is also set over to bring the axis of the work parallel with the taper attachment.

The same method could be applied as readily to the cutting of threads slightly finer than a standard pitch, if the lathe were supplied with gears to cut a little finer than the required pitch. For instance, if 0.197 inch pitch were required, it could be easily obtained if we had gears to cut 0.195 inch pitch. The way in which this result is attained by the writer is to insert in the change gear train compound gears of nearly the same size. Compound gears which are often used have 83 and 84 teeth, respectively, giving a pitch 83/84 of what the lathe would cut if the compound gears were not used. Thus, the 0.200 inch pitch (5 threads per inch) of W. B. T.'s problem would become 83/84 of 0.200 inch or 0.19762 inch. The length of the threaded part of the chuck jaw is not stated, but if it were 2 inches the contraction would reduce the 0.200 inch pitch to 0.19843 inch. Dividing 0.19762 by 0.19843 gives the cosine of 5 degrees 12 minutes, to which angle the taper attachment should be set.

The writer is aware that devices are in use on other tools than the engine lathe for giving a pitch slightly coarser or finer than standard, but has assumed that the thread is to be cut by one who has only the ordinary lathe at his command. It is often possible to obtain the desired pitch without the 83- and 84-tooth gears or their equivalent, if one has a metric lead-screw. For example, to cut a thread of 0.19843 inch pitch, as in the preceding case, gear the lathe for cutting a thread of 5 millimeters pitch (0.19685 inch); then set the taper attachment to 7 degrees 14 minutes, which will give a pitch of 0.19843 inch (0.19685 : 0.19843 = cos 7° 14').

The use of compound gears has the great advantage of wide applicability, as the gears can be used for any pitch. There is a well-known objection to cutting threads with the tailstock set over, as the dog does not drive the work with constant velocity, the tail oscillating in the faceplate slot. If the work is so fine as to make correction necessary, this defect can be overcome by driving with a pair of bevel gears, as is customary in some shops when taper work is to be threaded, and in the relieving of angular cutters.

New London, N. H. Guy H. Gardner

Regarding "W. B. T.'s" problem of decreasing the pitch of a screw, the condition of the piece which the screw is to fit is not quite clearly stated, as that much discussed matter of "pitch" is left open. As I understand the pitch of a screw, it is the length divided by the number of threads in that length, or, in this case, 1 inch divided by 5, which equals 0.2 inch pitch. If this is the case and the pitch has shrunk 1/64 inch, then the number of threads is 1 divided by 0.2 — 1/64, or 5.423 threads per inch. However, since W. B. T. wishes a compensating device and not a definition of the word "pitch," I will say no more about that.

A compensating device to increase the pitch is very simple, if a lathe with a taper attachment is at hand. It is done by setting over the tailstock of the lathe, either way, and setting the taper attachment to cut the screw parallel. This causes the center line of the work to form an angle with the travel of the carriage, the movement of the latter being along the side adjacent to the angle while the work represents the hypothenuse; hence the amount of compensation in any given length will be the difference between the length of the side adjacent and the hypothenuse of the angle.

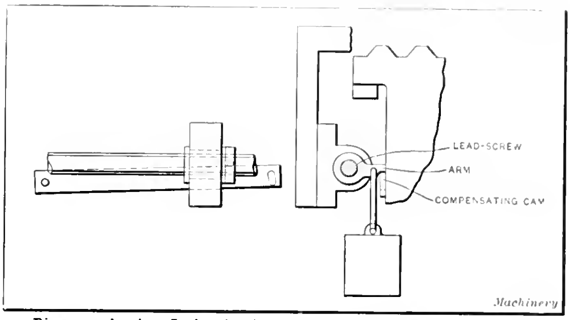


Diagram showing Lathe Carriage with Special Lead-screw Nut to decrease Pitch of Thread being cut

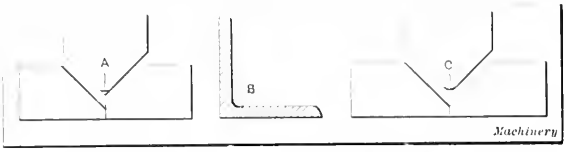
Decreasing the pitch is a more difficult proposition, and where the amount of compensation is known probably the simplest way is to make a special gear or number of gears to cut it. Another way, and a very good one, is to remove the regular nut from the lead-screw and fasten a bracket to the lathe carriage to carry a special nut that can be caused to rotate in the bracket. An arm is fastened to the nut and arranged to bear on the upper surface of a compensating strip or cam fastened to the lathe bed, the arm being held in contact with the cam by means of a weight. (The accompanying illustration shows the arrangement roughly). The compensating strip can be adjusted to give any desired increase or decrease of travel within reasonable limits.

I have never seen this device used for this purpose, but some time ago a similar one was described in some technical paper as a means of correcting inaccuracy in lead-screws, and I think it would answer W. B. T.'s purpose in every way. However, I believe it would be more practical to make the jaws of a grade of steel less liable to variation in hardening, and then correct the inaccuracy due to hardening by lapping on a long screw made of brass or soft steel, as this would give a more uniform contact.

Watervliet, N. Y. D. Tappan

ANGLES OF ANGLE BEAM SHEAR BLADES

I wish to submit an answer to J. D. Y.'s question in reference to the angle of the angle beam shear blades, published in the November number of MACHINERY. Some four years ago we were having a lot of trouble with our shearing machine, due to the point of the upper blade breaking off, as shown at *A*. The problem of overcoming this difficulty was turned over to me. I found that the angle beams we were shearing were of



Original and Improved Types of Angle Beam Shear Blades

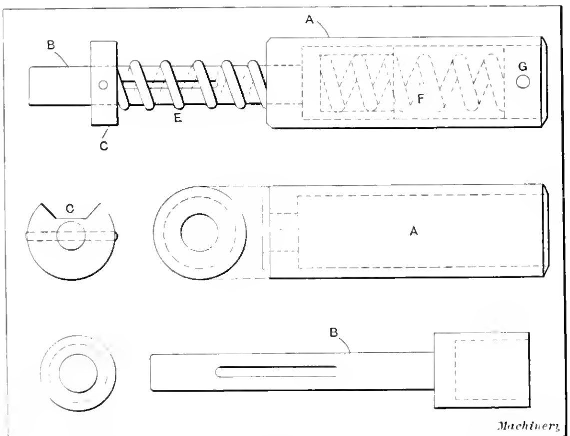
the form shown in cross-section at *B*, with the inside corner slightly rounded. It appeared reasonable to assume that the trouble was due to this rounded corner for in shearing such a beam, all of the pressure would be concentrated on the point of the blade for a short period of time. Acting on this assumption, I made the upper blade of the shear with a round point, as shown at *C*, instead of with a sharp point of the form shown at *A*. After this blade was put in operation, no further difficulty was experienced. In conclusion, it may be stated that the angles of the upper and lower blades should be the same.

Auburn, N. Y. JAMES BURKE

TURRET ARBOR AND EJECTOR FOR GANG CUTTING OPERATIONS

The arbor illustrated herewith was designed for use on the Cleveland automatic screw machine when cutting off collars or washers with a gang cutter. The illustration shows the parts assembled and in detail. This arbor has several advantages.

The hollow shank *A* is gripped in the turret of the screw machine and contains the plunger *B*, which is free to move backward against the coil spring *F* held in place by plug *G*.



Turret Arbor for Gang Cutting-off Operations—The Spring-plunger enters Drilled Hole and Collar C ejects the Cut-off Washers or Collars

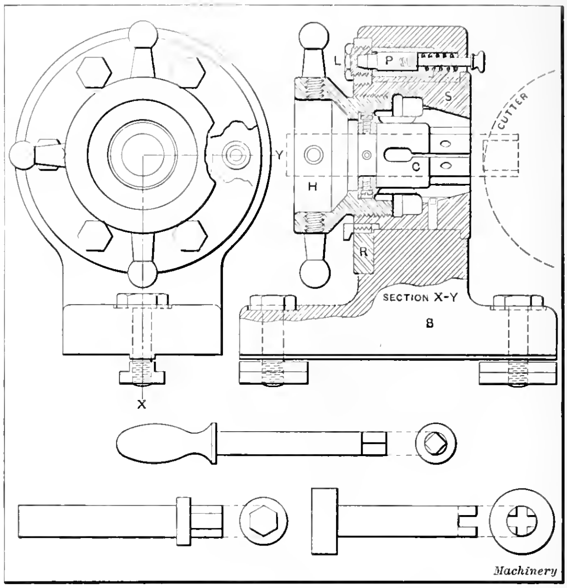
In using this fixture, the plunger *B* enters a hole drilled in the end of the stock, from which the collars are to be cut off by the gang cutter on the cross-slide. In case the cross-slide has traveled its entire distance before the turret has advanced to its limit of movement, the end of plunger *B* will strike the bottom of the hole and will cause a pressure against the coil spring *F*, which allows a sliding movement backward into shank *A;* this has proved to be a valuable advantage. The collar *C* is fitted with a pin for sliding in the slot shown in *B*, and is cut away (see end view) to provide clearance for the gang cutters. This collar acts as an ejector when the turret reverses. During the forward movement the collar recedes so that plunger *B* can hold a number of collars or washers. As soon as the turret has started on its backward movement, the parts are ejected into the work pan by the compressed coil spring *E*.

One great advantage this arbor or fixture has over others used for this purpose is that after the gang cutter has finished cutting the washers or collars from the bar stock, they have already passed over plunger *B* which holds them when the cross-slide moves away from the bar; thus, in case of chips clogging the gang cutter, there is no danger of the washers or collars hanging fast between the cutters and causing trouble.

O. GORDON

INDEX HEAD FOR HAND MILLING MACHINES

A useful index head for hand milling machines used for machining duplicate parts, is shown in the accompanying illustration. This head is made with a hole through the center, so that the parts to be milled can be inserted in the collet from the rear. The work projects through the front just far enough to allow clearance for the cutters. This fixture is especially suitable for milling pieces such as are shown in the



Index Head for Hand Milling Machines and Samples of Work

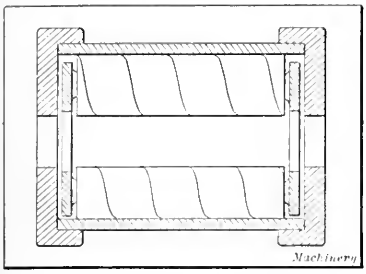
lower part of the illustration, although it can be used as a regular index center in connection with a tailstock center by using a special "dummy collet."

The upright part of the body is made as narrow as possible in order to accommodate short pieces, the heads or shoulders of which might be too large to pass through the collet. The fixture consists of a cast-iron body *B*, in which there is a hardened steel sleeve *S* carrying a spring collet *C*. The latter is equipped with pads and a bushing bored out to suit the part to be milled. The handwheel *H* serves for tightening the collet on the work and also for indexing. The index pin *P* slides in a hardened steel sleeve, and fits in the hexagonal bushings *L*. The latter are carried in an index ring *R*, which is screwed tightly to the sleeve and keyed. The ring is made to index either four or six holes, any holes not in use being plugged with "dummy bushings." The collet has four slots, and on account of its being quite short in proportion to the diameter, it is necessary that the side walls be only about 3/32 inch thick; the slots are also relieved in the middle by openings 1/2 inch wide, in order that the collet may not be too stiff to be closed easily by the handwheel. The largest stock that the collet will take through the pads is 1 1/8 inch diameter.

Oak Park, Ill. R. W. ULLMANN

ROLLER BEARING IDLER PULLEY

We recently received an order for a number of idler pulleys for a 1¼-inch belt. These pulleys were required for use on a group of machines, and aside from specifying that the diameter was to be about 1¼ inch and that they were to be carried on ½-inch shafts, the construction was not specified. The machines on which these idlers were to be used were built with roller or ball bearings and it seemed advisable to follow the same course with the idlers. The method that was finally hit upon is shown in the accompanying illustration. A standard Hyatt roller bearing was selected with a diameter over the sleeve of 1 3/16 inch, which was close enough for the required purpose. Two caps were turned to fit over the sleeve of the bearing, 1 7/16-inch bar stock being used for this purpose. The caps were machined to make them a press fit on the sleeve. By referring to the illustration it will be evident that these caps serve the double purpose of forming flanges for the pulley and heads for enclosing the cage of the roller bearing. The idler pulleys produced in this way were quite accurate and of good appearance; they were practically frictionless and cost less than turned pulleys with bronze bushings.

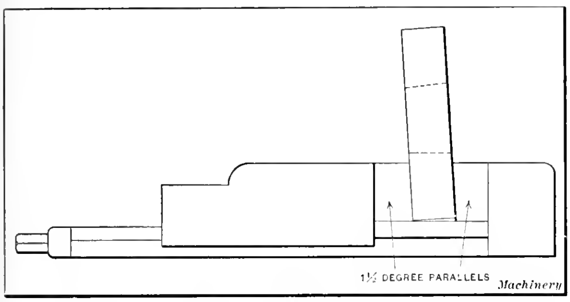


Idler Pulley made from a Standard Hyatt Roller Bearing

Middletown, N. Y. DONALD A. HAMPSON

MACHINING CLEARANCE IN DIES

On page 305 of the engineering edition of MACHINERY for December, A. J. Brickner shows a method of holding dies in the shaper while machining the clearance, by loosening up the shaper apron and tipping it forward. The accompanying illustration shows still another method. The die to be machined is held in the shaper vise by two 1½-degree parallels which hold the die in such a position that the desired angle of clearance is readily machined. These parallels, besides being inexpensive, greatly facilitate work of this kind, and should be a part of every tool-room equipment.



Die held between 1½-Degree Parallels for obtaining Clearance

Waterbury, Conn. CHARLES DOESCHER

BELTS IN COLD WEATHER

In the December number of MACHINERY the following note appeared:

> It has been found by experiments that the difference in power that can be transmitted by the same belt in damp and dry weather may vary as much as 50 per cent, especially if the drive is a vertical one; that is, if in general the pulleys are placed in an unfavorable position.

The writer can imagine no position so unfavorable to pulleys that a difference as great as 50 per cent is possible with belts that are correctly cared for, unless the pulleys are operated out in the open where they might become coated with ice or be subjected to rain or snow. It is true that an excess of snow, ice, or other slippery materials will greatly affect the transmitting capacity of a pulley, regardless of belt treatment, but the mere rise and fall of temperature in a dry or even in a wet atmosphere should have no effect whatsoever. In fact, belts are now waterproofed to such an extent that actual immersion in water for short periods, as in floods, has no appreciable effect on the pliability and pulling power of the belt. A belt that has not been made sufficiently pliable, that has not been waterproofed, and that has absorbed considerable moisture will naturally harden in cold winter weather. And a hard, stiff belt, of course, cannot pull as great a load as when it is pliable. Hardness and stiffness, however, are rapidly going out of date. N. G. NEAR

SPHERICAL BORING-BAR

In the following article is presented a design for a spherical boring-bar for use on a horizontal boring mill. I recently designed this bar and used it successfully in boring a housing for a flexible automobile jackshaft. The housing was first bored straight, forming a cylindrical bore of diameter *D* as shown in Fig. 1. The sides of the work were then faced off to make the total thickness *T*. After these preliminary operations had been completed, the spherical boring-bar was brought into action to machine the inside of the housing to the desired spherical form.

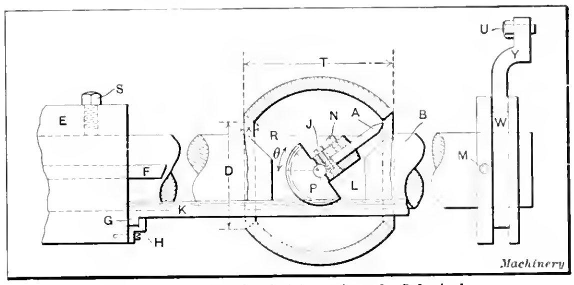


Fig. 1. Cross-sectional View through Spherical Boring-bar and Work

The design of the boring-bar will be readily understood by referring to the accompanying illustration, where it will be seen that the cutter *A* is pivoted in the bar *B*. The bar is keyed to the driving sleeve *E* by means of a feather key *F*. A second key *K* is secured to the driving sleeve; this key has rack teeth cut in it which mesh with a segment gear *P* secured to the lower side of the cutter. The periphery of this segment is of sufficient length to rotate the cutter through the desired angle. The key *K* with the rack teeth cut in it is held to the bar by means of fillister head screws working in slots. When the bar is used for boring cylindrical holes, the cap-screw *S* is used to secure the bar to the sleeve. The action is then the same as that of an ordinary boring-bar.

It will be seen that a grooved collar *W* is provided at the right-hand end of the bar, to which it is held by means of a taper pin *M*; this pin is removed when the bar is engaged in boring cylindrical holes, so that it can be fed through the collar. When used for spherical boring, lateral travel of the bar is prevented by means of the yoke *Y* which is secured to the frame of the machine by means of a stud *U*. The feed of the tool for spherical boring is obtained by the usual bar-feed which moves the sleeve *E* and key *K* along the bar, thereby imparting a uniform feed to the tool by means of the rack and segment gear. It will be seen in Fig. 2 that the key *K* is provided with a lug *G*, over which the keeper *H* is fitted; this prevents the slipping of the key and returns

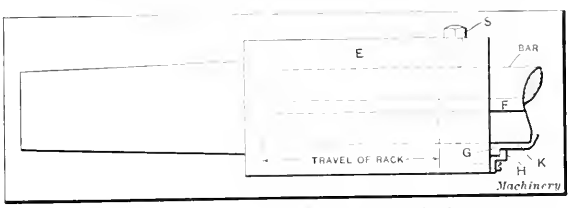

Fig. 2. Bushing for feeding Spherical Boring-bar

the tool to the original position ready for starting a second cut.

In setting up the tool it is necessary to remove the taper pin M and tighten the set-screw S. The bar may then be withdrawn a sufficient distance to the left to operate the gib-screw J and the set-screw N in order to obtain the desired setting of the tool. A fine adjustment is obtained by means of the taper gib L. Before starting the spherical bore, care should be taken to bring the pin upon which the tool is pivoted to a position exactly central between the two faces of the work or a distance $\frac{T}{2}$ from each end. The diameter D of the preliminary bore should be $2R \sin \theta$. The distance X on the work is $\frac{T}{2} - R \cos \theta$. Where a boring-bar of this kind is to be used on standard work, it is generally advisable to have a separate tool for the spherical boring, as the cutting point of the tool used for this work must have a greater radius than the radius of the cutting point of a tool used for cylindrical boring.

Denver, Col. STANLEY EDWARDS

A PLEA FOR BEVELED EDGES

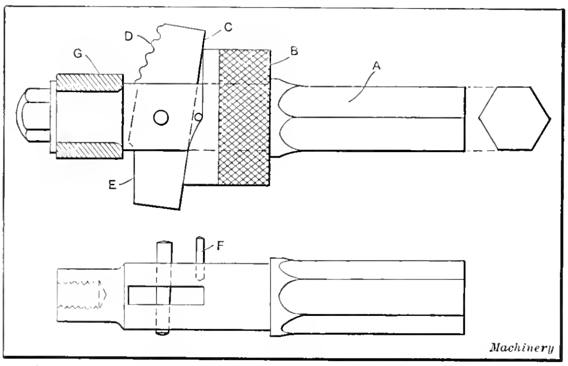
With the advent of modern grinding methods, a practice has developed that is to be deplored. The writer has noticed of late years, that many new machine tools have finished corners ground to a razor edge. A new dividing head (the product of a Cincinnati firm) was so bad in this respect that it was necessary to "break" the sharp edges before it could be handled with safety. One is almost forced to believe that the workmen who build such tools use steel gloves. It would be well if all tools, jigs and appliances were given a uniform curve on their finished lines.

The Brown & Sharpe milling machine is a good example of this practice. All sharp edges are rounded with a 1/16 inch radius tool. This takes little time, and permits the operator to handle the machine with much greater freedom. Let us not forget that the machine tool that is a success must be built for the operator's convenience.

Lafayette, Ind. WILLIAM H. ADDIS

TOOL FOR FACING HUBS

A tool for facing hubs or bosses on castings is shown by the accompanying illustration. As will readily be seen this tool is a roughing and finishing tool combined. The shank or body A has a knurled collar B which holds a high-speed steel cutter C in position. One side of the cutter has a serrated or scalloped edge as at D. This rough edge is set at right angles to the tool shank by turning collar B half a revolution from the position shown. The idea of the teeth is to rip or tear through the scale. After the scale is removed, the collar is turned to locate the smooth finishing edge of the cutter in position, as indicated by the illustration.



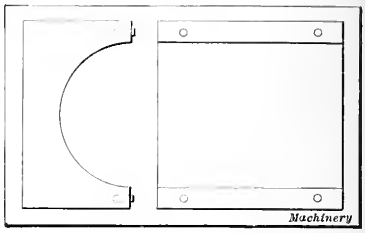
Combined Roughing and Finishing Tool for facing Bosses or Hubs

The pin F acts as a stop for the collar and, at the same time, holds the collar against a shoulder on A. Roller G acts as a pilot for the tool. It is free to rotate and can be exchanged for other sizes. This tool has a hexagonal shank which fits the jaws of the drill chuck and prevents slipping. The roughing and finishing edges of the cutter should be faced off in the lathe before hardening, the shank A being used as an arbor and collar B for holding the cutter in the proper position. The cutter, after being faced, is given the proper clearance. This tool is easily made and is effective, the teeth ripping their way through the scale and leaving clean iron for the finishing side.

B. J. F.

ADJUSTING BEARING BRASSES

It is the practice of some engine builders to leave a space between the brasses of connecting-rod ends, so that wear may be taken up without dismantling the bearings. Usually a piece of leather is put in the space to exert a more or less elastic pressure on the brasses, as well as help to retain the oil; but the first time the rod gets hot, the usefulness of the leather is gone and the joint is generally left open.



Method of adjusting Bearing Brasses

In the writer's experience, brasses thus fitted do not give such good service as when bolted close together. They are likely to cling to the pin at each reversal of stroke; and the play which should take place between the brass and the pin takes place between the brass and the rod, thus interfering with lubrication. Then, in the event of accidental heating, the edges of the brass close on the pin, causing serious damage to the bearing surfaces and invariably requiring the brasses to be removed and eased at the side.

The writer recently tried a little "dodge" on a pair of cross-head brasses which supplied the advantage of the solidly bolted joints and yet allowed wear to be taken up without dismantling the end.

The accompanying illustration shows the device. It consists simply in drilling four holes in the face of one of the half brasses, as shown, and driving in brass pins, which in this case are a little over 3/16 inch in diameter. These pins should be driven to the bottom of the holes. The projecting ends are then filed off until they allow the halves to come together to give a suitable working fit. When wear has to be taken up—if it is attended to in time, as it ought to be—it is found that these pins will crush or imbed in the opposite face sufficiently to allow of this, while the pressure required still leaves the brasses practically solid.

In making adjustments of such brasses as these, it is a custom that is successfully followed both with land and marine engines, to jerk the rod sideways, back and forth, using force according to the size of the engine. This method merely insures that you have not tightened them up too much, which, after all, is perhaps as important as anything.

Christchurch, New Zealand. JOHN PEDDIE

SHRINK VS. PRESSED FITS

In reply to the inquiry by "J. B. F." in the December number, relative to the merits of a pressed or a shrink fit, I favor the shrink fit for the following reasons:

In a large number of shops there are not yet facilities for pressing the machined ring on the shaft (see illustration in December number) other than the sledge hammer, and if the small end of the ring is to be placed last on the shaft there is a possibility of bruising the ring, if it is put on tight enough to hold. In making a pressed fit the average mechanic will file the shaft, cutting off the tops of the ridges left by the tool, and often filing the fit out of parallel, thereby weakening it. The bore of the ring cannot be filed, and it would be considered poor practice to grind or ream the bore as it would lessen, to some extent, the gripping power of the ring.

When the ring is pressed on, the ridges in the bore left by the tool become flattened and are sometimes sheared. To overcome the cutting of the metals, a foreign substance such as oil, paint, white lead, etc., is placed on the surface of the fit, which, in a measure, prevents the metal-to-metal contact. Scoring also takes place sometimes as the shaft is forced through the ring. If the small end of the ring is placed first on the shaft, there is a possibility of its becoming enlarged due to the pressure necessary to hold the ring securely, or ofttimes to the shock produced by the sledge, and sometimes by the cutting, scoring or balling up of the sheared tops of the ridges.

In regard to the molecular arrangement, the molecules adjacent to the fit become compressed or under a strain that is not uniformly distributed. If the ring is subject to shocks, as in the case of gears, the gradual realignment of the molecules will, in time, loosen the holding power of the ring.

In shrink fits it is not necessary to file the fit on the shaft or to ream or grind the bore of the ring, thereby leaving the tool ridges on both the ring and the shaft. When the ring is heated for shrinking, these ridges will clear each other when the parts are being assembled, and, upon cooling, they will, in many places, curl and interlock with each other, insuring a more permanent grip. Again, in shrink fits, it is not necessary to interpose any foreign substance, thereby obtaining a metal-to-metal contact. When the ring is hot it gives the molecules a chance to rearrange themselves, and the strain induced by the pressure upon the cooling of the ring is uniformly distributed.

Anyone having experience with shrink fits that have "stuck" fast knows that it is more trouble to get them loose than with a pressed fit, and, in many cases, the former requires drilling or boring. The only objection to the shrink fit is the discoloration of the parts due to the heat, but if the shrunk ring has to be further machined, this will not be a serious objection. Shrink fits are more easily put together than press fits, and generally a helper is not needed.

Dallas, Tex. SIDNEY HETHERINGTON

In the December number of MACHINERY, J. B. F. inquires about the relative merits of shrink and pressed fits. Assuming that the conditions are alike in both cases, there is this in favor of the shrink fit: The shrink fit can be successfully assembled without lubrication, whereas the press fit can not, and it is reasonable to assume that surfaces will move upon each other more easily with lubrication than without. Of course a hardening lubricant, such as white lead, could be used, but even with this I doubt very much if the adhesion would be as great as with no lubricant at all.

Again, suppose the surfaces were not perfectly smooth, then the irregularities, with a shrink fit, would become imbedded in each other with a doweling effect which could not be obtained with a press fit. I had this proved to my satisfaction about ten years ago by making a mistake in boring out a ring about 10 inches inside diameter, 12 inches outside diameter and 1 inch thick, to be shrunk on the outside of the base of a large valve to increase its diameter. Before heating the ring I happened to try it on the base of the valve and found that it slipped on readily. I mixed some sand and white lead and spread a liberal coat on the valve base, heated up the ring and shrunk it in place, after which the valve was chucked in the lathe and a cut fully one-fourth inch deep taken off the outside of the ring. To the best of my knowledge that fit is doing satisfactory service yet.

Where the quality of the steel is such that it is likely to be impaired by heating, that is, steel that has to be tempered to bring it up to certain physical requirements, care should be taken not to heat the piece above, or up to, the temperature at which it was drawn in its treatment; if this were done then the press fit would excel the shrink fit. This may possibly need some explanation. Suppose the piece of steel illustrated on page 313 of the engineering edition of MACHINERY for December were a good quality of carbon tool steel, and were heated to about 1200 degrees F., hardened in oil, and then drawn to 1100 degrees, which should give the steel its maximum strength and still leave it soft enough to machine. Such a piece would require more pressure to seat under a press than one made of soft machine steel, provided the allowance was the same in both cases.

Where a pyrometer is available it is not at all difficult to avoid overheating the steel, as very little steel whose qualities depend on its treatment is drawn below 700 degrees, and 600 degrees is ample for any shrink fit. If a suitable furnace and pyrometer is not available, the temperature can be obtained accurately enough for all practical purposes by measurement derived from the following formula: Taking the coefficient of linear expansion of tempered steel as 0.000007, D as the diameter of the piece before heating, S as the shrinkage allowance, C as the clearance, T as the difference in temperature, then

$$\frac{(S + C)}{0.000007\ (D - S)} = T$$

or

$$\frac{(0.002 + 0.003)}{0.000007 \times (1.9375 - 0.002)} = 366$$

degrees. If the piece to be shrunk is bored to 1.9355 at a temperature of 60 degrees (allowing 0.002 inch shrinkage) we have 366 + 60 as the heat necessary to increase the bore 0.005 inch, and when the bore measures 1.9405 inch we know that the piece is at 426 degrees approximately. For untempered steel and cast iron, a coefficient of 0.000006 should be used.

With larger diameters where there is likely to be a force exerted tending to push the piece off its seat, interlocking shoulders can frequently be used. In a piece 24 inches in diameter an expansion of 0.1 inch can readily be obtained, which would allow shoulders of 0.05 inch to be used. Of course it would be impossible to assemble such fits by means of a press.

Watervliet, N. Y. D. TAPPAN

CONSTRUCTION OF MOLDS FOR DIE CASTING

The following description of a die-casting mold is intended to give those not familiar with die casting, a general idea of the constructional features of such a mold; the writer has also given some practical pointers on the making of these molds which should be of value to any diemaker thinking of entering the die-casting business. The accompanying illustrations show a mold for a ball-and-socket joint. The mold for a die casting usually consists of the bottom die, top die, the base casting for supporting the dies, and the mechanism for operating the ejector-pins and core-pins. The surface A (Fig. 1) between the bottom and top dies represents the dividing line of the mold, the two dies being separated at this point when the casting is formed and is ready to be removed from the mold. The bottom die is located in the proper position by four dowel pins B (Fig. 2) fastened in the top die. Aside from these main parts of the mold, there is the core-pin plate C, Fig. 1, and the ejector-pin plate D; the former, which is shown to the left in Fig. 2, consists of two parts, E and F, which are fastened together by screws. This plate supports the core-pins G, which form the holes in the casting, and, in some cases, sections of the core which are under cut, as it is not always possible to design the cores in the die so as to provide clearance in all directions. Core-pins intended for clearance holes in the casting, are made not less than 0.003 inch larger than the regular clearance size. When core-pins are 1/4 inch and larger in diameter, spotted holes are preferable to oil grooves, because the lubricant stays in the spotted holes, whereas it has a free movement through an oil groove.

When a large number of core-pins is necessary to form the different holes in a casting, it is usually a good plan to give a number of them (and sometimes all of them) a "floating fit" in the core-pin holder E, Fig. 2. Otherwise, if the core-pins are driven in and headed or riveted over on the under side of plate E, they are sometimes forced out of alignment by being headed a little more on one side than the other, or perhaps the core-pin hole in E is not in perfect alignment with the core-pin hole in the top die, through which the pins pass when operating the mold. Both cases would tend to retard the movement of the core-pins and increase the wear on one side or the other, and in the constant operation of the mold, the

pins might be worn rough or work stiffly, thus making it necessary to have the die repaired. If the pins are given a floating fit in the holder, however, by making the core-pin holes in plate E from 0.001 to 0.002 inch larger than the diameter of the core-pin, the difficulties stated would be overcome.

For core-pins ¼ inch in diameter and larger, it is customary to have a shoulder of from 0.003 to 0.005 inch, so located that it will extend 1/64 inch into the casting. The reason for having this shoulder is that when withdrawing the core-pins from the finished casting, that part of the core-pin which forms the hole, being from 0.003 to 0.005 inch smaller than the core-pin hole in the top die, will have no bearing except in the hole formed in the finished casting. This clearance between the top die and core-pins reduces the liability of the core-pins being roughed up at this vital point, by the dirt that collects around them and is likely to be drawn into the holes when they are withdrawn below the working surface of the top die, preparatory to ejecting the finished casting.

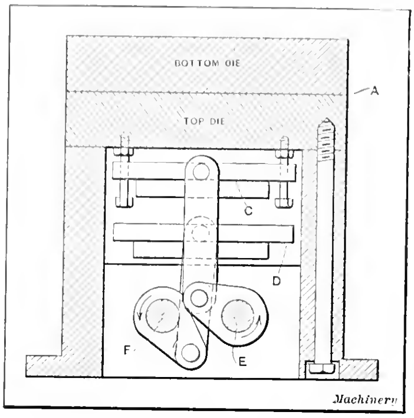


Fig. 1. Diagrammatical View showing Arrangement of Mold for Die Casting

The core-pins are withdrawn by an upward movement of the lever attached to shaft E, Fig. 1, and the shaft F operates the ejector-pins. The movement of the core-pin plate C is controlled by a positive stop consisting of four screws and check-nuts, as shown in the illustration. The length of this movement is governed usually by the thickness of the casting, plus the distance the core-pins enter the bottom die; but in all cases the pins must be withdrawn sufficiently to be entirely removed from the casting. The distance between the core-pin plate and the ejector-pin plate is governed entirely by the length of movement required to withdraw the core-pins, plus the distance necessary for ejector-pins of sufficient length to lift the completed casting clear of the die. The core-pins have a downward movement, whereas the ejector-pins move upward, but both operating levers work in an upward direction. The core-pin plate is usually located next to the top die, and the core-pins should pass through the top die (in the proper location to form the required holes in the casting) and into the bottom die about ¼ inch.

The ejector-pin plate D, Fig. 1, is placed under the core-pin plate and it is guided by the ejector-pins which pass through the top die. These pins are prevented from coming below the surface of the top die by means of four screws and check nuts, similar to the arrangement shown for the core-pin plate C. The ejector-pins usually are fastened rigidly to the plate and are not given a floating fit, as the core-pins are. The ejector-pins, as the name implies, are used only for ejecting the finished casting from the top die after the mold has been separated and the cores withdrawn. The ejector-pins, when in their proper location, should be about 0.001 to 0.002 inch above the working surface of the top die, if the casting is not to be finished, and if the casting is to be finished, they should be about the same distance below the surface. The location of the ejector-pins relative to the casting varies in different dies, and depends upon the form of the casting.

The sprue cutter is used to cut off the sprue in the bottom die after the metal has been forced in, thus leaving the casting free and clear in the die. In Fig. 2 the sprue cutter hole is represented by the cross-sectioned part. It passes from the under side of the base, through clearance holes in the core-pin and ejector-pin plates, and then through the top die (where it should be a perfect sliding fit) into the bottom die. The latter should also be perfectly fitted to the sprue cutter for about ⅛ inch below the cutting edge; beyond this point the hole is tapered for clearance. In operating the mold, the sprue cutter is entered into the top die until it is flush with the working surface, and the metal is forced through the sprue hole into the bottom die; then the sprue cutter is forced through the bottom die, cutting off the sprue, which passes out through the tapered sprue hole in the bottom die, thus leaving the casting in the mold free to be ejected when the mold is separated.

PROVING MULTIPLICATION AND DIVISION CALCULATIONS

The following is a very simple method of proving multiplication and division calculations which has proved extremely valuable to me in the course of my work, and should be equally so to readers of Machinery who have accurate figuring to do.

For multiplication, proceed as follows: First add the figures of the multiplicand, and if the sum is more than one figure, add again as many times as necessary to reduce the sum to one figure. Next, treat the multiplier and result separately in the same manner. Now multiply the two figures representing the multiplicand and multiplier, and reduce the result to one figure. If the calculation is correct, this figure and that representing the result of the calculation will be the same.

For division, find the sums separately each in one figure, of the divisor, dividend, quotient, and remainder if any. Next multiply the sums of the divisor and quotient, reducing the result to one figure. Now add the remainder, if any, to this result, and reduce the sum to one figure. If the division is correct, this figure will be the same as the one representing the dividend.

While at first sight this method may seem a trifle long and complicated, it is all mental work, and therefore can be done very quickly, which a trial will soon prove.

Montreal, Canada. Oscar W. Miess

SPIRAL PERFORATING

I have read a number of articles in MACHINERY describing methods of perforating, but they all pertain to producing holes in straight lines. We recently had to perforate a number of shells of the type shown in Fig. 1 which have four holes pierced on a spiral at four different places on the shell. After trying various methods, the die illustrated in Fig. 2 was finally designed and proved very satisfactory for handling the work. It will be seen that the tool consists of a die-holder *A*, which is carried by the die bed *B*. This die-holder is counterbored to receive the mandrel *C* and cam *D*, which controls the movement of the shell to obtain the desired location for the holes. An index ratchet *E* is keyed to the left-hand end of the mandrel and held in position by a nut *F* which holds it against the die bed. This ratchet is operated by a pawl carried by the ram of the press. In order to take up any backlash and secure accurate indexing, a spring pin *G* is provided. This pin enters counterbored holes in the ratchet, which are properly spaced to locate the holes in the desired positions in the shell; when the ratchet is moved on to the next station, the pin is forced back into the die bed and then enters the next hole in the ratchet.

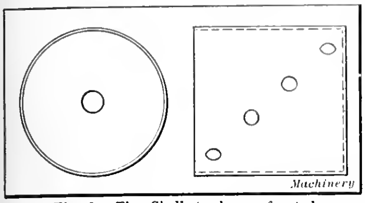

Fig. 1. The Shell to be perforated

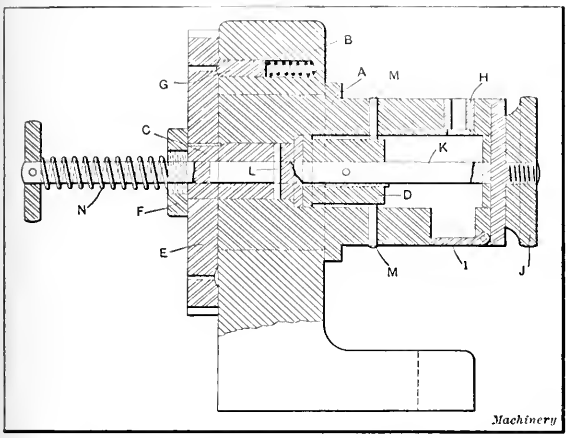

Fig. 2. Type of Die used for the Spiral Perforating Operation

The piercing die *H* is driven into the die-holder and the piercings are held inside the drum until all of the holes have been punched, by means of a trap door *I*. The shell is held in position by means of the nut *J* carried at the right-hand end of the shaft *K*. It will be evident from the illustration that the cam *D* which controls the movement of the shell is secured to the shaft *K* by means of a key and pin. Four pins *M* extend into the bore of the die-holder and these pins are engaged successively by the cam *D*. The left-hand hole of a series is first pierced; the ratchet then rotates the shell and the action of the cam moves it to the right. The indexing is effected as previously described, one hole being pierced at each station. After the four holes on one spiral have been pierced and the ratchet starts to index for the next hole, the pin *M* slips over the point of the cam and the tension of the spring *N* then returns the cam and the work to the extreme left where the cam is engaged by the next one of the pins *M*. This process is repeated four times to complete piercing the holes on the four spirals in the shell. The longitudinal movement of the shell is limited by the pin *L* which fits in a slot in the shaft *K*.

C. G.

HAND KNURLING TOOLS

The tools illustrated in Figs. 1 and 2 will be found handy for knurling small stock in the lathe, when the ordinary knurling tool cannot be used on account of the spring of the work.

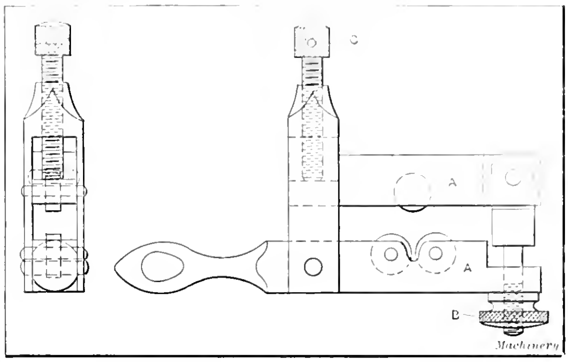

Fig. 1. Hand Knurling Tool for use on Slender Parts

To use the tool in Fig. 1, the bars *A* are adjusted by screw *B*, to come parallel to each other when the knurls are in contact with the work, and the pressure is applied by tightening screw *C*. The tool shown in Fig. 2 is a novelty, but is very cheap and useful. The body *A* is a cheap pair of six-inch pliers having soft jaws which are milled for the knurls. A pair of pliers with parallel opening jaws are the best for this purpose, although the common pliers work very well. The illustration is self-explanatory. The pressure for knurling is produced by the thumb-screw *B*.

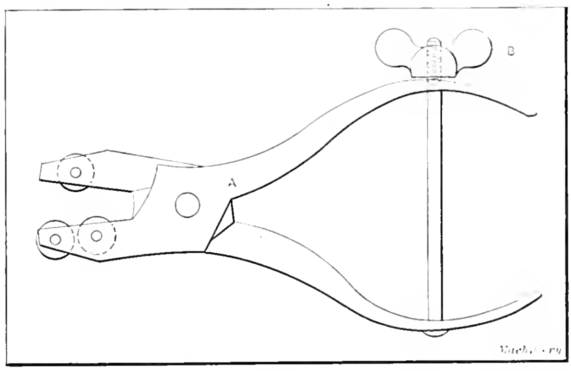

Fig. 2. Hand Knurling Tool made from Pliers

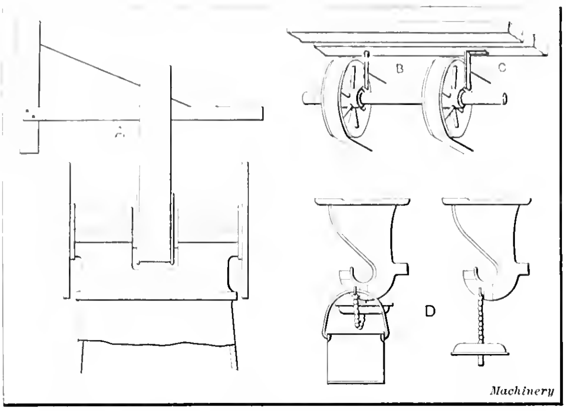
New Britain, Conn. W. C. Betz

OVERHEAD SAFETY SUGGESTIONS

In the average shop, nearly 50 per cent of the belt shifter handles are located out of the operator's reach when he is in the working position. The danger of having a shifter handle out of reach of the operator is evident, and when such a condition exists, some method should be provided whereby the operator can control the machine from the working position. Similarly, machines such as disk grinders, that have two working sides, should be equipped with double shifter handles or an extension should be placed on the

single handle. An example of this kind is illustrated at *A* in the accompanying illustration.

When a belt on an overhead pulley does not run properly, owing to its having become stretched on one side so that it slips off easily, or from any other cause, it is common practice to drive a pointed rod *B* into the beam on the side of the pulley where the belt has a tendency to run off. Should this rod work loose and fall to the floor, it is more than likely to injure someone passing underneath it. In every case where it is required to keep a belt from slipping off a pulley in this way, a forged bracket should be made and screwed onto the beam as shown at *C*. Such a method is but a makeshift at best, but where a bracket of this kind is screwed into place it cannot work loose.



Safety Suggestions for Belt-shifters, Belt-guides and Drip-cups

Accidents from falling drip-cups occur from time to time. There are few instances, however, in which any provision is made for securing drip-cups to the hangers, in order to prevent them from falling in case they become unscrewed due to the vibration of the shafting. To provide for the safety of those working under the shafting in shops, all drip-cups should be periodically inspected, and they should be fastened in such a way that they can be unscrewed in order to enable the oil to be emptied from them while they are still attached to the hanger. The right-hand illustration at *D* shows what happens when a cup becomes unscrewed or slips out of the workman's hand while he is attending to it. It will be seen that the drip-cup is secured to the hanger by a chain so that it cannot fall. Provision should also be made for the oiler or attendant to hang his pail on the hanger while attending to his work. The hook that holds the chain to the hanger could be utilized for this purpose, the idea being clearly shown in the illustration. Such an arrangement gives the oiler the free use of both hands when attending to the drip-cups.

Hartford, Conn. JAMES E. COOLEY

REMOVING A BROKEN TAP

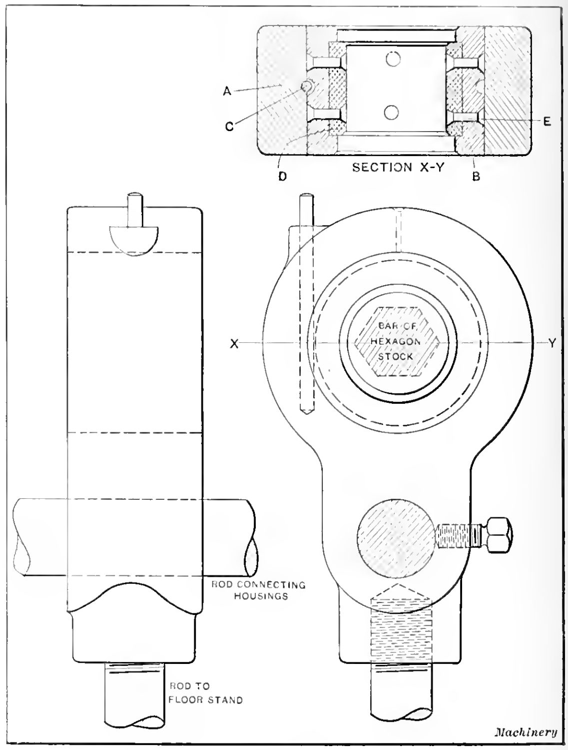
Of all the numerous ideas which have been applied in removing a broken tap, the use of a mixture of sulphuric and muriatic acid seems to be one of the best. In using this method, the first step is to clean all grease and other foreign matter from the hole, using either gasoline or heat for this purpose. Then apply the acid, a few drops at a time; in doing this, particular care must be taken if the tap is bottomed in the hole. The acid cuts both ways, reducing the size of the tap and enlarging the size of the thread, and after a short time the tap can be easily backed out with an extractor or an ordinary pair of pliers. After the acid has been applied, a constant pressure should be maintained on the tap in order to back it out as soon as possible. The hole is then washed out with water to prevent the metal being attacked any more than is absolutely necessary. The use of a little white chalk or alkali in the water is beneficial, as it tends to neutralize the acid and stop all further action. The application of heat will accelerate the rate at which the acid works. The idea is to cut a chip which is formed by the teeth of the tap. Of course where the tap is bottomed hard, a clearance has to be eaten away by the acid, as previously described.

Erie, Pa. A. N. HAMMOND

BACKSTAND FOR AUTOMATIC SCREW MACHINE

The backstand head for an automatic screw machine, shown in the accompanying illustration, was designed to eliminate the noise caused by bars of stock rattling around in the ordinary style of backstand. This improved backstand head consists of a cast-iron housing *A* in which a steel bushing *B* is held in place by a retaining pin *C* in such a manner that the bushing is free to rotate. The center line of the retaining pin is in line with the outside of the bushing, thus allowing half of the pin to enter a groove in the bushing and hold it in place. The groove is of such a size that the pin fits freely in it. The bushing is recessed on the inside to accommodate a piece of double thick leather belting *D* which is fastened to the bushing by brass rivets *E* with countersunk heads. The grip of the leather on the bar stock causes the bushing to rotate, thus distributing any wear which may occur. Bushings of this style are made in three sizes suitable for different diameters of stock.

Three heads of the type illustrated make up a complete backstand, thus supporting the stock at three points and preventing any "whipping" action on account of the short distance between the heads, which is about thirty inches. We have had a stand of this type in use for several months and have found it entirely satisfactory. The stock handled by this particular machine varies from 1 to 2 inches in diameter by 12 feet in length. At present, we are planning to put the same style of backstand on other machines which we are using.



One of the Heads used on the Noiseless Backstand for an Automatic Screw Machine

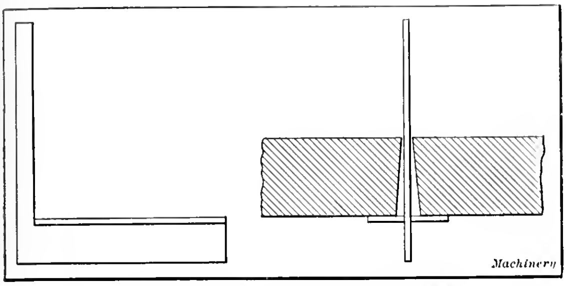
SHOP AND DRAFTING-ROOM KINKS

INGENIOUS MEANS AND SHORT CUTS FOR SAVING LABOR AND MATERIALS

TOOLMAKER'S SQUARE

Small squares or angle gages of the kind used by toolmakers when filing out a blanking or piercing die will be found much more useful if a flat piece of steel is soldered onto the inside of the stock. This piece of steel is brought exactly square with the blade, the arrangement being clearly shown in the



Useful Attachment for a Toolmaker's Square

accompanying illustration. It will be evident that such a square can be used to advantage when making a narrow die which will only take the blade of the square edgewise. In addition to this application, a square fitted up in this way will be found useful for many other toolmaking operations.

Meriden, Conn. JAMES GALLIMORE

SCALE OF FRACTIONS AND DECIMAL EQUIVALENTS

Of the numerous tables that a draftsman has to have for constant reference, one of those most frequently used is a table of fractions and decimal equivalents. Tables of this kind have been prepared in many different forms, the aim being to produce a form that will give the results in the quickest and easiest way. The accompanying illustration shows a diagram of fractions of an inch and corresponding decimal equivalents which takes the place of tables and is, in the writer's opinion, more convenient for many classes of work than an ordinary table would be. Such a diagram can be easily constructed by any draftsman, a pair of bow-dividers used with ordinary care enabling it to be laid out within the required limits of accuracy. Most of the calculations made by a draftsman do not involve the use of fractions smaller than 1/64 inch and as 0.01, or the second decimal place is smaller than a sixty-fourth, it is useless to use a smaller decimal. Regardless of this fact, many tables of decimal equivalents for fractions up to 1/64 inch are carried out to the fourth, fifth and even sixth decimal place.

The accompanying diagram gives the decimal equivalent of sixty-fourths of an inch to the second decimal place direct, and when desired the third decimal point can be readily estimated. The great convenience of this diagram lies in the fact that it shows at a glance the relative values of fractions of an inch and the corresponding decimal equivalents.

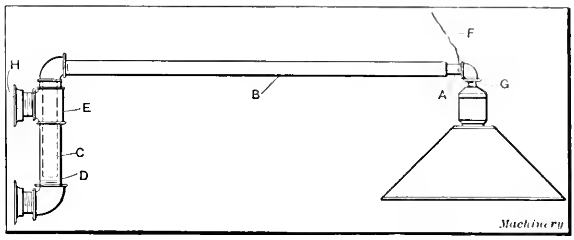
Diagram of Decimal Equivalents, giving Exact Values of Second and Approximations of Third Decimal Place

ADJUSTABLE DRAFTING-ROOM LIGHT

A serviceable form of adjustable lamp bracket for use in the drafting-room is illustrated herewith. This bracket is designed to be attached to the wall or to a window casing and may be used directly in front or to one side of the drawing board. Referring to the illustration, it will be seen that the bracket is made entirely of pipe and pipe fittings, the pipe being cut to the required lengths and threaded at one end only. Horizontal adjustment is secured by slipping the pipe *A* in or out of the pipe *B*, and vertical adjustment is obtained by raising the pipe *C* in pipe *D*. The overhang of the bracket will clamp the pipe *C* sufficiently to hold it at the desired height without the aid of a thumb-screw or other binding device. Any angular adjustment may be obtained by swinging the pipe *C* in pipe *D*.

In making the parts, a drill is run through the ¾-inch tee *E* in order to remove the threads so that it will slip over the



Adjustable Bracket for Electric Light

end of the ¾-inch pipe *D*. This tee is only used as a brace and when it is screwed onto the ¾-inch nipple, the pipe *D* is held in a vertical position. The ⅜-inch pipe *C* slips into the pipe *D* which is made of double strength pipe in order to give a tighter fit. The ⅛-inch pipe *A* slips into the ⅜-inch pipe *B*. A hole is drilled in the pipe *A* close to the elbow to receive the lamp cord *F* which passes down through the elbow and nipple *G* to the lamp socket. The lamp socket screws directly onto the nipple. It is evident that the bracket is secured to the wall by means of screws fitting into the flanges *H*. Dimensions have been omitted from the illustration, as the bracket will naturally be made of different sizes to meet the requirements of individual cases.

HOW AND WHY

QUESTIONS ON PRACTICAL SUBJECTS OF GENERAL INTEREST

DRAWING BRASS TUBING ON STEEL RODS

Answered by C. Fred Gorham, Chicago, Ill.

In answer to the query by G. W. A. in the November number of MACHINERY, regarding drawing brass tubing onto steel rods, I would suggest that instead of drawing or rolling the tubing onto the rod, the following method would give more satisfactory results. Rough-cut the required length of rod in a lathe without lubricating the tool, so that the rod will be perfectly clean but not smooth. Then heat the rod and cast brass around it without using a flux. After the brass has cooled, set the work up in a lathe and turn it down to the required size. The rod should be heated to about the same temperature as the molten brass, but neither the rod nor the brass should be hotter than is necessary to let the brass run freely. The rod should be heated immediately before the casting operation and should not be held at a high temperature any longer than necessary.

PERMANENT SET OF CAST IRON

P. A. L.—I am repairing air cylinders used for opening and closing the doors of elevated cars. Cast-iron spreaders are used to hold the leather packing rings out against the cylinder. I have found a number of these cast-iron spreaders collapsed after being several months in use, which indicates that cast iron can take a permanent set. My foreman says that there is no such thing as a permanent set to cast iron.

A.—Cast iron will undoubtedly take a slight permanent set. The softer the iron the greater the amount of set it will take. This is shown by common experience with piston rings, especially when made of soft cast iron. Often piston rings will be found in a collapsed state, being smaller than the cylinder bore by an amount considerably greater than that due to wear. A common expedient is to peen the inside of the rings, thus giving the rings a permanent set and enlarging the diameter sufficiently to fill the cylinder bore.

CHANGE OF LUMEN METAL BUSHINGS ASSEMBLED BY PRESSURE

H. K.—About sixteen months ago I finished a stock order for our company consisting of a large number of steel shrouds into which "Lumen" metal bushings had been pressed. After being pressed into place the bushings were reamed out to 1.5 + 0.002 inch (1.502 inch), to form a running fit on the shaft. The shafts were made of cold-rolled steel and did not vary more than 0.0005 inch under or over 1.500 inch. The reason for allowing only 0.001 to 0.0025 inch clearance is that the shafts rotated very little in the bearings. After being carefully inspected the parts were boxed and placed in the storehouse ready for use. A few weeks after, we had occasion to send a number of these parts to a contract job, and the construction men found on opening the boxes that the shafts would not enter the reamed holes in the bushings. On inspection we found that a plug gage 1.495 inch would not enter the holes. What was the cause of the trouble?

Answered by Bierbaum-Dollar, Inc., consulting engineers, Lumen Bearing Co., Buffalo, N. Y.

It would be difficult to make an experiment that would show more characteristically a peculiar physical property of "Lumen" metal, an alloy having a compressive strength of 70,000 to 80,000 pounds per square inch. That it should flow under pressure as much as indicated in the foregoing experience will seem rather strange to anyone who has had occasion to observe it for the first time, but that it does act in this way is well attested by our experience. One of the most difficult problems we encountered in the early history of the "Lumen" business was that we could not give satisfactory bushing service. But after experimenting and noting the experience of large users we arrived at the conclusion that "Lumen" bushings must never be forced into a bearing—in other words, made a forced fit. We recommend that all bushings be made a loose fit, or so they can be driven into place with a light pine wood block. Set-screws should be provided to hold the bushing in place. These set-screws should not bottom against the bushing, but should fit in holes drilled deeper in the bushing than the length of the projecting end of the set-screw. Our rule for journal clearance in "Lumen" bushings is 0.001 inch plus an additional 0.001 inch for every inch diameter of the journal. For example, a five-inch bearing should have a clearance of 0.006 inch.

TRADES WAGES IN NEW YORK CITY

F. D. J.—What are the prevailing rates of wages for the building trades, mechanics, etc., of New York City?

A.—The building trades wages per day for 1914 as specified by the United Board of Business Agents, New York, are as follows:

Asbestos workers, boiler felters, pipe coverers, insulators	$4.75
Asbestos workers' helpers	3.00
Blue stone cutters, flaggers, bridge and curb setters	4.50
Blue stone cutters' helpers	3.00
Boilermakers and iron ship builders	5.00
Boilermakers' helpers	3.50
Bricklayers	6.00
Bricklayers' helpers	3.00
Carpenters and framers	5.00
Cabinet makers	5.00
Cement and concrete masons	5.00
Cement, concrete and asphalt laborers	3.00
Derrickmen and riggers	4.00
Decorators and gilders	4.50
Decorative art glass workers	5.00
Elevator constructors	5.28
Elevator constructors' helpers	3.40
Electrical workers	4.80
Electricians' helpers	2.20
Electrical fixture workers	4.80
Engineers, portable hoisting, etc., $30.25 weekly; by the day	6.00
Engineers on boilers, pumps or pile driving machines, per week	30.00
Engineers, stationary	4.50
Framers	5.00
Granite cutters, $5.00 yard; bridge	5.50
House shorers, movers and sheath pilers	3.75
House shorers' helpers	2.65
Housesmiths and bridgemen	5.00
Ironworkers	5.00
Ironworkers' helpers	3.50
Ironworkers' apprentices	3.00
Metallic lathers	5.00
Marble cutters and setters	5.50
Marble carvers	6.00
Marble polishers	4.40
Marble sawyers	4.65
Marble bed rubbers	4.90
Marble cutters' helpers, $3.25; rigging and crane operators	3.75
Mosaic workers	4.50
Mosaic workers' helpers	3.00
Machine stone workers	4.00
Machinists of all description	5.00
Plate and sheet glass glaziers	3.50
Plasterers, plain and ornamental	5.50
Plasterer modelers, per week	$30.00 to 100.00
Plasterers' laborers	3.25
Plumbers and gas fitters	5.50

During 1913 approximately 30,000 applications for patents were made in the United Kingdom, 500 relating to aeronautics.

MACHINING A TRIPLE STAGGERED TOOTH GEAR

A steel gear that is very unusual and probably the largest of its kind ever built was shipped recently by the Mesta Machine Co. of Pittsburg, to the Inland Steel Co., Chicago, and will be used for driving a sheet mill. By the use of this gear and its mating pinion, a single-stage speed reduction is obtained from the motor to the mill. The accompanying illustration Fig. 1 shows this gear in the company's works at West Homestead, Pa. The diameter of the gear is 22 feet, 8 inches, the face width 38 inches, and the circular pitch 5½ inches. The mating pinion is 2 feet 11 inches in diameter. There are 154 teeth in the gear and 20 teeth in the pinion.

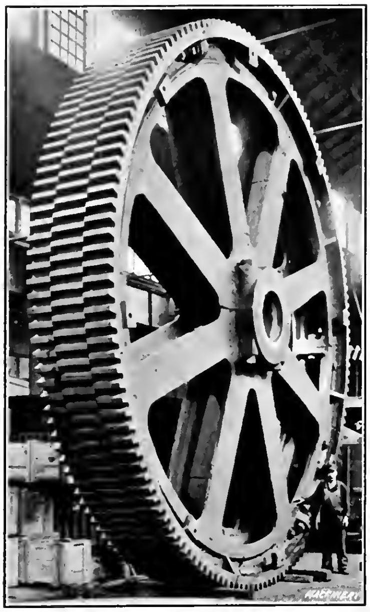

Fig. 1. Large Gear built by the Mesta Machine Co.—Diameter, 22 feet 8 inches: Circular Pitch, 5½ inches; Face Width, 38 inches

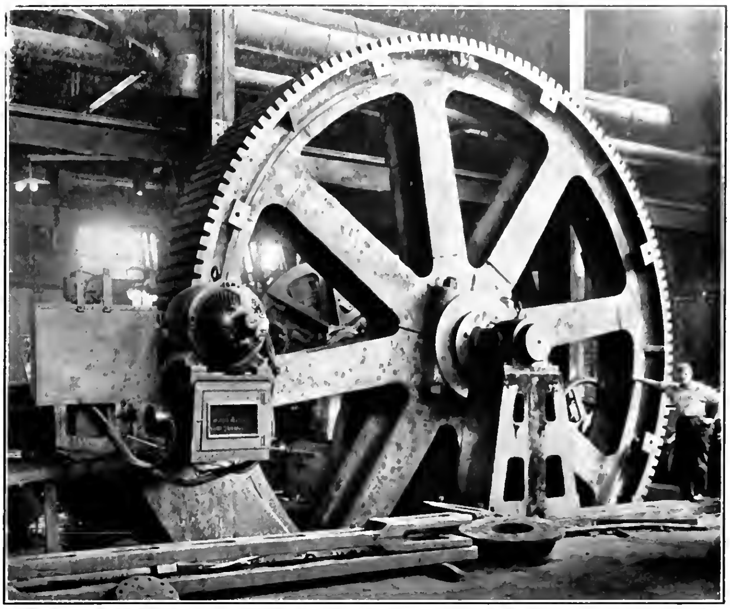

Fig. 2. Large Gear and Special Planer used for cutting the Teeth—Outer Sections of Rim were shifted after Teeth were cut to stagger the Teeth as shown in Fig. 1

The design varies from ordinary practice, the teeth being staggered, as the illustration shows. The gear is built up of six parts. The gear center, including the arms, etc., carries the central rim in which the central row of teeth are cut. The outer rows are cut in separate rims that do not form an integral part of the central casting. The two halves of the gear were bolted together and the separate rims fastened to the central part by bolts extending through the casting. On account of the axial motion to which the gear is subjected, it was necessary to use a spur gear. Herringbone gears were not considered because of the unequal pressures that would be exerted on the sides of the tooth faces. The gears have a peripheral speed of 2000 feet per minute. Because of this high speed the teeth were not only staggered, but very carefully cut, and the drive arranged to run in an oil bath.

The method of machining the gears is very interesting. All the teeth were cut on a planer (shown in Fig. 2) designed and built by the Mesta Machine Co. For such large work, crank-operated tools were found too yielding and, consequently, a special planer was built. The tool of this planer is driven directly by a heavy lead-screw, which, in turn, is operated by a variable speed reversing motor. Starting with the rough casting, the operation of machining this gear will be described. After annealing the casting, the joints at the hub and rim of the central part of the gear were planed. These joints were then drilled, reamed and the two halves

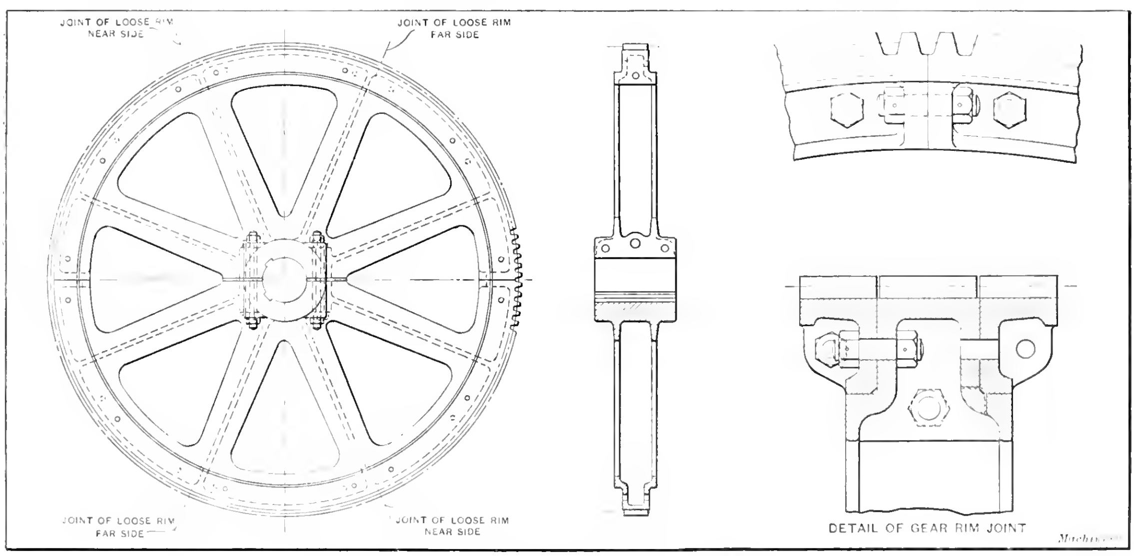

Fig. 3. Large Triple Staggered Tooth Gear made by the Mesta Machine Co.

of the central section bolted together. The wheel was then placed in the pit lathe and the gear center was turned down to the correct diameter; the surface or fitting for the rim segments was also machined. The main gear was then removed from the lathe and the rim segments machined. Lugs were cast on these segments to aid in holding the work onto the faceplate. After bolting a segment onto the faceplate, one side was turned; it was then reversed, the other side machined and the segment turned to the required diameter. The surface of the segment that was to rest on the main gear was also machined at this time.

The rims were next bolted securely to the main gear center with all the rough teeth in alignment across the face of the gear, as shown in Fig. 2. The teeth were then planed through the center and side sections at the same time. The final cut was taken without removing the tool during the entire operation of cutting.

The method of machining the mating pinion was, in a way, similar to that employed for the large gear. After the teeth were cut the bolts were taken out and the two side sections shifted around the center section to give the proper stagger to the teeth. This was done by using an indicating micrometer so that the slightest variation from the required dimensions could be detected. After the teeth of the pinion were staggered, the teeth of the large gear were set to match those of the pinion. Holes were then drilled through both outer rims and the center of the gear, and after these holes were reamed, machined bolts were inserted. The gear was then taken apart and shipped. Inasmuch as the gear is built up of six parts which are fitted together at the plant with machined bolts, its installation will be very simple and it will not be necessary to disturb the machinery already installed.

THE PARIS AEROPLANE EXPOSITION

The Fourth International Exhibition of Aerial Locomotion, which was held in Paris last December, indicated the keen interest that is taken in all matters pertaining to aviation. The exhibition showed clearly that the aeroplane has reached fixed and definite types. Its development in this respect is similar to that of the automobile. There were no longer displayed the startling novelties and innovations seen in the earlier exhibitions. The monoplanes were exceptionally prominent, and most of them were provided with an enclosure or metallic hood for the motor and pilot, affording protection from wind and storm, and, in military machines, from bullets fired from beneath. All parts of the machine—motor, wings and maneuvering apparatus—were stronger and more durable than in the past. The most marked improvements that have been made are almost exclusively in the direction of stability and safety from breakages and failure of parts. Experience has also taught that with a powerful and trustworthy motor the great spread of wing which was formerly thought essential is not necessary. Great improvements have been made in motors and the best of those exhibited have really attained a standard of reliability very near perfection. These motors have made possible the long continued flights without descents which have marked the past year and which were considered impossible only two years ago, the record being a continuous flight of over 500 miles in somewhat more than eight hours.

There was an interesting and large display of hydro-aeroplanes. The majority of these, as well as of the other types exhibited, were intended for military use, many being protected by armor and fitted with quick-firing rifles. Besides the aeroplanes, there was exhibited a huge military car for a dirigible, which was about 30 feet in length, enclosed in a bullet-proof armor and equipped with quick-firing guns and a complete wireless telegraphy outfit.

The only important American exhibit was the new Curtiss four-passenger hydroplane which is essentially a motor-boat with a biplane attached to it. It was the only four-passenger machine in the exhibition. It has a speed record of sixty miles an hour and is especially adapted to meet the requirements of naval service. The exhibition was attended by a large number of military and naval officers from all countries, who studied every detail of the latest improvements with a view to the requirements of their own army and navy service.

DIFFERENCE IN ACTION OF PLANING AND MILLING CUTTERS

BY H. A. S. HOWARTH*

Reference was made in the March, 1913, number to the marked difference in all planer tools and face milling cutters on the grids of magnetic chucks, quoting from the experience of the Walker Magnetic Chuck & Grinder Co. Mention was made of the tendency of cast iron to break out at the edge as the planer tool passes over the edge when it completes the cut, whereas with the face milling cutter the tendency to break at the edges of the grids is much less pronounced. Let us assume that the planer tool is ground exactly the same as one of the inserted blades of the face mill, which is a reasonable assumption because it leads us to look elsewhere for the answer. Following are some differences in the action of the two tools:

(1) The path of the planer tool is straight while that of the milling cutter is curved; (2) the planer tool crosses an edge at right angles while the milling cutter crosses at an angle varying from 0 to 90 degrees; (3) the planer tool takes a heavy cut, usually with a single cutting edge, while the milling cutter takes a light cut with each of several cutting edges; (4) the planer tool lacks the support or control of other edges cutting at the same time, thus it is free to jump forward as soon as the resistance ahead of it is reduced; the milling cutter presents several cutting edges to the work at one time and hence only one edge begins or ends its cut at a time; the rest of the cutting edges under cut are buried in the metal, thus preventing the departing cutter jumping forward; (5) the cutting speed of the planer is likely to be much less than that of the milling cutter because of the difficulty of reversing the table when moving at high speed. Obviously, there is no such condition limiting the speed of the milling cutter. (6) The planer in most cases when small has a pinion, gear and rack drive for the table. The driving mechanism is full of spring, due to the twisting shafts. The milling machine table almost invariably has a screw feed for the table. The milling cutter has a gear drive usually, and this corresponds in a large degree with the gear drive of the planer table, as far as jumping effect is concerned.

Looking over the above comparisons, it seems probable that (3), (4), (5) and (6) explain the difference in action noted. The planer tool is given a comparatively heavy feed in order to get the work out quickly. The result is that the tool jumps forward at the end of this cut and breaks off a piece that extends slightly below the planed surface. The milling cutter takes several fine chips at once and only one breaks over the edge at a time. Hence, the cutter does not jump forward because it is supported by several other cutting edges. The screw feed of the milling machine table steadies its motion and to a large degree removes the tendency to jump.

NEW SIZE JOURNAL, A. S. M. E.

The *Journal* of the American Society of Mechanical Engineers has been enlarged from 6 by 9 inches to 9 by 12 inches. The new size of page favors the presentation of tables, large diagrams, etc., and it will rarely be necessary to resort to inserts and folders, which are costly and inconvenient to the reader. The transactions of the society will not be bound and distributed to the members hereafter. The numbers of the *Journal* will contain the complete transactions and should be kept and bound if the members wish to preserve them.

* * *

During 1913, out of a total of nearly 3200 passenger cars ordered for the railways in the United States, 2765 were of steel, 171 were steel under-frame, and only 177 were of wood; the construction of the remainder is not specified. There is also a very marked increase in the use of steel-frame box cars.

* Address: 3732 Dawson St., Pittsburg, Pa.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW DESIGNS AND IMPROVEMENTS IN AMERICAN METAL-WORKING MACHINERY AND TOOLS

CLEVELAND ROTARY TILTING MAGAZINE

The rotary type of tilting magazine, front and rear views of which are shown in Figs. 1 and 3, is a recent product of the Cleveland Automatic Machine Co., Cleveland, Ohio, that has been developed for use in connection with the Cleveland "automatic." This attachment is used on second-operation work and is shown producing pieces of the form illustrated in

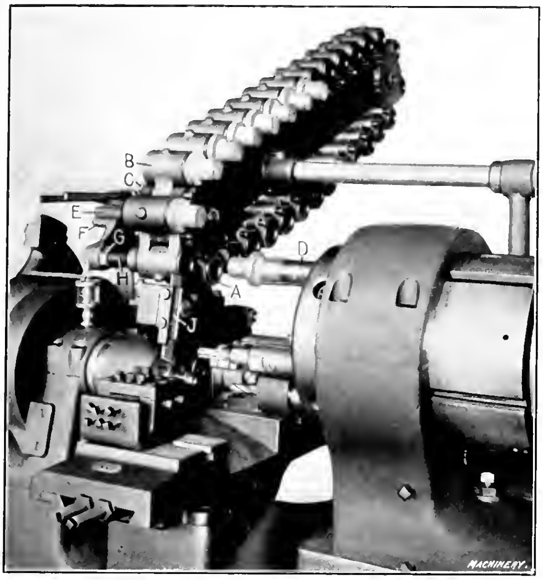

Fig. 1. Front View of Cleveland Rotary Tilting Magazine

Fig. 2. These pieces are produced from cast-iron blanks and it is necessary in this case to separate the work that is gripped in the chuck from the remaining portion. For this purpose the independent cut-off is used. Pieces of this type were produced in five minutes with an actual labor cost of one-half cent. A feature of the attachment is that a bushing required for a large piece of work can be provided with internal bushings to adapt it for holding smaller sized pieces. Occasionally when the magazine is used for some odd shaped piece that has surface enough to grip in the chuck, it is

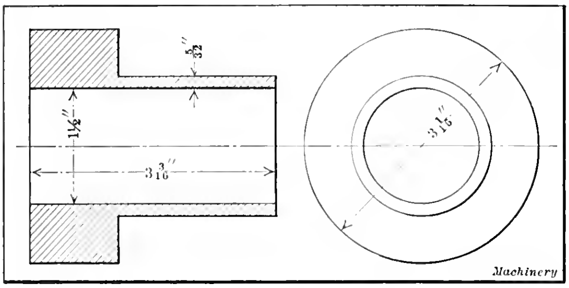

Fig. 2. Example of Work handled by Cleveland Rotary Tilting Magazine

necessary to employ a simple form of latch held by a spring to keep the piece from falling out. This statement applies only to second-operation work and is referred to to show that the magazine may be employed for practically any shaped piece upon which a second operation must be performed. Aside from the tools required for different jobs, the only special equipment necessary is bushings of the required size.

Fig. 1 shows the magazine in the working position. The magazine tilts to the working position and after the piece has been removed it rises to clear the turret tools. In this respect it is similar to the original form of tilting magazine built by this company, but differs from the preceding design in that the parts to be machined are placed in the bushings *A* which are mounted in the links *B*. This arrangement permits of handling a greater variety of irregular shaped parts than was possible with the original form of magazine, where the parts were laid one upon the other and guided by parallel bars. The chain composed of the links *B* is indexed by means of the lower pair of sprocket wheels *C*, one of which is provided with a series of pins that engage an index pawl not shown in the illustration. This pawl rotates the sprockets upon the downward tilt of the magazine and brings each link *B* in line with the conveyor *D* in the turret hole; upon the upward tilt, the pawl drops down and engages the pin following the one that has acted upon it. The sprocket shaft *E* rests in the saddle *F* on the main supporting arm *G*, which serves as a stop and also maintains the required alignment while the conveyor is removing the part to be machined.

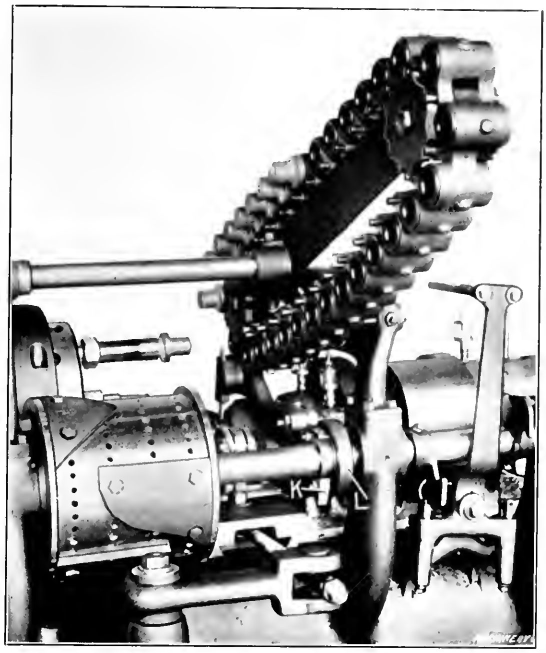

Fig. 3. Rear View of Cleveland Magazine

The adjustable stop *H* mounted on the main supporting arm prevents the conveyor straining the magazine while removing the work from the bushing. Fig. 3 shows the cam *K* and the disk *L* that are employed to operate the independent cut-off attachment. The cam and lever which operate the magazine are mounted on the cam-shaft at the extreme left of Fig. 3, and are not shown in the illustration. This magazine does not interfere with the use of the independent cut-off attachment shown at *J* in Fig. 1, or with the operation of the machine on bar work.

LANGELIER DRILLING AND TAPPING MACHINE

The four-spindle horizontal drilling and tapping machine shown in Figs. 1 and 2 is a recent product of the Langelier Mfg. Co., Providence, R. I. This machine is intended for drilling and counterboring or for tapping four holes simultaneously. An idea of the classes of work for which it is adapted will be obtained by referring to Fig. 3. The positions of the spindles are adjustable to enable the machine to handle a great variety of work. Machines of this type

are built with different numbers of spindles and in different sizes. The four-spindle machine shown in Figs. 1 and 2 has a capacity for drilling and tapping holes up to 3/8 inch in diameter in cast iron, mild steel, brass and other metals. The height from the top of the fixture platen to the center line of the spindles is 5 3/4 inches, which allows plenty of room for handling work or jigs of considerable size.

The two heads at each end of the machine may be moved back until the ends of opposing spindles are 18 1/2 inches apart, or the heads may be advanced toward each other until the distance between the ends of the spindles is only 8 1/2 inches. The front spindle at each end of the machine is provided with transverse adjustment so that these spindles may be located at distances ranging from 1 1/4 to 3 1/2 inches from the center line of the rear spindles. This adjustment is obtained by a cross-slide and screw. Each head is mounted separately on a finished and gibbed saddle interconnected with the feed. The two heads at each end of the machine are withdrawn as a unit by manipulating a single hand lever. Positive adjustable stops are provided for accurately controlling the movement of the saddles so that work produced by an unskilled operator will be uniform, and time losses resulting from over-travel of the saddles are eliminated.

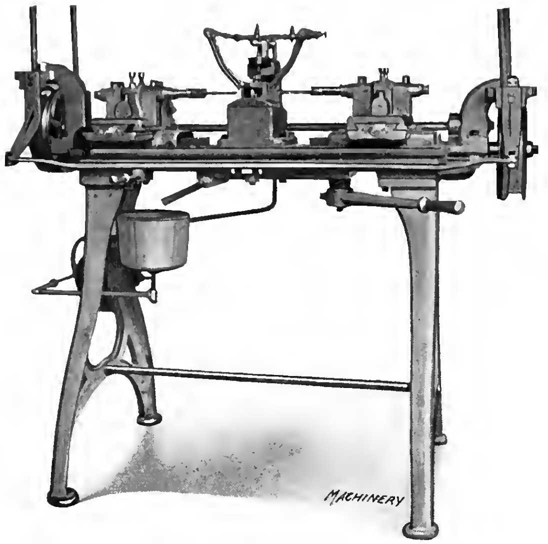

Fig. 1. Front View of Langelier Four-spindle Drilling and Tapping Machine

The spindles have No. 1 Morse taper to receive drill chucks or tap-holders with No. 1 taper shanks. A hard phosphor-bronze gear is keyed to each spindle and driven by a steel driver mounted at right angles to the spindles. The cross-shafts on which the driving gears are mounted are driven from the main horizontal shaft at the back of the machine through another right-angle spiral gear drive. Drilling and tapping thrusts are carried by hard phosphor-bronze and hardened steel washers, and means are provided for taking up end-play.

The machine is driven by tight and loose pulleys which are grooved to carry built-up round leather belts located at the left-hand end of the main driving shaft. Round belts were selected for this purpose because the machine can be reversed with them more quickly than would be possible if flat belts were used. In fact, reversal may be obtained almost simultaneously and without any slipping of the belt. As previously stated, the spindles are driven by the pulleys at the left-hand end of the machine. For tapping operations, when the stop governing the depth to which the work is to be tapped is reached, the tap-holders unclutch and the operator shifts the driving belt to the loose pulley. In so doing, the reverse driving belt at the right-hand end of the machine is shifted from the loose to the tight pulley, thus reversing the direction of rotation of the spindles and backing the taps out of the holes. The taps are backed out at a faster speed than that at which they are fed into the work. The change of speed and direction of rotation is obtained without employing crossed belts, by the use of accelerating gears interposed between the jack-shaft and the main horizontal driving shaft. A special countershaft has been designed for use in connection with this machine which provides two drilling and two tapping speeds.

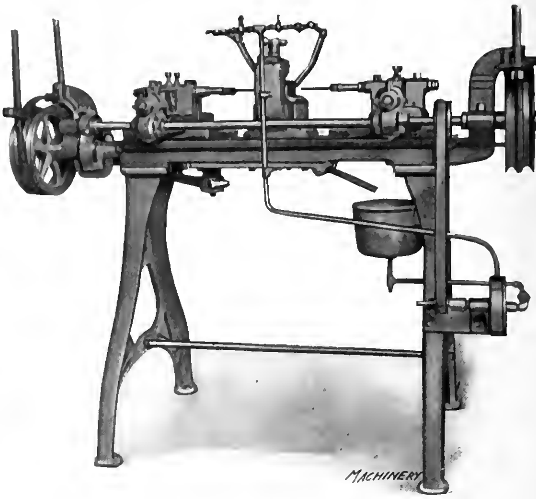

Fig. 2. Opposite Side of Machine shown in Fig. 1

The flow of oil is under the direct control of the operator. Suitable flexible piping connections with pet-cocks lead the oil supply delivered by the rotary pump to the required points. This pump is located at the back of the machine, as shown in Fig. 2, where it will be seen that it is belted to the main driving shaft. All surplus oil and chips are retained on the bed of the machine by the high rim which runs around it. The oil runs into a self-straining reservoir which is piped to the pump suction. In this way the oil is kept in constant circulation without requiring any attention from the operator. Efficient oilers are provided for lubricating the spindles, gearing and other moving parts. This machine occupies a floor space of about 24 by 60 inches; the height from the floor to the spindles is 42 inches, and the weight of the machine is 1750 pounds.

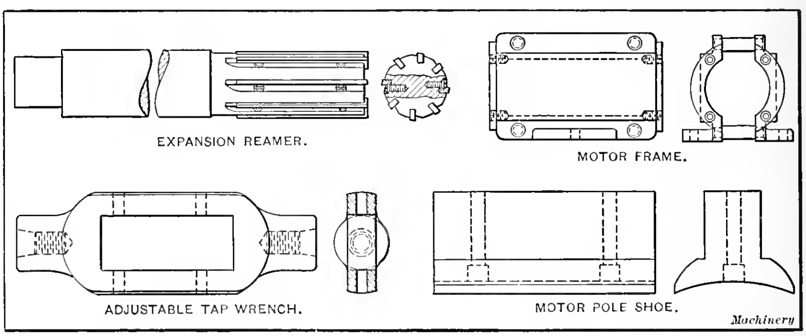

Fig. 3. Examples of Work done on Langelier Drilling and Tapping Machine

ROCKFORD MULTIPLE SPINDLE DRILL

In the design of a line of multiple spindle drills which has been brought out by the Rockford Lathe & Drill Co., Rockford, Ill., the idea has been to produce a simple and accurate machine that is convenient to operate and of ample weight to meet the requirements of modern manufacturing

methods. Referring to the accompanying illustration, which shows one of these machines, it will be seen that the column is of the box type. The table is raised and lowered by a handwheel and has adjustable supports. It may be removed for replaning in event of its becoming badly worn. The spindles are made of high-carbon steel, forged and accurately ground. Ball-thrust bearings and stop-collars are provided, and the spindles are counterbalanced by chains and weights.

Rockford No. 210 "Economy" Floor Drill

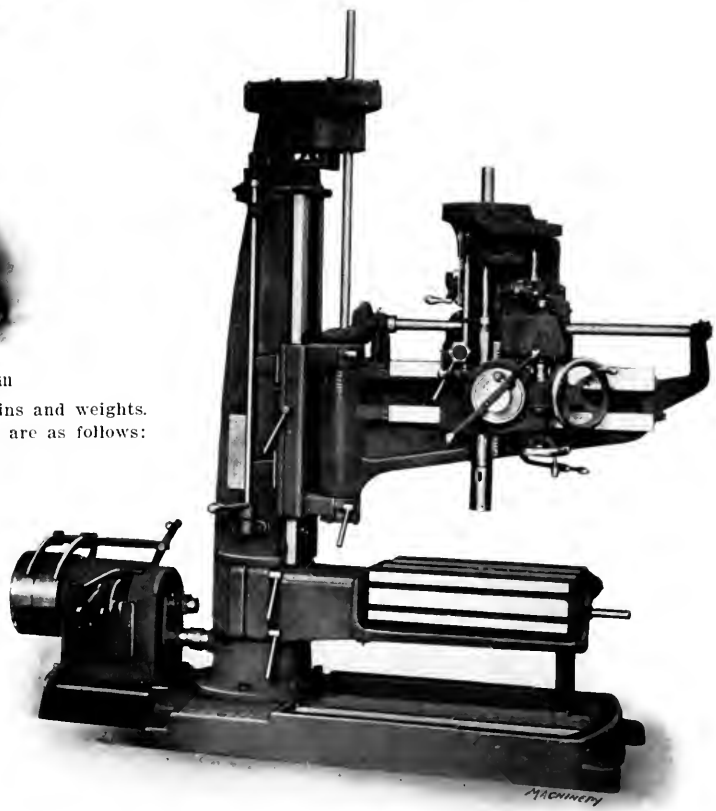
The important dimensions of this machine are as follows: Distance from column to center of spindles, 7¼ inches; greatest distance from spindles to table, 27 inches; distance from center to center of spindles, 10 inches; vertical travel of spindles, 5½ inches; vertical adjustment of head, 9 inches; holes in spindles, No. 2 Morse taper; size of table, 12 by 20 inches; and net weight of machine 655 pounds. The capacity is for drills up to ⅝ inch in diameter. In addition to the two-spindle machine shown in the illustration, this line comprises three- and four-spindle machines.

FOSDICK HEAVY-DUTY RADIAL DRILL

The three-foot size heavy-duty radial drill illustrated herewith is the latest product of the Fosdick Machine Tool Co., Cincinnati, Ohio. With the exception of the box type of column, the arm and the table, this machine is similar in design to the round-column radial drill of the company's manufacture which was illustrated and described in the August, 1913, number of MACHINERY. This new radial drill is adapted for handling a great variety of work. Correct feeds and speeds are instantly obtainable for all sizes of drills from 5/16-inch carbon up to 3-inch high-speed steel. A complete feed and speed table is attached to the column of the machine where it may be conveniently referred to by the operator. To provide means of lubrication for heavy drilling and tapping operations in steel, an oil channel is cast around the base of the machine; this channel drains into a large reservoir under the column where a pump and piping system may be attached. For lighter drilling and tapping operations in steel, a liberal sized channel has been provided around the table; this channel drains to one corner under which a receptacle may be placed to receive the lubricant, thus avoiding the necessity of using a pump and return piping.

It has already been mentioned that the design of the column and arm are one of the new features of this machine. The column is a heavy one-piece box section internally ribbed to provide the necessary rigidity. The arm is of pipe and beam section, this form of construction having proved itself to be an exceptionally rigid combination. This design also provides for a long saddle bearing which can be securely gibbed to the wide flat face of the column, thus reducing the possibility of the arm sagging to a minimum. Means are provided for taking up any amount of wear, and the binder levers are located close to the operating position. The arm rests on a special ball bearing, which reduces the effort required to swing from one position to another, and as the pivoting point is in the saddle close to the work the movement of the arm is made very sensitive. This enables exact settings to be made very rapidly.

The elevating screw which raises and lowers the arm on the highest speed by power is suspended from a ball bearing and the handle is placed in a convenient position for the operator. Safety trips are provided at both extremes of the movement. The tapping reverse frictions are of simple construction and afford ample power. They may be instantly adjusted for any amount of wear, this adjustment being made from the outside of the case in which the gears run in oil.



Fosdick Three-foot Heavy-duty Radial Drill

The back gears are located on the head and give three changes, any one of which is obtained by the operation of a single lever. These changes can be made without the necessity of stopping the machine. The back gears are located between the spindle and the frictions and permit the heaviest work to be handled without slipping. The bevel gears used on this machine are planed to a theoretically correct outline, and the spur gears are cut with special cutters which insure noiseless operation. The gears are of steel, and where exceptionally heavy service is encountered the gears are hardened.

The feed worm-wheel runs in oil. Five changes of feed are available, all changes being made by a single lever without requiring the machine to be stopped. The feed-box is designed to give support at both ends of the feed worm. The speed box provides six changes, any of which is obtained by the operation of a single lever which is secured by a latch to prevent chattering when the machine is engaged on the heaviest class of work. A positive over-take keeps the machine running at a reduced speed, thus avoiding shock when making speed changes. All of the gears are adequately covered and yet readily accessible. The lubrication system is very complete. Oil chambers or felt wipers are used accord-

Fig. 1. Victor Bolt and Pipe Threading Machine

ing to the location, and the bearings are bushed with phosphor-bronze.

Motor drive may be employed on this machine at any time without requiring a special base or speed box. A constant speed or a 3 to 1 variable speed motor is suitable for this purpose, the size required being from 3 to 5 horsepower. The motor should be arranged to drive through a rawhide pinion. Although this machine is nominally a three-foot size, the maximum distance from the spindle to the column is 39 inches, and the distance from the spindle to the base is 52 inches. The net weight of the machine is 4200 pounds.

VICTOR BOLT AND PIPE THREADING MACHINE

The Victor Tool Co., Waynesboro, Pa., recently added to its line the bolt and pipe threading machine shown in Fig. 1. This machine is equipped with a patented die-head which opens and closes positively, no springs being employed. The head is equipped with an adjusting device for regulating the chasers to the required size. All four chasers are moved at the same time by means of this adjustment. When the chasers have been set to the size of the thread to be cut, the head is locked, thus holding the die to a uniform size. Each chaser holder is fitted with a set-screw at the side, by which the angle of the chasers can be regulated to suit the pitch of the thread to be cut. All adjustments can be easily and quickly made. There are no delicate or complex parts of the mechanism to get out of order and cause delay in operation.

Fig. 2 shows a side view of the die-head, illustrating how the opening and closing ring operates. The graduated adjusting screw and the locking screw are also shown in this illustration. Front and rear views of two chasers are shown, from which their design will be readily understood. The chasers are held in the holders by means of hardened screws which enable them to be quickly removed. They are hardened for their entire length and the rake can be ground to suit the various kinds of material that are being threaded. The same chaser can be used on either right- or left-hand work by using a special holder for left-hand threading operations and reversing the chaser. The chasers can be adjusted independently of each other by using the backing-up screw in the end of the holder. This die-head can be attached to any make of bolt threader.

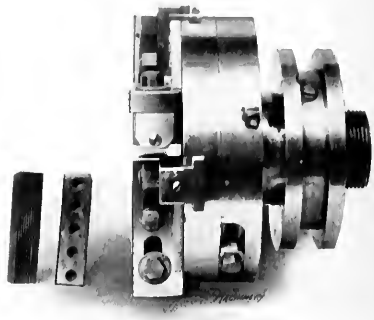


Fig. 2. Die-head used on Victor Bolt and Pipe Threading Machine

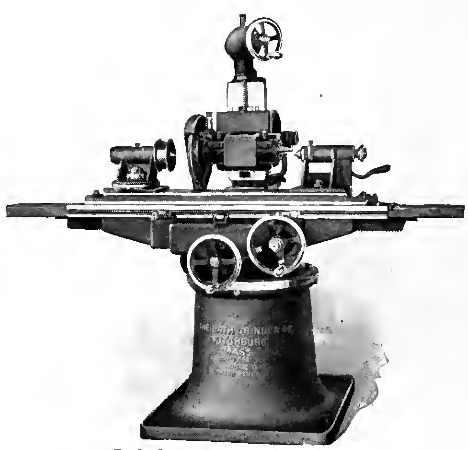
BATH CUTTER AND REAMER GRINDER

The accompanying illustration shows the No. 0 cutter and reamer grinder developed by the Bath Grinder Co., Fitchburg, Mass. The general lines are somewhat similar to those of the universal grinder of this company's manufacture, but the present machine embodies a number of distinctive features which are essential for rapid and accurate production on cylindrical, internal, surface, disk, cutter and reamer grinding. The base of the machine has the column permanently bolted to it, the column being internally ribbed to resist torsional strains. The wheel-head is gibbed to the column and has but one movement, which is vertical.

The cross-slide knee carries the cross and longitudinal slides, and has a circular base of liberal proportions. It swings around the vertical column through an arc of 90 de-



Bath Cutter and Reamer Grinder

grees so that the work-table may be brought to the required position for the various grinding operations for which this machine is adapted. The cross-slide is substantially ribbed and of liberal dimensions. The ways are scraped to master plates and thoroughly protected from water and grit. The table is provided with a swivel-plate for grinding taper work.

and has a scale graduated to indicate tapers in inches per foot. The headstock has a swivel base graduated to 180 degrees, and dead and live centers may be used.

The wheel-head is of rigid construction, the wheel spindle being hardened and ground. The spindle runs in adjustable phosphor-bronze boxes which are thoroughly protected from grit. The handwheel which feeds the wheel-head vertically is graduated to 0.001 inch, and is provided with a positive stop. This handwheel can be readily operated from either the front or side of the machine. The table is operated by hand and equipped with slow and fast travel. Positive stops are provided for both longitudinal and cross feeds, the cross feed handwheel being graduated to 0.001 inch. Water may be used on all operations for which this machine is adapted. The machine is of massive construction and the full universal feature adapts it for grinding large inserted tooth milling cutters up to 20 inches in diameter.

The principal dimensions of the machine are as follows: length between centers, 20 inches; swing, 10 inches; normal range for surface grinding, 9 inches wide by 15 inches long by 5½ inches high; normal range for disk grinding, 10 inches in diameter by 2 inches thick. The vertical movement of the grinding wheel head is 7 inches, and the swivel-plate is graduated to provide for grinding tapers up to 3 inches per foot. The net weight of the machine is about 2100 pounds.

Special attachments which can be obtained for use in connection with this grinder are a water attachment, a radius attachment, an internal grinding attachment and a gear-cutter attachment. The equipment includes a universal work-holder and flange plate, a horizontal vise, a 5-inch four-jaw chuck, a faceplate and draw-in collet, a combined spring and center-rest and countershafts. The following accessories are made for use in connection with this grinder: High and low tooth rests, a diamond stand, two swivel plate clamps, two grinder dogs, three wheel collets, a wheel hood and a wheel flange. The machine may be obtained with full or partial equipment, as desired.

UNITED STATES UNIVERSAL DRILL

The important feature of the portable electric drill illustrated in this connection is that the motor is applicable for use on either 110 volt direct current or 110 volt alternating current of 25, 30, 40 or 60 cycles, single phase. This type of motor was designed by the Westinghouse Electric & Mfg. Co. for use in connection with these drills, the motors being of the series wound type and air cooled.

The gears used in this portable drill are made of chrome-

United States Universal Electric Drill for Use on Alternating or Direct Current

nickel steel; they are hardened and run in grease. The spindle bearings also run in grease. The electric switch is simple in design and construction and is capable of standing up under hard service. This type of electric drill is adapted for either metal drilling or wood boring. Drills of this type are made in three sizes having capacities of ⅜ inch, ½ inch and ⅞ inch by the United States Electrical Tool Co., 6th Ave. and Mount Hope St., Cincinnati, Ohio.

BAKER HIGH-SPEED DRILL

Baker Brothers, Toledo, Ohio, have recently added to their line of drilling machines the No. 1-B high-speed ball bearing drill shown in Fig. 1. One of the characteristic features of this machine is the arrangement of the drive; this is effected through hardened steel gears mounted on shafts which run in ball bearings. Six speed changes are obtainable through the arrangement of sliding gears shown in Fig. 2. For a driving pulley speed of 500 revolutions per minute, the

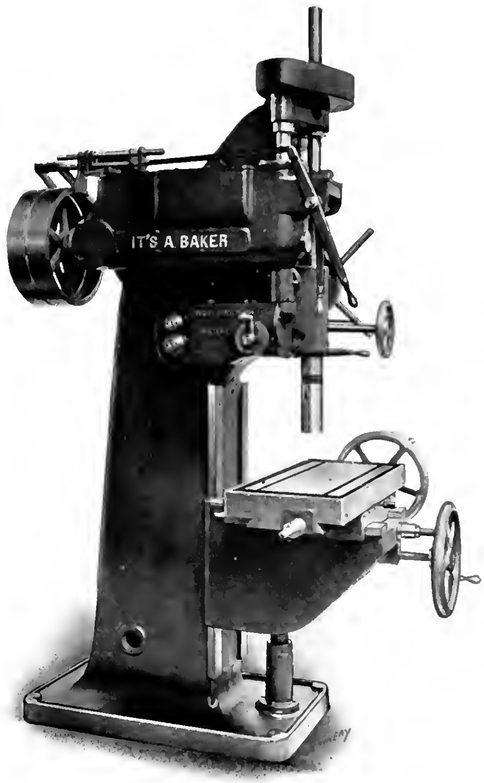


Fig. 1. Baker No. 1-B High-speed Drill

spindle speeds are as follows: 500, 369, 258, 179, 130 and 92.5 revolutions per minute. This corresponds as nearly as possible with the proposed "chromatic scale" of speeds which is advocated by some of the well-known efficiency engineers. It will be noticed by referring to Fig. 2 that with any of the six speed changes, only one pair of gears is in mesh. This not only increases the efficiency of the machine, but also adds to its durability. The latter is a particularly essential feature, as drilling machines experience very rough treatment at the hands of the average drill press operator. The gears are shifted by three parallel rods, the gear shifting lever sliding across an H-plate, giving positive interlocking and at the same time a smooth quick change.

The spindle is made from a high carbon steel forging and the thrust is effectively taken by ball bearings. The diameter of the spindle at the driving end is 2 inches, and the diameter in the quill 2¼ inches. It is bored No. 5 Morse taper. The spindle has a vertical feed of 16 inches, and is equipped with a depth stop. Twelve changes of feed are obtainable, these changes being as follows: 0.006, 0.007, 0.008, 0.010, 0.012, 0.013, 0.015, 0.017, 0.020, 0.024, 0.028 and 0.032 inch per revolution of the spindle. These changes are obtainable by means of a powerful drive key and quick change slip gears. A safety device on the spindle feed shaft is provided to protect the mechanism from injury, and to provide uniform wear on the large worm-gear.

Machines of this type are equipped with either a plain or a compound table. The size of the plain table used is 24 by 29 inches over-all, and 17 by 23 inches inside the oil

grooves. The table is elevated by a screw. The compound table has screw adjustments in all directions and micrometer collars are provided for making accurate in-an-out and cross movements. With the screw adjustments it is not necessary to lock the table in position after adjustments have been made. The over-all size of the compound table is 16 by 30 inches. By way of conclusion, it may be mentioned that drilling machines of this type are equipped for either parallel drive, as shown in Fig. 1, or for the right-angle drive illustrated in Fig. 2.

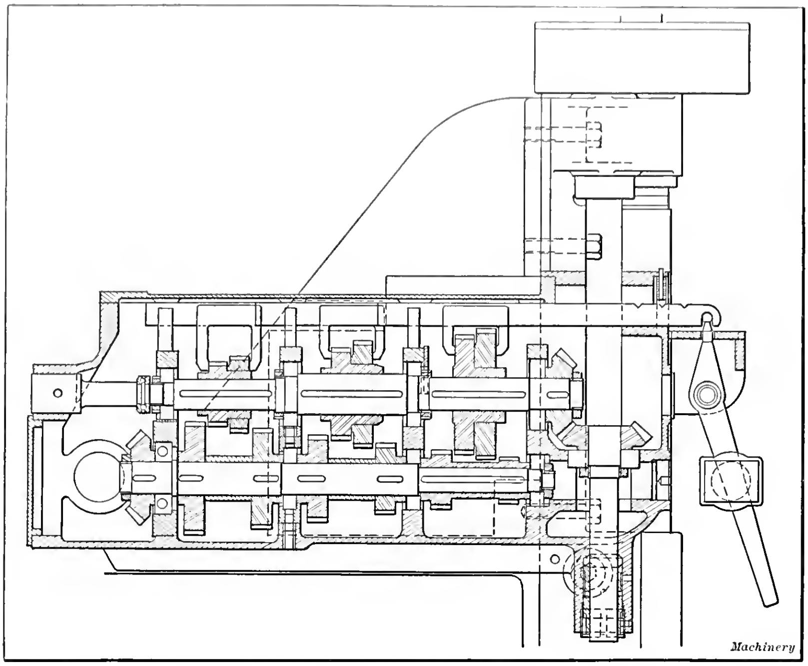

Fig. 2. Speed Box on Baker Drill arranged for Right-angle Drive

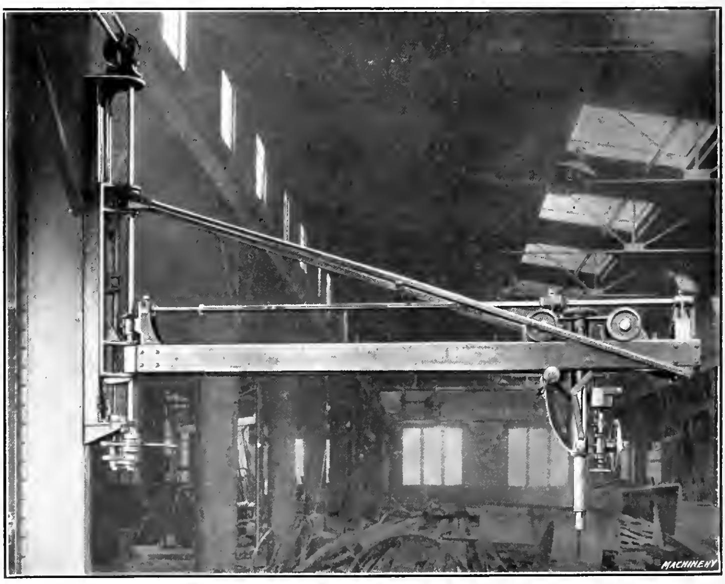
MILWAUKEE WALL TYPE RADIAL DRILL

The accompanying illustration shows the Milwaukee wall type radial drill which is a recent product of the J. C. Busch Co., Lake and Ferry Sts., Milwaukee, Wis. The Vulcan Engineering Sales Co., 2059 Elston Ave., Chicago, Ill., is the sales agent. This drill was designed to meet the requirements of bridge and structural shops and numerous other factories where large surface areas are to be covered for drilling, reaming or countersinking. In working out the design it has been borne in mind that the average machine in such shops receives very hard usage and correspondingly slight attention. To produce a drill that would stand up under such service, the construction has been made exceptionally rigid. All gears are cut from solid blanks and all bearings are bronze bushed, thus reducing friction losses to a minimum.

The machine can either be bolted to a building column or to the wall, or it may be carried on a truck in order to obtain the advantage of a portable tool. A stud is furnished at the end of the arm to afford a means of anchoring the arm to the floor when the machine is engaged in drilling holes of large diameter. Power is obtained by coupling a countershaft to the upper horizontal friction-clutch shaft. The wall plate is a heavy casting with machined ways to guide the elevating carriage which supports the arm and stay-bars. This carriage is provided with bronze bushed lugs by which the vertical shaft is carried. Cupped bronze frictions engaging with spur gears operate the screw shaft for actuating the carriage. Ball bearings take the vertical thrust.

The spindle carriage is a heavily ribbed casting and the wheels on which the carriage runs are carried by roller bearings. Provision is made for locking the carriage in position when drilling and reaming. A substantial sleeve ground to fit the bore in the carriage frame is fitted with ball bearings to receive the end-thrust. The large bevel gear guides and drives the upper end of the spindle. The changes of power feed are obtained through an arrangement of four sets of change gears which operate in connection with a worm-gear and friction clutch. The hand feed is operated by a handwheel which also constitutes the quick return device that is brought into action when the power feed is disengaged. A counterweight automatically raises the spindle when the hand feed is released. All levers and handwheels are located within easy reach of the operator, making the machine easy to control without requiring the attention of more than one man.

The principal dimensions are as follows: The spindle is bored No. 4 Morse taper, and the available spindle feed is 15 inches. The minimum distance from the wall to the spindle is 3 feet, and the spindle carriage has a horizontal traverse of 10 feet, 9 inches. The vertical traverse of the arm is 3 feet, 6 inches, and the arm can be swung through an angle of 180 degrees. The four available feed changes are 0.008, 0.016, 0.030 and 0.069 inch per revolution of the spindle. The weight of the machine is approximately 5000 pounds.



Milwaukee Wall Type Radial Drill

THOMAS SHAFT COUPLING

The accompanying illustrations show two styles of the "Little Giant" shaft coupling which are manufactured by the Thomas Coupling Co., Warren, Pa. The design of the coupling is worked out along lines which eliminate the necessity of cut-

ting keyways in the shafts before they are mounted in the coupling, the keyways in this case being cut by the keys which constitute a part of the coupling. Figs. 1 and 2 illustrate a coupling designed for shafts from 1 3/16 inch to 2 15/16 inches in diameter, and Fig. 3 shows a coupling for shafts ranging from 3 to 6 inches in diameter.

It will be seen from the illustrations that this coupling consists of a round iron or steel casting through which a

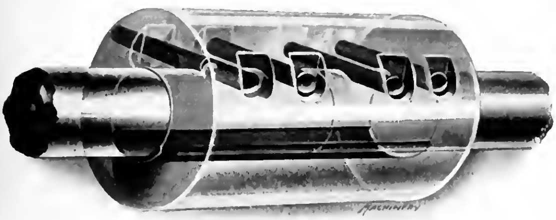


Fig. 1. The Thomas Self-seating and Self-keying Shaft Coupling

longitudinal hole is bored to receive the ends of the two shafts which are to be coupled together. A clearance space is also milled through the body of the coupling in a lengthwise direction, this clearance space being shown at *A* in

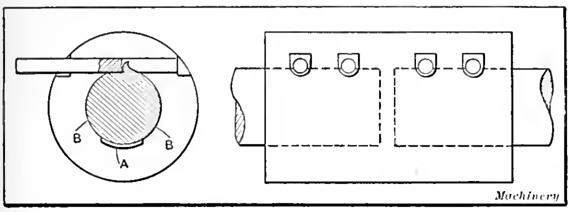

Fig. 2. Details of Coupling shown in Fig. 1

Figs. 2 and 3. The keyways are accurately located and drilled, as shown in the illustrations, so that a portion of the key enters the bore of the coupling. Special heat-treated tool steel pins or keys with cupped ends are driven into the coupling after the shafts have been entered to the desired positions. These keys are driven in by an ordinary hammer and cut away a portion of the shaft which extends above the keyways, the action of the key in cutting away the shaft being illustrated in the end view, Fig. 2. In this way the shaft is securely held against either rotary or longitudinal movement.

Referring again to the clearance space *A* shown in the end views, Figs. 2 and 3, it will be seen that there is a double bearing surface for the entire length of the coupling, these bearing surfaces being shown at *B*. In this way a wedging action is produced and the resistance offered at the surfaces *B* is always proportional to the power which the shaft is transmitting. A feature of this coupling is the entire absence of set-screws, bolt heads or other projections which are likely

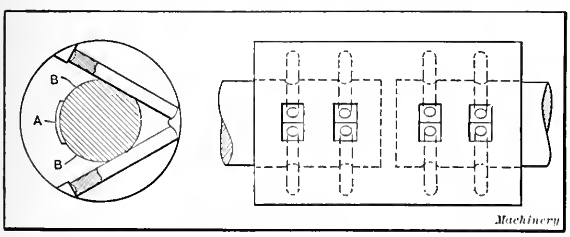

Fig. 3. Thomas Coupling with Keys on Both Sides of Shaft

to catch the clothing of men who are engaged in attending to the shafting in a factory.

FULLER TOOL-HOLDER

The tool-holder shown in Figs. 1, 2 and 3 has recently been developed and placed on the market by S. S. Fuller, 59 Wordsworth St., East Boston, Mass. This holder was designed with the idea of eliminating the breakage of cutters and set-screws which occurs when using tool-holders where the cutter is held in place by a set-screw. The features of the Fuller tool-holder are its simplicity and the flat clamping effect on the cutter. Fig. 1 shows a tool-holder open, in position to receive the cutter, while Fig. 2 shows a holder with the cutter clamped in position ready for use. The principle upon which this holder operates will be better understood by referring to Fig. 3, where it will be seen that the holder consists of two parts—the shank *A* and the movable block *B*. End stops *C* and *D* are provided on the shank, which limit the movement of the block *B*. The seat *E* upon which the block *B* slides is at an angle to the cutter seat *F*, and when the block slides in the direction of the stop *C*, the cutter seat

Fig. 1. Fuller Tool-holder in Position to receive Cutter

G in the block moves toward the seat on the shank of the tool-holder. This causes the cutter to be clamped between the seats *F* and *G*, the pressure being applied over a flat surface which eliminates the danger of breaking the cutter through concentrating the pressure at a single point.

The clamping block *B* is operated by a removable key which is shown in the operating position in Fig. 1. This key has a cam which engages the sides *H* and *J* of a recess in the clamping block when the key is rotated about a pivot fitting in the hole *K* in the shank of the tool-holder. In this way the cutter can be tightened in or released from the tool-

Fig. 2. Fuller Tool-holder with Cutter in Place ready for Use

holder as desired. The key may be used on either side of the tool-holder, and in the event of its becoming lost, the clamping block may be manipulated by tapping it with a soft metal

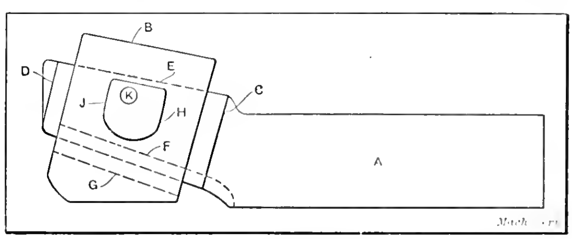

Fig. 3. Principle upon which the Fuller Tool-holder operates

hammer. Another feature of this tool-holder is the self-wedging effect which results from the pressure of the cutter against the work. This pressure tends to clamp the cutter more firmly as the feed is increased, so that the security with which the cutter is held is proportional to the severity of the service.

HORVATH INTERMITTENT MOVEMENT

The accompanying illustrations show a spiral cam and roll plate which was designed by the Horvath Mfg. Co., 190 Hague Ave., Detroit, Mich., to transmit an intermittent motion to a dial. This movement was designed for use on a high-speed automatic machine which required very accurate indexing and locking of a dial at each 1/8 revolution. The Geneva or other intermittent movement could not be used on account of the high speed at which the machine was to be operated, but the cam and roll plate arrangement which forms the subject of this article proves very successful at a speed of 350 revolutions per minute. It operates without shock or

Fig. 1. Horvath Intermittent Movement in the Operating Position

vibration and is noiseless, the curve of the cam being so designed that it starts the dial slowly, then accelerates the speed at the middle of the movement and gradually slows it down again before coming to rest. There is positively no lost motion of the dial in any position.

The operation of this intermittent movement is as follows: The spiral cam, which is the driver, has spiral grooves cut in it, the length and curve of these grooves determining

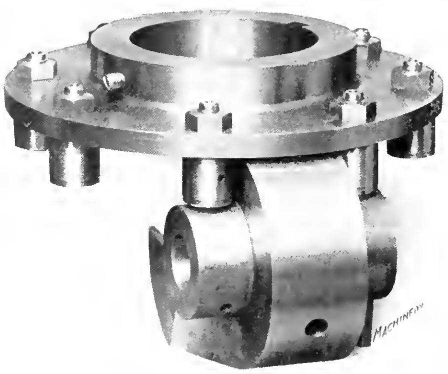

Fig. 2. Horvath Intermittent Movement locked during the Period of Rest

the time required to turn the dial and the period of rest between movements. This relation can be varied to obtain any desired result. The cam groove engages a roll on the plate and revolves it through the required part of a revolution. Any number of stops can be made according to the spacing and number of rolls. The part of the machine to receive the intermittent motion is fastened to the same shaft as the roll plate. As previously stated, the cam and roll plate could be designed to transmit any kind of intermittent motion that was desired. The advantages of this movement may be briefly summarized as follows: The dial is positively locked in every position; any desired period of rest or motion can be obtained; the movement is noiseless at high speed; and as it is of compact form, it occupies very little space. The Horvath Mfg. Co. is prepared to make this type of intermittent movement to meet various requirements.

FAFNIR BALL BEARING BOX

The Fafnir double ball bearing box, illustrated herewith, is a product of the Fafnir Bearing Co., New Britain, Conn. This box was designed to replace plain bearings on existing installations of lineshafting, the substitution being easily accomplished with little loss of time. The dimensions of the casting are such that the ball bearing box may be installed in any standard type of shaft hanger; consequently it is unnecessary to tear down the complete line of shafting, as the substitution of ball bearings for plain bearings may be accomplished by simply removing the coupling and possibly a pulley on each section of the shafting. The ball bearing box is then slipped onto the shaft.

Fig. 2 shows a cross-sectional view of the Fafnir bearing box, from which the construction will be readily understood. The sleeve is an integral part of the two bearings, having a ball raceway ground at each end. The outer rings of the

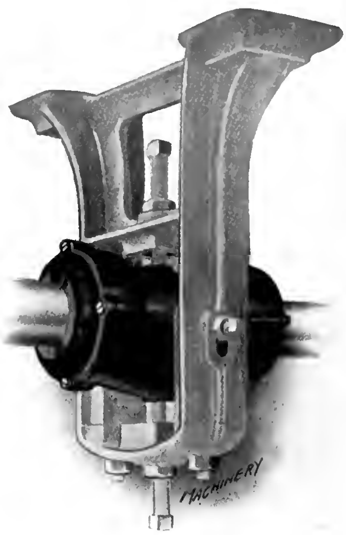

Fig. 1. The Fafnir Ball Bearing Box for Lineshaft Hangers

bearings are held in the box casting, the box being supported in the hanger frame by means of two vertical adjusting screws fitting into cups placed on the casting for this purpose. Where a hanger frame is also provided with side adjusting screws, bearings for the screws are provided by lugs on each side of the casting. As a matter of fact, the top and bottom adjusting screws afford ample support, the side adjustment being unnecessary. The sleeve is a tight slip fit and revolves with the shafting. The two end caps are furnished with grooves which become filled with grease when the bearing is first charged with lubricant, and afford an effective frictionless seal which excludes dust or moisture. Another feature

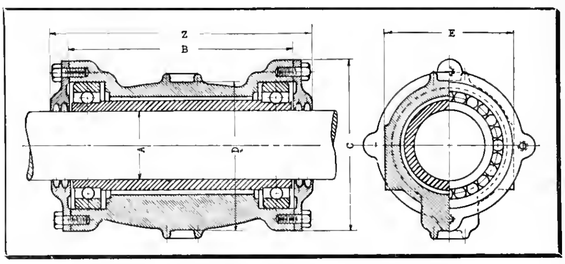

Fig. 2. Cross-sectional View of the Fafnir Bearing Box

of the construction is that it eliminates the necessity for adapters, slip bushings or adjusting nuts of any kind.

The bearings are made of high-grade alloy steel of a special composition that has been found particularly well suited for ball bearings. The rings are subjected to a special heat-treatment, and then ground and polished with the greatest

care. The balls are perfectly spherical and accurate to within 0.0001 inch. The complete bearing operates without noise and is practically frictionless. The manufacturers claim that the substitution of this type of bearing in place of plain bearings effects a reduction of friction losses on the line-shaft ranging from 25 to 60 per cent, and even as high as 75 per cent in certain cases. These figures apply when the shafting is running either idle or loaded. The bearings are charged with non-fluid oil and it is not necessary to replenish this lubricant oftener than once a year. It will be evident from this that the use of these ball bearings also effects a material saving in the cost of shafting maintenance.

HUTHER INSERTED-TOOTH MILLING SAW

Huther Brothers Saw Mfg. Co., 1108 University Ave., Rochester, N. Y., has recently added to its line the inserted-tooth type of milling saw shown in the accompanying illustration. The body of this saw is made of two crucible steel plates which are spring tempered and firmly riveted together. The inserted teeth are made of high-speed steel and they are so formed that sharpening is done only at the front of the teeth. A set of inserts adds about three inches to the diameter of the saw. The construction has been worked out along lines to combine strength and thinness. The latter is a particularly important feature where the saw is engaged in cutting expensive stock, as the saving of material is an important factor. The inserted tooth feature makes it possible to replace worn or damaged teeth at a slight expense.

The manufacturers recommend driving these saws to give a peripheral speed of 60 feet per minute. When operated at this speed the saw can be advanced at the rate of two or three inches per minute according to the capacity of the machine.

Huther Inserted-tooth Milling Saw

Saws of this type are made in a variety of different sizes. The thickness of the teeth for saws of various diameters is as follows: For a 14-inch saw, 3/16 inch; for an 18-inch saw, 7/32 inch; for a 26-inch saw, 1/4 inch; for a 30-inch saw, 9/32 inch; for a 40-inch saw, 5/16 inch; and for a 60-inch saw, 3/8 inch. The thinness of these saws enables them to cut faster and effect a saving in power and material.

GERSTNER TOOL CASE

The accompanying illustration shows a new design of portable tool case which has been brought out by H. Gerstner & Sons, 15-23 Columbia St., Dayton, Ohio. It is known as Style No. 41, and is made in three different sizes to meet different requirements. A convenient set of drawers affords a place for the tools, which are instantly accessible and adequately protected from damage. The top compartment of the case affords space for the larger and more bulky tools.

This case is neatly finished and of light weight, although it is quite substantial and capable of giving good service. The handle, which is similar to that of a suit case, is fastened to the top and enables this tool case to be conveniently carried from one job to another. To close the case, the front lid is pulled out from under the bottom drawer; this lid is mounted on hinges and is swung up at the same time that the top lid is lowered. The case is provided with a lock.

The drawers have felt-lined metal bottoms and the fronts of the drawers are finished in quartered oak. The outside of

No. 41. Gerstner Tool Case

the case is covered with black imitation seal grain leather which is very serviceable and gives the case a neat appearance. The top compartment is felt-lined throughout, and the metal trimmings used on the case are of either polished or nickel plated brass.

ATHOL VISE TAPER ATTACHMENT

Toolmakers frequently find it necessary to hold tapered pieces of work in a vise and for this purpose vises are made with a swiveling jaw. Figs. 1 and 2 show two simple attachments which can be used on an ordinary vise to adapt it for holding tapered work. In this way the plain vise is made to serve in place of the more expensive vise equipped with a swiveling jaw. These attachments are a recent product of the Athol Machine Co., Athol, Mass.

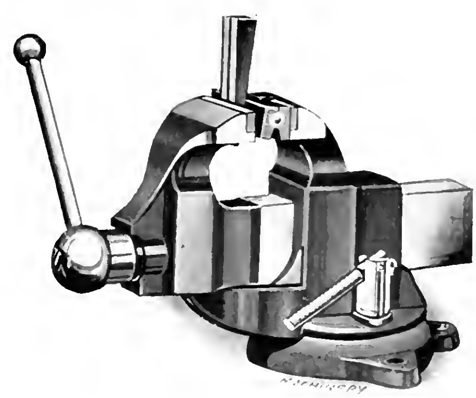

Fig. 1. Athol Vise Attachment for holding Tapered Work in a Vertical Position

Fig. 1 shows the attachment used for holding tapered work in a vertical position. Referring to this illustration it will be seen that the attachment consists of two blocks which are secured to each other by a horizontal pivot. One of these blocks is secured to the stationary jaw of the vise while the other swings on the pivot to adjust its position for the required taper angle of the work.

Fig. 2 shows the attachment for holding a tapered piece in a horizontal position. It will be seen that this attachment consists of a block which is held to the fixed jaw of the vise. This block has two small blocks secured to it by vertical pivots. When the vise is tightened on the tapered piece, these two blocks adjust themselves to the required angle.

This attachment is particularly useful for holding short pieces of tapered work. It will be seen that these two attachments are shown mounted on the Athol swivel base vise

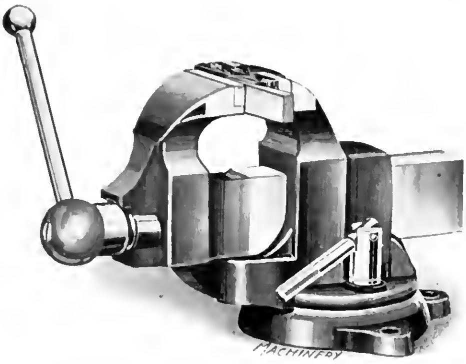

Fig. 2. Viso Attachment for holding Tapered Work in a Horizontal Position

which was illustrated and described in the April, 1913, number of MACHINERY.

SCHUCHARDT & SCHUTTE PROFILE MILLING MACHINE

Schuchardt & Schutte, Cedar and West Sts., New York City, are now building the duplex automatic profile milling machine shown in Fig. 1. This machine is adapted for handling any form of work within its range that can be held on the end of a revolving spindle. It will be seen from the illustration that the machine is equipped with duplex heads, and this feature, in connection with the automatic feeds and trips with which the machine is provided, gives a high rate of production and a corresponding reduction of manufacturing costs. The cutter spindles are belted to the countershaft which is driven at 240 revolutions per minute, except when the machine is engaged in profiling brass parts, in which case the countershaft speed recommended by the manufacturers of the machine is 360 revolutions per minute. These figures are by no means exact, and in many cases it will be found desirable to depart from them. The cutter spindle is hardened and runs in adjustable bearings, the end thrust being taken on a hardened pin which runs in oil. Spiral

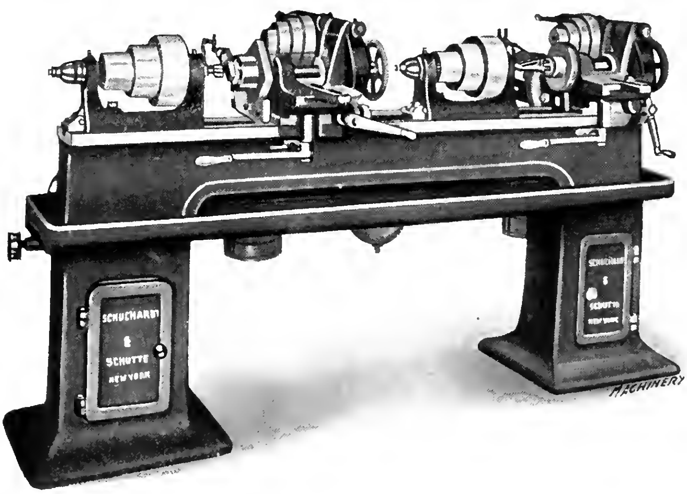

Fig. 1. Schuchardt & Schutte Duplex Automatic Profile Milling Machine

cutters are used which are inexpensive to make and to maintain.

The work is mounted on the ends of spindles carried by the duplex heads of the machine. These heads are supported on cross-slides with adjustable bearings and are moved in and out by means of the master-cams or "copy-plates" which are held in contact with the rollers by weights at the back of the machine. The feed motion which revolves the work against the cutter is driven from the countershaft by means

RATE OF PRODUCTION ON WORK SHOWN IN FIG. 2

Mark	Description	Material	Output	
			Pieces per Hr.	No. of Cuts
A	Pinion cam for motor cycle.	Steel	15	2
B	Cam for gas or oil engine ...	Cast iron	15-30	2-1
C	Valve rod bushing..........	Gun metal	50	1
D	Ball bearing cup............	Steel	50	1
E	Trigger-guard for rifle	Steel	4	2
F	Nut for wheel cap	Gun metal	6	2
G	Hexagon nut	Steel	15	2
H	Cam for gas engine	Steel	15	2
I	Gland for gas engine........	Gun metal	30	1
J	Ball-head lug for bicycle....	Steel	50-60	Either operation
K	Connecting-rod end.........	Steel	30	1

Machinery

of a cone pulley and worm-gearing. Automatic feed trips are provided which can be set to stop the feed at any point

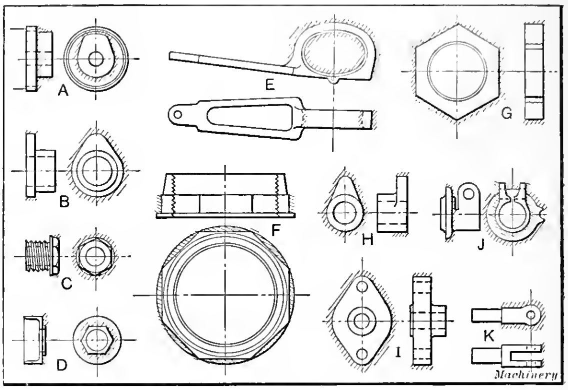

Fig. 2. Examples of Work done on Schuchardt & Schutte Profile Miller

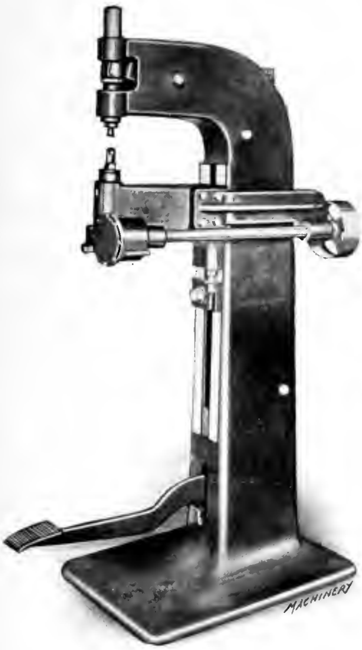
in the revolution. In cases where it is desired to take a second or finishing cut, the trip can be set to operate at the end of the second revolution. Relief clutches are provided on the worm-wheels which enable irregular profiles to be milled that could not be handled by other means. Fig. 2 shows examples of profile milling done on this machine and the table gives the rate of production for each piece.

The saddles have a short movement along the bed to provide for withdrawing internal work from the cutters. The brackets upon which the rollers are mounted which run in contact with the copy-plates are secured to the saddles. The copy-plates are milled on the machine. In arranging the machine for milling the profile of any given piece, the first step is to make a model. This model is then used to control the movement of the machine in milling the master cams or so-called "copy-plates." The copy-plates produced in this way are then used for controlling the machine in profiling subsequent pieces. Each of the duplex heads on this machine is independent of the other so that the two heads can be engaged on different classes of work if such a procedure is desirable. The bed of the machine is of rigid construction and is surrounded by an oil tray equipped with a reservoir and strainer. All of the gears are cut from solid blanks, and all gearing is carefully enclosed to provide for the safety of the operator. The equipment regularly provided comprises two counter-

shafts, master plates, cutters, oil pumps and connections, one copy generating attachment and two cutters.

GRANT RIVETING MACHINE

The riveting machine shown in the accompanying illustration is a recent product of the Grant Mfg. & Machine Co., 80 Silliman Ave., Bridgeport, Conn. This machine represents a departure from the preceding designs which have been brought out by this company in that the riveting is accomplished in a reverse position from that of the regular rivet spinning machines. It will be noted that the riveting rollers are located on the under side instead of at the top, which is the usual practice. This machine was designed for operating on the inside of circular work such as electric light fixtures and a variety of similar articles. The riveting spindle is driven by helical gears which run in an oil-tight case and can be packed with grease or other lubricant. Power is supplied to the machine through a pulley at the rear. Means of adjustment are provided on the countershaft for maintaining a uniform tension on the belt when the table is raised or lowered for work of various thicknesses, thus insuring an efficient transmission of power at all times. The illustration makes the construction and method of operating the machine quite clear.



Grant Rivet Spinning Machine with Rollers on Lower Side

NEWTON CYLINDER BORING MACHINE

The Newton Machine Tool Works, Inc., Philadelphia, Pa., has recently built two large boring mills for machining modern locomotive cylinders, in which the circular valve chamber is bored from the solid cylinder casting. The machine is fitted with a compound table having transverse, longitudinal and vertical adjustment. This enables the circular valve chamber to be bored first, after which the cylinder is bored. While the cylinder is being bored the valve chamber bushing can be fitted, and the final operation then consists of boring this bushing. The adjustments provided by the compound table enable all of these operations to be handled without disturbing the location of the work, and this elimination of the necessity for resetting is the means of effecting a material saving of time. The spindle is 7 inches in diameter and has a continuous travel of 140 inches. There are six changes of geared feed and rapid power traverse in both directions. The capacity of the machine is to bore and finish both ends of cylinders up to 50 inches in length. The cross adjusting table is 54 inches in width by 72 inches long, and the vertical adjustment gives a range of from 39 to 51 inches from the top of the table to the center of the spindle. The maximum distance between the facing arms is 60 inches.

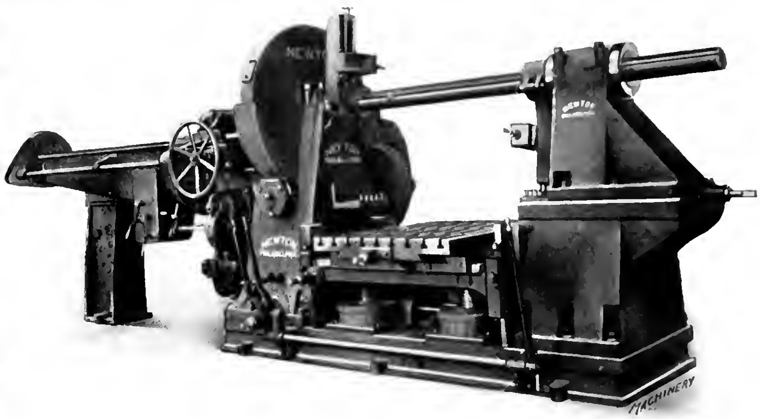


Fig. 1. Front View of Newton Locomotive Cylinder Boring Machine

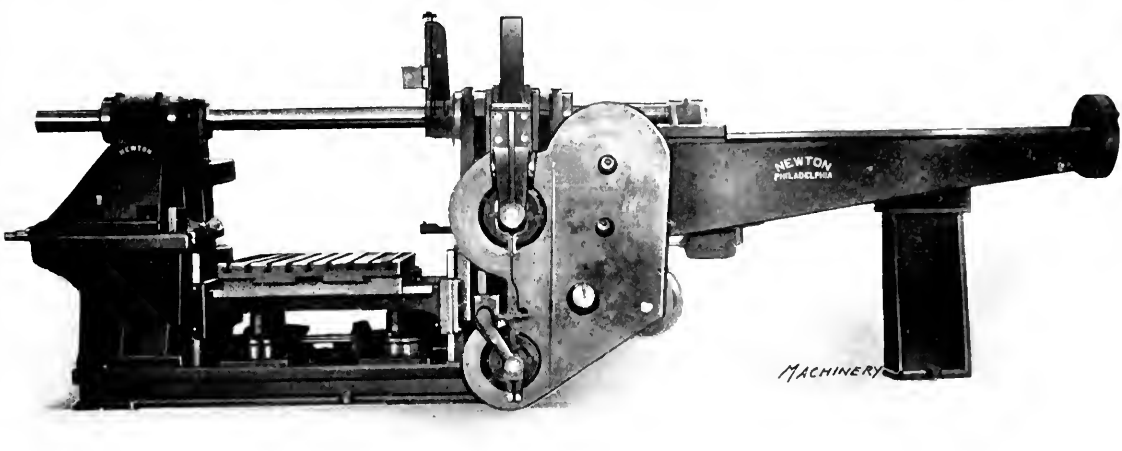

Fig. 2. Opposite Side of Boring Machine shown in Fig. 1

The main drive for the spindle is through a steep lead worm-wheel which engages a hardened steel worm fitted with roller thrust bearings. The worm and worm-wheel are encased and run in oil. The drive is so arranged that the fast power traverse of the spindle may be used while the spindle is not rotating, and this fast power traverse, the rotation of the spindle, and the power elevation of the table

may be disengaged or engaged by levers located at the operating side of the machine beside the main head without stopping the motor. The feed is taken from the gear-box, having eight gears mounted on sliding sleeves. Six feed changes are available without requiring the removal of gears, and the sleeves are easily adjusted by means of latch levers.

The saddle has roller bearings to take the thrust in both directions. The outboard bearing is provided with independent in and out adjustment so that the cylinders may be mounted on the main table and adjusted to come within the range of the facing head on the main spindle sleeve. The outboard bearing can then be adjusted to bring the dependent facing head within range of the adjacent spindle flange. It will be noticed that the facing heads are provided with an eccentric clamp permitting the spindle sleeves to be rotated while the facing heads hang idle.

VALLEY CITY WHEEL-GUARD

The illustrations show a new adjustable wheel-guard which the Valley City Machine Works, 12-16 Campau Ave., Grand Rapids, Mich., has added to its line of grinding equipments. While primarily developed for use in connection with Valley City grinders, this hood is applicable for use in connection with any type of emery wheel stand. An important feature is that it protects the nut on the arbor as well as the wheel.

Fig. 1. Small Size of Valley City Grinding Wheel Guard

Fig. 2 shows a 24-inch guard which has been adjusted to fit over a grinding wheel 18 inches in diameter. It will be evident from this illustration that the hood has been moved back so that the face of the wheel is available; at the same time adequate protection is provided. Guards of this type are made in sizes for grinding wheels ranging from 8 to 24 inches in diameter.

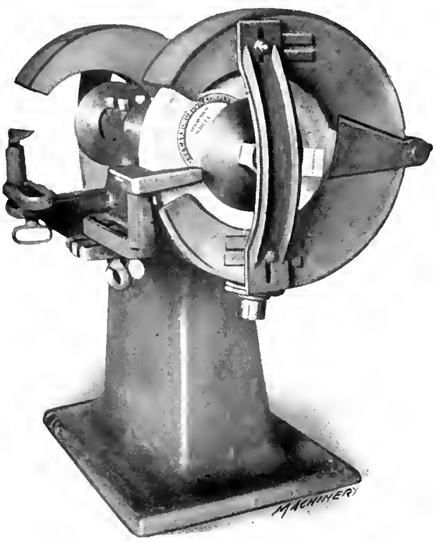

Fig. 2. Grinding Machine equipped with Valley City Wheel Guards

NEW MACHINERY AND TOOLS NOTES

Cutter Head: Joseph Villiger, Dixon, Ill. A cutter head designed for use on rotary slitting machines. The head is clamped to the shaft by means of a square headed collar screw.

Hydraulic Pump: Defiance Machine Works, Defiance, Ohio. A double plunger, hydraulic pump for use in connection with hydraulic presses where the required pressure ranges from 5 to 100 tons.

Hydraulic Press: Hydraulic Press Mfg. Co., 84 Lincoln Ave., Mt. Gilead, Ohio. A 500 ton inverted hydraulic press intended for straightening steel castings. This press can also be used for other heavy straightening operations.

Engraving Machine: George Gorton Machine Co., Racine, Wis. A machine intended for engraving serial numbers on the oval edges of cream separator bowls. Motor drive is provided by a motor carried on a shelf secured to the standard.

Plate Joggling Machine: Hilles & Jones Co., Wilmington, Del. A machine with a capacity for handling plates ¾ inch in thickness at the rate of 10 feet per minute. The machine is driven by a 50 horsepower G. E. motor, taking current from a 220-volt direct-current circuit.

Tapping Chuck: W. L. Procunier, 208 N. 5th Ave., Chicago, Ill. A tapping chuck arranged with a safety friction drive to prevent breaking the taps. One of the features of this chuck is that there are no projecting parts, such as set-screws, which can injure the operator.

Threading Machine: Williams Tool Co., Erie, Pa. A 16-inch pipe threading and cutting-off machine which is known as the No. 6 size. This machine is adapted for the heaviest classes of work that come within its range. Pipe ranging from 7 to 16 inches in diameter can be handled.

Gages: Reed & Prince Mfg. Co., Worcester, Mass. This company has recently brought out an adjustable templet gage provided with a fitting pin to keep the gage in alignment. Other recent products are a solid templet gage for screw stock, a thread limit gage and a screw thread micrometer.

Diamond Holder: Thomson Tool & Supply Co., Indianapolis, Ind. A diamond holder for use in dressing grinding wheels. The diamond is held in place against the pressure of a spring and in case of shock the spring absorbs the excessive pressure and greatly reduces the possibility of breaking the stone.

Friction Socket Wrench: Allen Wrench & Tool Co., Providence, R. I. This wrench consists of three working parts, designed in such a way that it grips the socket head and turns it by the action of a friction drive. The wrench can be made to grip at any point and is available for use in very limited spaces.

Portable Geared Electric Hoists: Detroit Hoist & Machine Co., Detroit, Mich. A line of geared electric hoists which is quite similar to the line of pneumatic hoists made by this company with the exception of the motive power. The hoist is of simple and compact design and is said to be essentially "fool proof."

Disk Grinders: Gardner Machine Co., Beloit, Wis. Two styles of patternmaker's disk grinders. One of these machines is equipped with direct connected motor drive and is only adapted for wood-working. The other is a combination machine which can be used by patternmakers and is also suitable for grinding metal.

Pneumatic Drill: Ingersoll-Rand Co., New York City. A pneumatic drilling machine built in five sizes. A feature of this machine is that the entire motor apparatus may be assembled or taken apart through the crank case by simply removing the cover. The motor is of the angular, four-cylinder, single-acting reciprocating type.

Cylinder Boring Machine: Moline Tool Co., Moline, Ill. A multiple spindle machine equipped with a cross adjustable table to adapt it for milling ports in the cylinders of Knight engines, the design of the head being carefully worked out to secure a degree of accuracy in machining that makes a subsequent grinding operation unnecessary.

Vertical Saw: Newton Machine Tool Works, Inc., Philadelphia, Pa. A vertical spindle cold metal saw, designed for cutting off risers from relatively flat castings such as driving wheels, large gears, etc. The casting is placed on the table of the machine and bolted in place, after which the riser is cut off by feeding the work up to the saw.

Speed Regulator: Standard Engineering Works, Woonsocket, R. I. A speed regulating device where the speed variation is obtained by adjusting the relative sizes of the driving and driven pulleys. The rims of these pulleys are made in sections and provided with means for expanding or contracting them to adjust the diameters to the required sizes.

Cutter and Reamer Grinder: Matson Machine Co., Concord, N. H. A machine with a range that enables it to handle grinding operations on all types of milling tools up to 11 inches in length by 8¾ inches in diameter. Tools with either straight or spiral flutes may be sharpened and the machine is also capable of handling end mills with straight or taper shanks.

Gang Drill: Rockford Drilling Machine Co., Rockford, Ill. A vertical chucking gang drill designed for handling work requiring considerable power but where a great amount of swing is not necessary. The machine is provided with a simple type of positive geared feed providing a wide range

for boring, drilling and reaming operations. Hand feed is also available.

Screw Driver: Benjamin Electric Mfg. Co., Chicago, Ill. A friction screw driver which combines the features of an ordinary and a ratchet screw driver. The handle of the screw driver is insulated, making it particularly suitable for the use of electricians. The friction drive is obtained by a V-bearing between the two parts of which the hard rubber handle is composed.

Heat-treating Furnace: Industrial Furnace Co., 671 Atwater St., Detroit, Mich. A line of furnaces for use in the heat-treatment of high-speed steel. These furnaces are provided with an exceptionally large burner capacity to adapt them for furnishing the high temperatures required for high-speed steel treatment. The lining is particularly heavy to enable them to withstand the intense heat.

Plain Grinding Machine: Brown & Sharpe Mfg. Co., Providence, R. I. A variable speed mechanism is the chief feature of this machine. This device consists of multiple friction disks located at the rear of the machine. By adjusting two levers at the front of the machine a wide range of table feeds and work speeds is obtainable. A dial provides for setting the levers for the required speed and feed.

Boring Mill: Pratt & Whitney Co., Hartford, Conn. A boring mill equipped with a side head. With the side head in operation, the machine is capable of turning, boring or facing work up to 38 inches in diameter. With the side head lowered below the surface of the table, work up to 44 inches in diameter can be faced with the vertical turret. Both turrets are provided with independent feed and rapid traverse.

Upright Drill: W. P. Davis Machine Co., 305 St. Paul St., Rochester, N. Y. This machine has a geared feed box and dial for regulating the feed changes. There are three changes of positive geared feed ranging from 0.007 to 0.017 inch per revolution of the spindle. The dial shows at a glance the feed that is in use. The back gears on the machine are thrown in and out of engagement by the movement of a single lever.

Countersinking Machine: Chicago Pneumatic Tool Co., Chicago, Ill. This machine has been developed with the view of eliminating the necessity of employing rigging, back stops and feed-screws that were formerly necessary for drilling and countersinking holes in the flanges of channels, I-beams and similar work. This countersinking machine is intended for use in connection with the "Little Giant" drill built by this company.

Four-spindle Boring Mill: Newton Machine Tool Works, Inc., Philadelphia, Pa. Each of the four spindles of this machine is provided with individual drive. Two of the spindles are driven by 7½ horsepower G. E. motors running at 400 to 1200 R. P. M. and giving spindle speeds of 6 to 54 R. P. M. The other two spindles are driven by 5 horsepower G. E. motors running at 400 to 1200 R. P. M. and giving spindle speeds of 18 to 54 R. P. M.

Radial Drill: William Sellers & Co., Inc., Philadelphia, Pa. A high power radial drilling machine built in 60, 72, 84 and 96-inch sizes. The drilling head is designed to bring the spindle close to the face of the arm to eliminate torsional strains as far as possible. The drill head is moved on the arm through a spiral pinion and steel rack, the handwheel being placed directly on the head. The machine is driven by a 20 horsepower variable speed motor.

Alligator Pipe Wrench: Shaw Propeller Co., Boston, Mass. This wrench is composed of a single piece of metal and is capable of doing any work that can be handled by a Stillson-, monkey-, alligator- or flat-wrench. Work can be done rapidly with it, and a sure grip is obtained, the wrench being of ample strength for work that comes within its range. No adjustment is required to adapt the wrench for different classes of work. The grip is proportional to the effort which is required to loosen a nut or fitting, being automatically adjusted by the effort applied by the operator.

Die Casting Machine: Indiana Die Casting Development Co., Indianapolis, Ind. A semi-automatic rotary type die casting machine. A Bellevue gas-fired soft metal melting furnace is used to melt the metal, which is delivered to the machine pots as required. Sheet metal covers are provided to protect the operator from danger resulting from the liability of the metal to spurt out if the pressure is applied before the die is properly closed. The machine is of the non-plunger type. It is operated under high air pressure and the metal is drawn from the bottoms of the pots, which insures obtaining dense castings.

Boring Mill Pressure Compensator: H. D. Bennett, Baltimore, Md. A device intended for reducing frictional resistance of the table of boring mills. This compensating device was designed to eliminate the difficulty experienced in a shop where the lineshaft was driven by an engine that was occasionally subjected to severe overloads. At such times the frictional resistance of the boring mill table was sufficient to put the machine out of action. The use of this pressure compensator has proved a means of eliminating this difficulty, and it is capable of saving a considerable amount of power in the operation of boring mills.

Rack Cutting Machine: Gould & Eberhardt, Newark, N. J. A rack cutting machine designed for use on medium sized work. This machine is made up of parts of the 36 by 12 inch vertical cutter type of gear cutter built by Gould & Eberhardt. The work table is indexed automatically and while the indexing is being performed the cutter slide is locked so that it cannot feed down until the indexing has been completed. Single or gang cutters may be used and the machine may be arranged to index automatically for the number of cutters that are in use. The capacity of the machine is for racks up to 36 inches in length by 10-inch face width, and it will cut teeth of 1½ diametral pitch in cast iron or 2 diametral pitch in steel.

* * *

HIGH-SPEED DRILL USAGE

The Cleveland Twist Drill Co., Cleveland, Ohio, states that the cutting ability and hardness of drills are not the same thing, especially in high-speed drills. The apparent hardness which varies with the composition of the steel is no indication of its power to stand up under cut. A high-speed drill that cannot be filed may be made to drill extremely hard material by exercising great care, but it is so brittle as to be worthless for softer material. Numerous tests have proved that files vary in hardness quite as much as other hardened tools, and for this reason file tests are unreliable. No drill that files hard or soft should be condemned for this reason alone, but should be first given a drilling test in material of known hardness.

The recommendation is made that high-speed drills be warmed before using, especially where the conditions of service are severe. Any hard piece of steel is brittle when cold, and high-speed drills are no exception. They work better when warm, often giving good results when the chips are turned blue by the heat generated. Never turn cold water onto a high-speed drill, as it is very likely to crack. It is also bad practice to plunge a drill into cold water after the point has been heated in grinding. The drill may be impaired by starting a number of fine cracks in the point.

The following lubricants are recommended for the given materials: Turpentine, kerosene or soda water for hard and refractory steel; lard oil or soda water for soft steel and wrought iron; soda water for malleable iron; a flood of paraffine oil, if any for brass; kerosene or soda water for aluminum and soft alloys. Cast iron should be drilled dry or with a jet of compressed air.

* * *

The Bullard Machine Tool Co., Bridgeport, Conn., has issued a catalogue and treatise on the Bullard vertical turret lathe which is not only unusual typographically but a decided departure from the conventional catalogue. In fact, the idea in the preparation of this book was, first of all, to make it of practical value to shop superintendents and others interested in the efficient production of what is commonly known as faceplate work, and to subordinate the catalogue feature. For this reason, a large amount of space is given to illustrations showing many typical as well as unusual machining operations. It is pointed out that the cutting time only is productive in machine tool operation and that the design of the machine tool is only effective in so far as it reduces the waste time between cuts hence, the significance of the title of this treatise, "Cutting Time Between Cuts." It contains 103 pages, 8½ by 11¼ inches, is printed on heavy paper and is beautifully illustrated. The fore part of the book contains large halftone illustrations, showing in detail the adaptability of the Bullard vertical turret lathe and its application to various classes of faceplate and chuck work. Beneath each illustration the operation is briefly described. Following, there are about twenty-four pages filled with diagrams showing the tool equipment and successive order of operations on a great variety of vertical turret lathe work. These diagrams are interesting as well as instructive, and show graphically the most modern practice in the boring and turning of many different machine parts. The latter half of the book relates to the turret lathe with its accessories and attachments. Various noteworthy features of the machine are described and illustrated, including such important parts as the table spindle, the bed, the cross-rail, the turrets, feeding mechanism, the lubricating system, the thread cutting attachment, the forming attachment, etc. The specifications for vertical turret lathes of various sizes and designs are also given. This book should be of value to every machine shop manager and superintendent, and every mechanical man, no matter what his position, should find a study of its pages instructive and interesting to an unusual degree.

DEVELOPMENT IN PLANER TYPE MILLING MACHINES

The modern superintendent or foreman who is responsible for the maintenance of the rate of production of a factory or shop is apt to take the most efficient forms of manufacturing equipment for granted. Such men make it their business to know the rates of production that are possible with different types of machine tools, and when a new job comes up they carefully consider the merits of the different machines

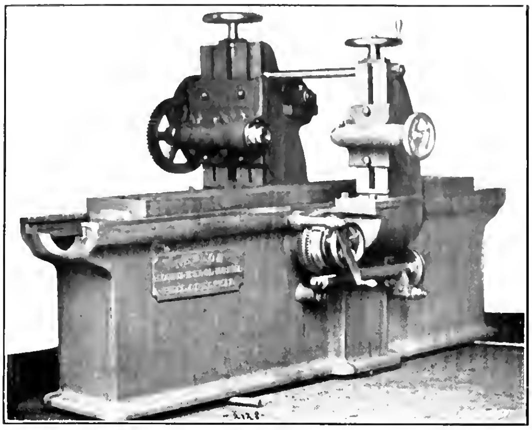

Fig. 1. First Heavy-duty Milling Machine built in the United States

on which it could be performed in order to select that type which they believe to be best suited for the requirements of the work. But the time of these men has been so fully occupied by their work that they have had little time to watch the development which has taken place in the machines that they use, unless such machines have been the product of the particular factory in which they are employed.

Although of little practical value, it will doubtless be of interest to look back upon the progress which has been made in machine design—for instance, in the planer type of milling machine. The accompanying illustrations give an idea of the progress which has been made in this particular type of machine in the last thirty years. Fig. 1 shows what is said to be the first heavy-duty milling machine built in the United States. This particular machine is a product of the Newton Machine Tool Works, Inc., Philadelphia, Pa., and was built for the Stearns Mfg. Co., Erie, Pa., in 1884. Referring to the illustration it will be seen that the outer end of the cutter arbor was supported by a center, and the intermediate driving gears were supported by links. Later machines of this design were furnished with simultaneous vertical adjustment. Unfortunately, no records are available to show the rate of production obtained by this machine, which had a weight of about 10,000 pounds.

Previous to 1905 very few records were kept showing the output and cost of production of work on different types of machine tools, but in the opinion of the Newton Machine Tool Works a feed of about 1 inch per minute on slabbing operations is the best rate that was obtainable at this period with planer type milling machines. At about this time the Newton Machine Tool Works contracted for two machines for use in a large locomotive shop. These machines were built under a guarantee to take feeds of 2 inches per minute on slabbing operations; this was regarded as considerably in excess of average practice and was felt to be quite a risk. After the machines were shipped, the user reported that slabbing operations were being performed with feeds of from 6 to 8 inches per minute. Upon receipt of this advice an investigation was made and it was found that the increase in feed was made possible by the invention of the spiral inserted tooth high-speed milling cutter by Mr. C. D. Peck. This type of cutter is now known as the Taylor-Newbold cutter.

Fig. 2 shows a 50-inch size planer type milling machine which is one of the modern designs of the Newton Machine Tool Works. A comparison of this machine with the one antedating it by thirty years will show the wonderful progress which has been made. This machine is equipped throughout with steel or bronze gears. The table is of exceptionally heavy box-type construction, and the feed is obtained through an angular steel rack and spiral bronze pinion. The feed is obtained from a 50 horsepower motor shown at the left of the machine and the elevating of the rail is provided for by a special 3 horsepower motor mounted on the tie-beam. The spindle is driven by a steep lead bronze worm-wheel meshing with a hardened steel worm fitted with roller thrust bearings. The spindle has 12 inches cross adjustment by hand; it is $7\frac{3}{8}$ inches in diameter and the minimum distance from the center of the spindle to the top of the table is 5 inches. The spindle speeds range from 15 to 31 revolutions per minute, power being obtained from a 50 horsepower General Electric 220 volt motor. The net weight of this machine is 70,000 pounds.

This machine is shown channeling to full depth and full width, in one operation, two large size rods at a table advance of $2\frac{3}{4}$ inches per minute. The maximum cut for channeling would probably be two channels 5 inches wide by $1\frac{3}{4}$ inch deep, milled to the full depth and full width with a table advance of $2\frac{1}{2}$ to $2\frac{3}{4}$ inches per minute. Although the exact power required for this kind of work has not been determined, the thrust on the cutters is considerably greater than in slabbing operations on account of the resistance offered by the depth of the cut. For slabbing operations this machine would be capable of removing $1\frac{1}{4}$ cubic inch of metal per horsepower per minute. These rod milling operations are cited because they are among the most severe work that is encountered in milling practice. In order to stand up under such work, it is important to have all shafts and gears subject to opposed stresses with bearings in a common

Fig. 2. A Modern Planer Type of Milling Machine

casting, in order to prevent the possibility of chatter or misalignment. Responsible builders are now producing machines capable of driving the best grade of cutters to the limit of their capacity. Efforts toward increased production will now be in the direction of securing continuous operation.

Electric iron ore smelting is making decided headway in Sweden, where during the past year some of the most prominent concerns in the iron industry have adopted the process.

SAVING OPERATIONS ON TURRET LATHES

BY CONRAD

In the September number of MACHINERY "Albion" contributed an article entitled, "Turret Lathe Set-up for a Small Screw," in which he explains how to save time in machining a conical headed screw. He points out the necessity of cutting down the number of operations to a minimum, owing to the heavy turret of the Herbert No. 2 turret lathe, so that

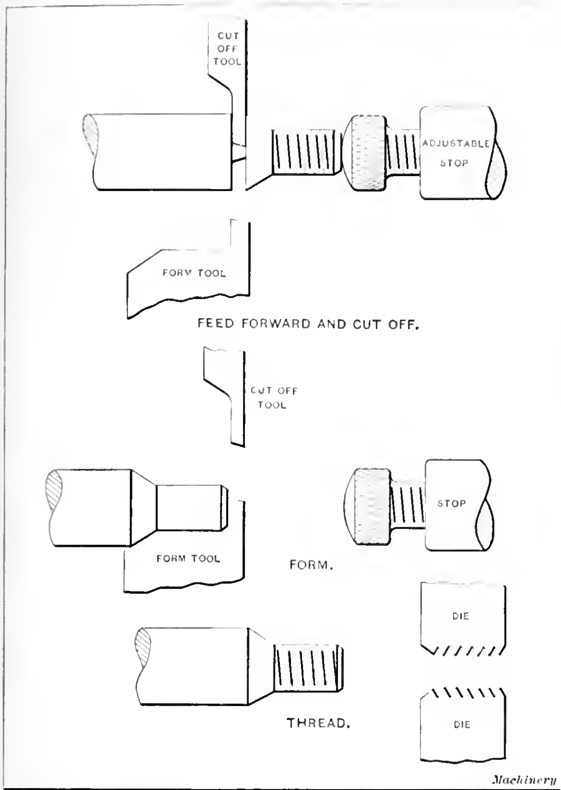

Fig. 1. Method of producing Screw of the Form shown

the fatigue caused by advancing, withdrawing and rotating the turret may be cut down as far as possible. The method advanced by "Albion" reduces the number of operations from six to three, the process being as follows: 1. Cut off and feed bar forward. 2. Turn and round end. 3. Thread.

If it is merely a question of simplicity and saving a few seconds on each piece, the writer suggests an even simpler method, which is illustrated in Fig. 1. This illustration shows the screw to be manufactured, with a slight difference in shape, the end being made flat and chamfered. The order of operations is: 1. Feed the bar forward to the stop held in a hole of the turret, with a screw finished by the preceding operation still to be cut off. 2. Cut off the finished screw with a tool in the back-rest of a tool-holder bolted onto the same face of the turret, and form the next screw with a tool in the front of the holder. These two operations are performed without rotating the turret. 3. Thread the work with a die-head held in the turret. In this way the whole job is finished with only two movements of the turret instead of three, as necessitated by "Albion's" method. Moreover, the die-head and the tool-holder may be located in two adjacent faces of the turret so that it is only necessary to move the turret through 1/6 of a revolution forward and back instead of having to revolve it all the way around. It will also be evident that as the outline of the forming tool is composed entirely of straight lines, it is quite simple to make.

It may not be out of place to state at this point that the question of the fatigue of the operator has evidently received due attention by the builders of the Herbert turret lathes, as all of their machines are now provided with a patent quick traverse motion for the saddle. With this arrangement it is only necessary to press down or lift up a small lever to start the mechanism, which automatically advances or withdraws the turret at a quick rate.

As a further example of how operations can be saved on automatic and semi-automatic machines, a brief description will be given of the method of procedure followed in producing pieces of the form illustrated in Fig. 2. This illustration shows a brass piece which was made on a full automatic machine. The machine was formerly arranged to make one of these pieces at a time, the order of operations being as follows: 1. Drill. 2. Form from front slide. 3. Countersink hole. 4. Tap. 5. Cut off from back slide. By speeding up, the best output that was obtainable by this method was three pieces per minute, but this was found to be insufficient.

In order to increase production, it was decided to make two pieces at a time, according to the method illustrated in Fig. 2. Working on this principle, the order of operations is as follows: 1. Drill through the depth of two pieces. 2. Form two pieces from front slide. 3. Countersink first piece. 4. Tap two pieces. 5. Cut off first piece from back slide. 6. Countersink second piece. 7. Cut off second piece from

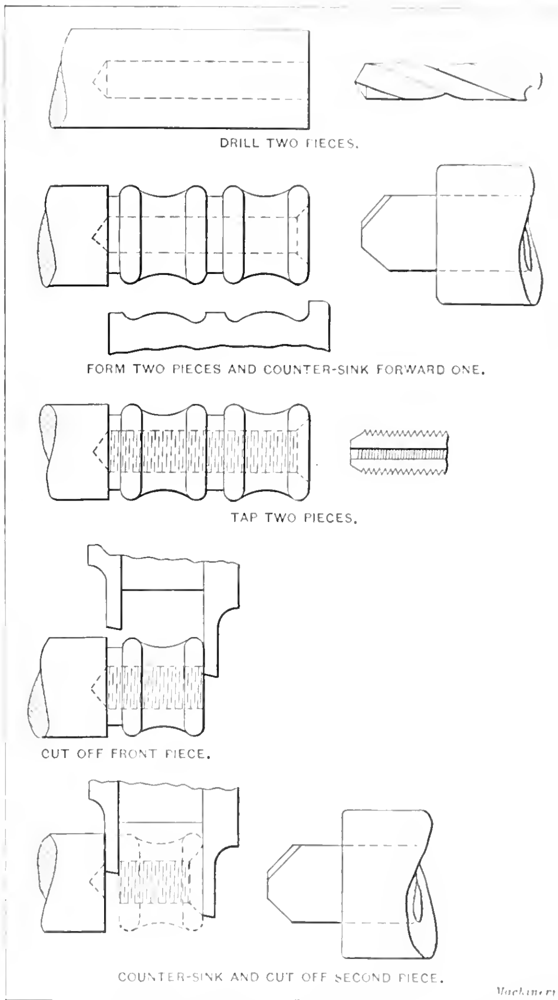

Fig. 2. Operations involved in producing Pieces Two at a Time

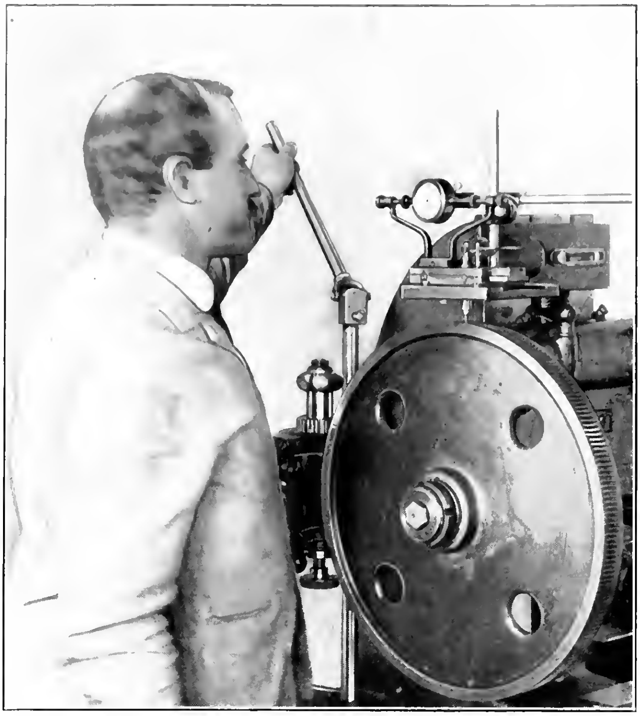
back slide. In this way two pieces were made in seven operations, requiring one complete revolution of the turret; whereas, the original method made it possible to produce only one piece in practically the same length of time. The change in the method of procedure effected an increase of output of about 30 per cent

From the foregoing it will be evident that although automatic and semi-automatic machines are generally run by un-



A Final

To Insure Accuracy of the Index Wheel and its Mounting—Inaccuracy Here Causes Incorrect Gear Teeth.

Inaccuracies in the index wheel of Automatic Gear Cutting Machines show at once in gears cut by it as thick or thin teeth. B. & S. Index Wheels are cut with special machinery having master wheels which are as exact as skilled methods can produce. Each wheel is held to very close limits, ten hours being required to cut the index wheel of the machine shown opposite. Great care is also taken in finishing the bearings of the index wheel and spindle and in mounting the wheel to avoid error at this point. The cut above illustrates the careful manner in which we test every index wheel after it is mounted, with a special device for instantly detecting the slightest error in the teeth. Inaccuracy in the indexing mechanism is another cause of incorrectly cut gears, even with an accurate index wheel. To detect such errors, we apply another special testing mechanism capable of locating any error in the various positions of the wheel when rotated by its own power.

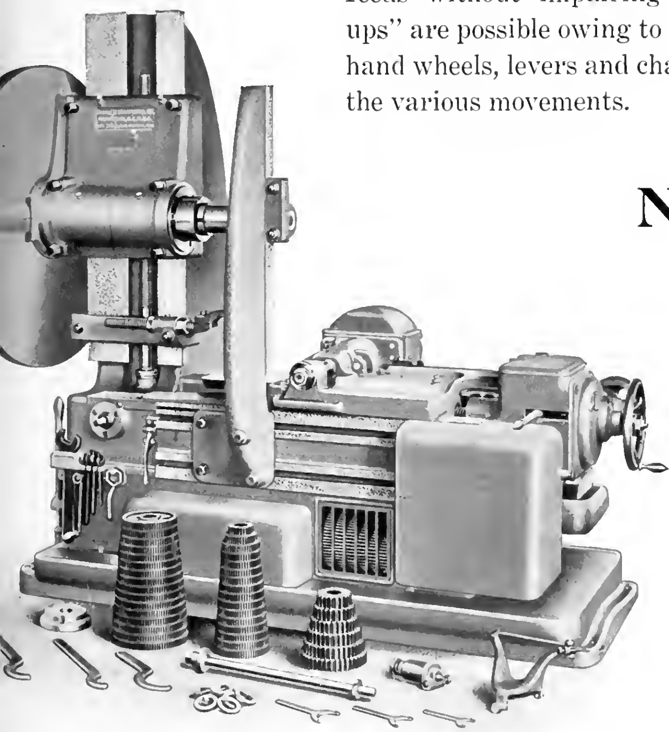
Test For Each Machine

B. & S. Automatic Gear Cutting Machines are designed for rapid production, in addition to their accuracy of workmanship. They have the three features which insure this point — a rapid, powerful drive, rigid design and convenient arrangement of parts. Ample power is delivered by the large diameter driving pulley to the cutter spindle through a worm drive, giving rapid yet smooth cutting action. A glance at the cut below shows the lines and proportions of the machine as a whole, the rigid, compact base, the massive column and work slide, the long bearing surface of the cutter slide, the unusually large cutter and work spindles and the correct relation each part bears to the other. These are the features that allow maximum speeds and feeds without impairing accuracy. Quick "set-ups" are possible owing to the accessibility of all the hand wheels, levers and change gears for controlling the various movements.



No. 6 Automatic Gear Cutting Machine

Capacity:

Spur Gears to 72" in diameter, 13" face.

Cast iron, 1 3-4 diametral pitch; steel, 2 diametral pitch.

skilled labor, it is of great importance to have such machines in charge of a competent superintendent who is up to all sorts of "kinks" and methods of cutting down the time of production. The greatest savings in work of this kind are effected by reducing the idle operations as far as possible. It is not possible to go on increasing speeds and feeds *ad infinitum*, but it *is* possible to cut down the number of operations and the time which elapses between them, and this is the point that should receive attention when an endeavor is made to increase production.

* * *

LARGE OUTSIDE MICROMETERS

BY WILLIAM S. ROWELL*

Much has been done in recent years toward providing both inside and outside micrometers, but a more plentiful supply, especially in the large sizes, could be used to advantage in almost any shop. Doubtless first cost has much to do with keeping the stock down to its slender proportions. Consideration of the following may prove helpful to those who would help themselves.

The commercial inside micrometer up to about thirty-six inches is so good and cheap that it leaves little to be asked; above that size the writer has used a number of designs. Providing additional and longer rods to be used with the same head is usually a satisfactory solution. Solid rods may be used for almost any length but tubes are better adapted to the larger sizes.

Fig. 1. Large Micrometer for making Outside Measurements

There are a number of reasons for the scarcity of larger outside micrometers, but when the merits of sheet aluminum for the bow or frame become better known more of it will be used for this purpose. To use it, as is often done, by cutting as many and as large bows as can be laid out on a sheet of the metal without making use of its high ductility, is a waste of time and material. The proper way is to lay out the sizes wanted directly on the sheet metal and saw along the lines with a band saw. Kerosene is a good lubricant. The illustration Fig. 3 will give an idea of how a sheet of aluminum can be cut with a minimum of waste. The parts that come from the saw needing shaping can be easily forged into shape at a low heat. The smith should, if not familiar with the materials, experiment with a waste piece and note the proper forging heat. Sheet aluminum 3/8 inch thick is easily obtained and is generally conceded to be thick enough for all sizes up to thirty-six inches without any stiffening against side flexure. For larger sizes a thicker sheet, or perhaps better, an approximation of an I-beam section would provide the necessary stiffness.

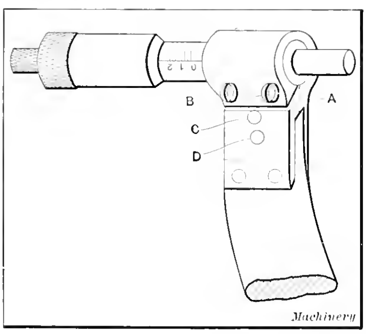

Fig. 2. Arrangement of the Clamp for holding the Micrometer Head

* Address: 1026 Dayton St., Hamilton, Ohio.

Tail-pieces should be drill rod steel 5/16 inch diameter if they are to extend six inches. The measuring points of both screw and tail-piece should be slightly rounded. This is more important than might at first appear. Such bows are not stiff enough to insure the flat ends remaining parallel. With both contact points slightly rounded a little lack of alignment makes no difference.

The illustration Fig. 1 shows an instrument of about thirteen inches capacity. The tail-rod shown is the short rod from an eight- to thirty-two-inch inside micrometer. The micrometer screw is held in place by two clamping screws *B* shown in Fig. 2. The steel clip that holds the micrometer screw was not originally intended for a removable screw and was held to the aluminum bow by the three rivets *D*. When the saw cut *A* was made, a rivet was added at *C* to stiffen the clip. In this way one micrometer screw may serve two or more large size bows. Bows as small as eighteen inches and under should usually each have its own screw, as small size instruments are generally in use.

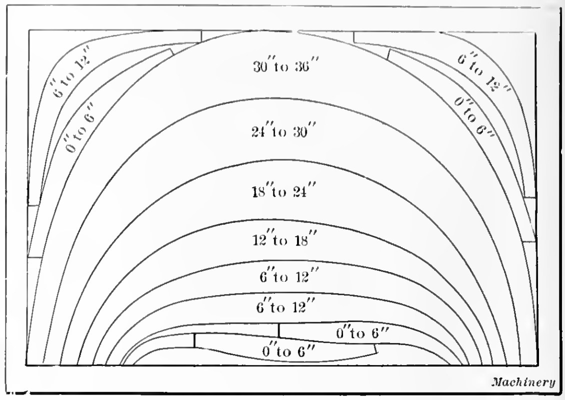

Fig. 3. Method of cutting up a Sheet of Aluminum for a Set of Micrometer Frames

Of course it is understood that such instruments are never standards. They are transfer instruments as strictly as were the two-leg calipers of our fathers, but when provided with a micrometer screw of one-inch run eighteen standard gages will suffice to set such calipers for all sizes from zero to thirty-seven inches.

* * *

ADVERTISING WITH MOVING PICTURES

The possibilities of the moving picture as an advertising agent is fully realized in Europe as well as in America. A firm in London has prepared an exhibition of moving pictures illustrating British manufactures and industries, and films dealing with this subject are to be shown in the leading cities of the European continent, North and South America and the British colonies. The first tour will be one of northern Europe, during which exhibition the films will be shown in some sixty cities. These exhibitions will be held during the daytime and will be free, invitations being issued to the leading business men in each city, the cost being defrayed by the manufacturers whose products or methods are shown. In connection with this tour, a commercial reference book in English, German and French will be published and about sixty thousand copies will be distributed to the visitors to the exhibitions. It is expected that this method will do much to bring the names of British manufacturers before foreign buyers.

* * *

The following mixture is, according to *Foundry*, suitable for cores for aluminum and brass castings: Silica or lake sand, 28 parts; molding sand, 12 parts; and linseed oil compound, or plain linseed oil, 1 part, by weight. The lake and molding sands are first thoroughly mixed, water being added until almost damp enough for use, when the linseed oil is thoroughly mixed into the sand. It is very important that there is a complete mixture of the oil and sand. The cores should be baked in a hot oven.

LONGEST RAILWAY BRIDGE IN WORLD

The longest railway bridge in the world will be constructed shortly for the improved line between Berlin, Germany, and Stockholm, Sweden. At present, the railway trains are carried by large ferries a distance of about seventy miles from a point in southern Sweden to the island of Rügen, in Germany. The trains then pass across the island of Rügen, but must again be ferried from this island to the German mainland, a distance of about two miles. The bridge will connect the island of Rügen with the German mainland and make the second ferry trip unnecessary. The length of the bridge will be 10,725 feet, divided into twenty-two spans. The height of the bridge from the water level will be 105 feet.

* * *

PERSONALS

J. L. Peden, general manager of the Universal Screw Cutting Co. of America, Philadelphia, Pa., has resigned his position.

D. Walker Wear, formerly purchasing agent of the Chicago Tunnel Co., has been elected vice-president and director of the Stow Mfg. Co., Binghamton, N. Y.

Henry M. Leland, general manager of the Cadillac Motor Car Co., Detroit, Mich., was elected president of the Society of Automobile Engineers at the January meeting in New York City.

H. H. Robertson, president of the Asbestos Protected Metal Co., Beaver Falls, Pa., has been elected vice-president of the Pittsburg branch of the National Council for Industrial Safety.

L. G. Daniels has been made general manager of the Rockford Drilling Machine Co., Rockford, Ill., succeeding S. H. Reck, who sold out and withdrew from the company a few months ago.

C. R. McCullough, who has been connected with the Detroit office of Manning, Maxwell & Moore, Inc., for the past two years, has entered the employ of the Lees-Bradner Co., Cleveland, Ohio.

John Becker, Jr., was elected treasurer and general manager of the Becker Milling Machine Co., Hyde Park, Mass., following the resignation of his father, John Becker, who has retired from business.

E. A. Muller of the King Machine Tool Co., Cincinnati, Ohio, has been appointed receiver for the Modern Machine Tool Co. of Cincinnati. The company is said to be solvent, having $50,000 assets and $20,000 liabilities.

S. Wolff, former manager of the Cleveland office of the Allis-Chalmers Mfg. Co., Milwaukee, Wis., has been appointed Chicago manager for the DeLaval Steam Turbine Co., Trenton, N. J., manufacturer of steam turbines, centrifugal pumps, etc., with offices in the People's Gas Bldg.

E. M. Chadwick, formerly of the Fairbanks Co., has been appointed manager of the Buffalo branch of Manning, Maxwell & Moore, Inc., and D. A. Hamilton, formerly of the Reed-Prentice Co., Worcester, Mass., has been appointed assistant at the Detroit branch of Manning, Maxwell & Moore, Inc.

W. H. Shafer, formerly with the Cincinnati-Bickford Tool Co., Cincinnati, Ohio, and recently with the Rochester Boring Machine Co. of Rochester, N. Y., has again become associated with the Cincinnati-Bickford Tool Co. as special representative in connection with the company's selling organization.

Albert A. Dowd, formerly in charge of the estimating department of the Bullard Machine Tool Co., Bridgeport, Conn., is now in business for himself as a production engineer. He is prepared to furnish details of horizontal and vertical lathe tool equipments as a specialty. His address is 84 Washington Terrace, Bridgeport, Conn.

C. U. Scott, Davenport, Iowa, has resigned his position at the Rock Island Arsenal, where he has been for the past ten years in charge of the hardening and heat-treating department, in order to devote all his time to his own business of tool hardening, heat-treating, casehardening, galvanizing, tinning, brazing, bluing and manufacture of furnaces.

A. D. Pentz is the inventor of the toolroom boring machine built by the Newton Machine Tool Works, Philadelphia, Pa., and illustrated and described in the November, 1913, number of MACHINERY. Mr. Pentz, who is with the General Electric Co., West Lynn, Mass., received the John Scott medal from the Franklin Institute in 1891, for machines in which the same principles that make this machine distinctive and unique were embodied.

Prof. David N. Camp, president of the Skinner Chuck Co., New Britain, Conn., was the guest of honor at an annual banquet tendered by the company to its employes at the New Britain Club, December 23. There were about one hundred and twenty men present and Prof. Camp was the principal speaker and honored guest of the evening. He will soon be ninety-four years old, a fact that made his presence at the banquet the more notable.

* * *

OBITUARIES

Herman C. Meinholtz, vice-president of the Heine Safety Boiler Co., St. Louis, Mo., died in St. Louis December 24, aged forty-five years. Mr. Meinholtz entered the employ of the Heine Safety Boiler Co. at the age of nineteen as a draftsman and was continuously connected with that company up to the time of his death. He was made superintendent in 1895 and vice-president in 1907. He had entire charge of the company's shop when it was established in 1899, and under his general direction the new factory was designed and built in 1909. He is survived by his widow and five children.

COMING EVENTS

April 4-11.—First National Efficiency Exposition and Conference, Grand Central Palace, New York City. Walter H. Tallis, director, Efficiency Society, Inc., 41 Park Row, New York City.

May 1-October 31—Anglo-American Exposition, London, England, to celebrate the centenary of peace between the United States and Great Britain. American executive offices: Woolworth Bldg., New York City. Charles J. Kiralfy and Albert E. Kiralfy, commissioners general.

June 15-17.—Annual convention of the American Supply & Machinery Manufacturers' Association at White Sulphur Springs, West Virginia; New Green Brier Hotel, headquarters. General offices of the association, Woolworth Bldg., New York City.

September 20-25 (1915).—International Engineering Congress, San Francisco, Cal., in connection with the Panama-Pacific International Exposition. W. F. Durand, chairman, Foxcroft Bldg., San Francisco, Cal.

Foreign Publications for Advertising American Goods. 236 pages, 6 by 9 inches. Published by Bureau of Foreign and Domestic Commerce, Department of Commerce, as No. 10 of the Miscellaneous Series.

This publication will be useful to American manufacturers who wish to advertise their wares in foreign journals. It gives the foreign publications, advertising rates, circulation, subscription prices, etc., for Canada, Mexico, West India, South America, Europe, Asia, Oceania, Africa, etc.

Bureau of Supplies of the Department of Water Supply, Gas and Electricity, New York City Report. To Henry S. Thompson, commissioner. By Elihu C. Church, secretary. 6½ by 10 inches. 93 pages. Illustrated. Published by the City of New York.

This report is of much interest to municipal officers in general. It outlines the plan and scope, the organization and administration of the Bureau. Details of purchasing and inspection are given, and storage and issue of supplies, methods of keeping records and accounts are described.

Mechanical World Electrical Pocket Book for 1914. 311 pages, 4 by 6 inches. Illustrated. Published by Emmott & Co., Ltd., Manchester, England. Distributed in the United States by Norman & Remington, Baltimore, Md. Price 25 cents.

This book is similar in plan and scope to the well known Mechanical World Diary and Year Book in the mechanical field. It treats of the electrical units, magnetic laws, characteristics of dynamos and motors, direct and alternating current systems, transformers, accumulators, wiring, electrical measuring instruments, electric lamps, electric lighting, electromagnets, electricity in coal mines. Tables of logarithms and other useful tables are included, and a diary for every day in the year.

Bulletins of the Engineering Experiment Station, University of Illinois. Vol. 9. Comprising Bulletins 63 to 67. 6 by 9 inches. Published by the Engineering Experiment Station, University of Illinois, Urbana, Ill.

This volume comprises bulletins which have been previously noticed in MACHINERY as follows: "Entropy Temperature and Transmission Diagrams for Air," by C. R. Richards; "Tests of Reinforced Concrete Buildings Under Load," by Arthur N. Talbot and Willis A. Slater, "The Steam Consumption of Locomotive Engines from the Indicator Diagrams," by J. Paul Clayton; "The Properties of Saturated and Superheated Ammonia Vapor," by G. A. Goodenough and William Earl Mosher; "Reinforced Concrete Wall Footings and Column Footings," by Arthur N. Talbot.

Mechanical World Pocket Diary and Year Book for 1914. 143 pages, 4 by 6 inches. Illustrated. Published by Emmott & Co., Ltd., Manchester, England. Distributed in the United States by Norman & Remington, Baltimore, Md. Price 25 cents.

This well known compilation of useful engineering notes, rules, tables and data has been issued consecutively for twenty-seven years. The low price of the publication, the large amount of valuable data contained, and the small size have made it justly popular. It treats of steam and steam engines, steam turbines, condensers, boilers, etc., gas engines, gas producers, steam generators and materials of construction, shafting, gearing, machine shop practice, belting, micrometers, hydraulics, gages, weights and measures, logarithms, trigonometrical tables, etc. A diary for every day in the year is included and a complete index makes easy reference to the matters contained.

Investigating an Industry. By William Kent. 126 pages, 5 by 7½ inches. Published by John Wiley & Sons, Inc., New York City. Price $1.

In the introduction, written by H. L. Gantt, the purpose of the book is outlined as based on the old saying, "Look before you leap," or in other words, "Find out all possible facts about an industry before drawing conclusions." The contents by chapters are: General Considerations, A Business Diagnostician, The Diagnosis—The Factory, The Accounting and Sales Department, The Doctor's Preliminary Report, The Salesmen's Conference, The Doctor's Opinions and Recommendations, Proposed Reorganization of the Board of Directors, Duties of the Functional Committees of the Board of Directors, A New Kind of Factory Expert—The Leak Hunter, Locating an Industry. The author likens a run-down business to a sick man and the efficiency expert to the doctor. It is the doctor's function to diagnose the ailment of the patient and to prescribe the remedies.

Bulletins of the Engineering Experiment Station, University of Illinois. Vol. 8. Comprising Bulletins 58 to 62. 6 by 9 inches. Published by the Engineering Experiment Station, University of Illinois, Urbana, Ill.

These bulletins, which have been previously reviewed in MACHINERY, are as follows: "A New Analysis of the Cylinder Performance of Reciprocating Engines," by J. Paul Clayton; "The Effects of Cold Weather Upon Train Resistance and Tonnage Rating," by Edward C. Schmidt and F. W. Marquis; "The Coking of Coal at Low Temperatures with a Preliminary Study of the By-products," by S. W. Parr and H. L. Olin; "An Extension of the Dewey Decimal System of Classification Applied to the Engineering Industries," by L. P. Breckenridge and G. A. Goodenough; "Characteristics and Limitations of the Series Transformer," by A. R. Anderson and H. R. Woodrow; "The Electron Theory of Magnetism," by Elmer H. Williams.

Work, Wages and Profits. By H. L. Gantt. 312 pages, 5 by 7½ inches. Published by the Engineering Magazine Co., New York City. Price $2.

The second edition of this work which appeared in 1910 has been thoroughly revised and much enlarged, the first edition containing only 194 pages. The work contains twenty-seven illustrations, including charts in two colors. The new material includes an extended treatment of the task idea and a new chapter on the results of scientific management. The contents by chapter heads are: The Application of the Scientific Method to the Labor Problem, The Utilization of Labor, The Compensation of Workmen, Day Work, Piece Work, Task Work With a Bonus, The Task Idea, Training Workmen in Habits of Industry and Cooperation, Fixing Habits of Industry, Results, Prices and Profits, A Practical Example. A pleasing feature of Mr. Gantt's work as an efficiency expert is his sympathy with all concerned. He regards greater efficiency from the standpoint of the true economist and not from the merely selfish viewpoint of an employer who would increase his profits without consideration of the effect on the workman or on humanity as a whole.

Practical Patternmaking. By F. W. Barrows. 347 pages, 5¼ by 7¼ inches. 159 illustrations. Published by Norman W. Henley & Son, New York City. Price $2.

The first edition of Barrows' work on patternmaking was published in 1906. New material has been added and incomplete sections filled out. The number of specific examples has been increased. The contents comprise: Patternmakers and Patternmaking, How Some Folks Make Patterns, Some Methods, Patternmakers, Lumber, Varnish, Miscellaneous Materials, The Bench and Its Attachments, Hand Tools, Bench Work, Machine Tools for Patternmakers, The Band-saw, The Circular Saw, The Lathe, Fillets, Stavework, Cant or Segment Work, Patterns for Belt Pulleys, Patterns for Cable Pulleys, Making Patterns for Chain Wheels, Patterns for Steam Cylinders, One Way of Making a Crosshead, Making Gear Patterns, Propeller Wheels, Patterns for Screws, Traction Wheels for Farm Engines, Globe-valve Patterns, An Example in Projection, Common Practice, Some Patterns, A Stripping-plate Job, A Vibrator-plate Pattern, The Evolution of the Globe Valve Core-box, Multiple Core-boxes, Cost of Patterns, The Marking and Record of Patterns, Pattern Accounts.

Heating and Ventilation. 335 pages, 6 by 9 inches. Published by the B. F. Sturtevant Co., Hyde Park, Boston, Mass.

This book forms part of the advertising literature of the company and bears the catalogue number 215. It is, however, a textbook and work of reference on heating and ventilating for engineers and all others concerned with any phase of the problems of heating and ventilating buildings. The first edition of the work was published over twenty-five years ago and new editions have been frequently published since. The advancement of the science of heating and ventilating has been rapid, and in the present edition the work has been revised in such a manner as to make it equally useful to both engineer and layman. The work is divided into two parts, the first part containing the text matter and the second a collection of tables for the use of engineers, etc. The contents by chapter heads are as follows: Theoretical Considerations; Ventilation; Heat, Heating and Cooling; The Sturtevant System; Heating and Ventilating Apparatus; Heating and Ventilating Calculations; Testing; Special Problems of Application; Typical Installations; Sturtevant Apparatus; Tables. While the book is intended for wide circulation, its cost makes general free distribution prohibitive.

Compressed Air Practice. By Frank Richards. 326 pages, 6 by 9 inches. 94 illustrations. Published by the McGraw-Hill Book Co., Inc., New York City. Price $3 net.

The author published a small book called "Compressed Air" about twenty years ago, and this work forms part of the present volume. The advance in compressed air practice and the many developments of its use during the twenty years elapsed are great and varied. The contents comprise: Atmospheric Generalities, Definitions and General Information, The Compressed Air Problem, Tables and Diagrams for Computations in Air Compression, The Indicator on the Air-compressor, Single-stage Compression, Two-stage Air Compression, Two-stage and Three-stage Compression, Air-compressor Regulating Devices, The Drive of the Compressor, The Turbo Compressor, The Taylor Compressor—The Humphrey Pump, Power Cost of Compressed Air, Power from Compressed Air, The Air Receiver, Pipe Transmission, Re-heating Compressed Air, Compressor and Receiver Fires and Explosions, Side Lines for the Air-compressor, Gasoline by Compression—Liquified Natural Gas, Rock Drill Developments, The Electric Air Drill, Compressed Air for Raising Water, The Air Lift, Air for Large Steam Hammers, Diving Bell and Caisson, Air Jet—Sand Blast—Cement Gun, Liquid Air—Oxygen from the Atmosphere. The work will be welcomed by all who appreciate clear common sense treatment of an engineering subject.

Machinery's Handbook. Compiled by Erik Oberg and Franklin D. Jones. 1400 pages, 4½ by 7 inches. Published by the Industrial Press, New York City. Price $5.

In 1898 MACHINERY began the publication of data sheets in supplement form. These sheets comprised a great variety of tables, diagrams and data for the machinist, toolmaker, draftsman, designer, mechanical engineer and others in the mechanical engineering field. As time passed the data sheets grew in volume until they formed a mass of material difficult to index and handle. Recognizing the need of putting this valuable material in convenient form for general use, MACHINERY'S editors have compiled a Handbook using the best of the material published in MACHINERY and the data sheets during the past twenty years. Much additional matter has been included in order to round out a complete work of reference, for the user, and it is believed to be the most condensed and best arranged work of the kind ever published for the mechanical man in any position, whether it be that of a machinist, toolmaker, draftsman, designer, foreman, superintendent or general manager. Special pains have been taken to present the mathematical tables and formulas in attractive and convenient form. In many cases the formulas are accompanied with examples worked out, and with such illustrations the practical man is able to use formulas that he would shrink from otherwise. The sections on heat-treatment of steel, strength of materials, motor power of machine tools, broaching and screw threads are exhaustive. Within the covers of the book are included a complete treatise on spur, bevel, helical and worm gears, and the section on springs is believed to be the best treatment of the subject extant. Space does not permit of reviewing the contents in full, and the heads of sections only are quoted to give a general idea. They are as follows: Mathematical Tables; Principal Methods and Formulas in Arithmetic and Algebra; Logarithms and Logarithmic Tables; Areas and Volumes; Solution of Triangles and Trigonometrical Tables; Geometrical Propositions and Problems; Principal Methods and Formulas in Theoretical Mechanics; Strength of Materials; Riveting and Riveted Joints; Strength and Properties of Steel Wire; Strength and Properties of Wire Rope; Formulas and Tables for Spring Design; Torsional Strength—Shafting; Friction; Plain, Roller and Ball Bearings; Keys and Keyways; Clutches and Couplings; Friction Brakes; Cam Design and Cam Milling; Spur Gearing; Bevel Gearing, Worm Gearing, Spiral and Herringbone Gearing; Epicyclic Gearing; Belts and Pulleys—Machine Tool Drives; Rope Transmission; Transmission Chain and Chain Drives; Crane Chain and Hooks; Belts, Nuts, Screws, Wrenches, Handles, Handwheels and Other Machine Details; Speeds and Feeds for Machine Tools—Tool Grinding; Automatic Screw Machine Practice; Tapping and Threading; Lubricants for Machining Operations; Running, Shrinkage and Forced Fit Allowances; Measuring Instruments and Gaging Methods; Change Gears for Spiral Milling—Leads and Corresponding Angles; Milling Machine Indexing; Jigs and Fixtures; Grinding and Grinding Wheels—Polishing and Lapping; Punches, Dies and Press Work—Drop-forging Dies; Broaches and Broaching Operations; Classification, Testing and Application of Files; Screw Thread Systems and Thread Gages; Taps and Threading Dies; Milling Cutters; Reamers; Twist Drills, Counterbores and Boring Bars; Heat treatment of Steel—Hardening, Tempering and Annealing; Testing the Hardness of Metals; Principles of Iron and Steel Manufacture; Foundry and Pattern Shop Practice; Extrusion of Metals; Die Casting; Forge Shop Equipment; Forge Shop Welding Methods; Autogenous Welding; Welding with Thermit; Electric Welding; Soldering and Brazing; Etching and Etching Fluids; Coloring Metals; Horsepower Required for Machine Tools and Forging Machinery—Electric Motor Drive; Care of Electrical Machinery—Dynamo and Motor Troubles; Properties and Weights of Materials; Composition of Alloys; Information Relating to Heat—Comparison of Thermometer Scales; Pneumatics—Air Compression—Flow of Air; Water Pressures and Flow of Water; Pipe and Pipe Fittings; Lutes and Cements; Weights and Measures; Metric System of Measurements and Conversion Tables; Manufacturing Plant Appraisal; Drawing, Tracing and Blueprint Papers; Principal Patent Law Regulations.

NEW CATALOGUES AND CIRCULARS

Cincinnati Iron & Steel Co., Cincinnati, Ohio. Circular of the "Cisco" eighteen-inch engine lathe.

General Electric Co., Schenectady, N. Y. Bulletin No. A 4199 illustrating and describing railway motor gears and pinions.

Deane Steam Pump Co., 115 Broadway, New York City. Bulletin D 224 on horizontal double-acting single-cylinder power pumps.

Brown Instrument Co., Philadelphia, Pa. Calendar for 1914 illustrated with a view of a twelve-inch gun in action at Fort Wadsworth, New York City.

General Electric Co., Schenectady, N. Y. Bulletins A 4143 and A 4148 on belt-driven alternators Form B and small plant direct-current three-wire switchboards of 125 and 250 volts and 10 to 100 K. W. capacity, respectively.

Noble & Westbrook Mfg. Co., Hartford, Conn. Catalogue of Dwight Slate marking machines, dieholders and dies. The company is prepared to make steel marking dies for all purposes.

Morse Chain Co., Ithaca, N. Y. Circular of Morse chain drives, showing applications to motor-driven machine tools, engine drives, textile machinery, rubber mills, calender rolls, etc.

Stow Mfg. Co., Binghamton, N. Y. Circular of portable tools comprising emery grinders, light drilling machines, toolpost grinders, electric hand buffers, electric breast drills, etc.

Challenge Machine Co., Inc., Philadelphia, Pa. Catalogue of "Challenge" floor grinders, illustrating a variety of grinders, details of construction, wheel guards, belt polishing attachment, etc.

Shepard Electric Crane & Hoist Co., Montour Falls, N. Y. Bulletin No. 1002 on Shepard electric cranes and hoists, illustrating their use in steel car plants and on the docks of New York Harbor.

Allen-Bradley Co., 495-497 Clinton St., Milwaukee, Wis. Circular describing "Type H" alternating-current motor starters. Special emphasis is laid on the motor protective features of the rheostats on these starters.

Wheelock, Lovejoy & Co., 23 Cliff St., New York City. Circular of the Keen impact ball tester for testing the softness of steels and other metals. The tester was illustrated and described in the July, 1913, number of MACHINERY.

Watson-Stillman Co., 192 Fulton St., New York City. Catalogue 89 on heating, chilling and die presses of the hydraulic type. Die sinking presses, both power and hand operated are illustrated. The hand die sinking presses include the four-column and open-jaw types.

Hammacher, Schlemmer & Co., 4th Ave. and 13th St., New York City. Circular of the "Yankee" bench drill, hand-operated, and "Yankee" vise for same. The "Yankee" bench drill weighs fifty-seven pounds and is intended for small shops, farm use, etc. The vise may be used on the drill or on a bench.

Chicago & Northwestern Railway Co., Chicago, Ill. Safety Bulletin No. 4. These bulletins show the dangers of railroading and how accidents happen, and illustrate the rules provided for avoiding accidents. A slogan of the company is, "Remember that it is better to cause a delay than to cause an accident."

National Malleable Castings Co., Sharon, Pa. Circular of electric steel castings, illustrating a Heroult furnace installed at the company's Sharon works and typical castings made from it. The advantages of steel castings made from the electrical furnace are enumerated and records of fatigue tests are given.

Doehler Die-Casting Co., Court and Ninth Sts., Brooklyn, N. Y. Circular of Doehler babbitt-lined bronze bearings for internal combustion motors. These bearings were used by the Moline Automobile Co. on the engine recently tested at the Automobile Club of America laboratory, running two weeks without a stop.

Edward Wilbur, 125 Summer St., Boston, Mass. Card advertising and illustrating the Greenerd belt pole for facilitating the shifting of belts while standing on the floor. The pole is 9 feet long, made of hard wood and steel, and is provided with a

DRAWING CARTRIDGE CASES*

MACHINES, DIES, TOOLS AND METHODS USED BY THE FRANKFORD ARSENAL

BY DOUGLAS T. HAMILTON†

THE difficulties met with in producing cartridge cases from sheet brass are the same as those encountered in practically all drawn sheet metal work. Admitting this, and considering the advances made in cartridge making, it would seem that a description of the methods and tools used for this work should be of general value when modified to suit the various requirements. In this article the data given refer more particularly to the drawing of cases for 0.30 caliber cartridges, the tools and methods used being taken up in detail. The practice followed by the Frankford Arsenal, Philadelphia, Pa., is interesting and presents some novel ideas in this class of work. The writer is indebted to Colonel George Montgomery for the material contained in this and subsequent articles.

Making the Cups from which Cartridge Cases are Drawn

The first operation in the making of a cartridge case is to produce a cup, then by successive redrawing operations this cup is reduced in diameter and extended to the required length. Fig. 1 shows the various steps in the sequence of redrawing operations following that of making the cup. From this illustration it can be seen that five operations are necessary to bring the case to the required length—these are called redrawing operations because the work accomplished consists in reducing and redrawing a piece that has already been drawn to cup form. The press used for making the cups from which cartridge cases are made is shown in Fig. 3. It is of the double-action type, and carries four punches and dies, thus making four cups at each stroke. This punch press operates at 100 revolutions per minute, producing 400 cups a minute, or 24,000 cups per hour. The type of blanking and cupping dies used in this machine are shown diagrammatically in Fig. 2, and also in Fig. 10 together with the tools required to make them. Fig. 2 shows the shape of the die more clearly, and gives a comprehensive idea of the action that takes place in the formation of the cup. At *A* the blanking punch is shown in contact with the top face of the brass sheet. At *B* the blanking punch has cut out a disk of the required size and carried it down to the first shoulder in the combination blanking, cupping and drawing die. At *C* the combination cupping and drawing punch has come into operation and has started to form the blank to cup shape; whereas at *D* the blank has been forced completely through the die and has been given the first drawing operation.

The sheet stock is held on the roll *A* located to the right of the machine shown in Fig. 3, and is drawn into the press under the blanking and drawing punches by means of feed rolls. After the stock passes through the rolls *B*, it is oiled by means of a rag saturated with lard oil that is contained in the tank *C*. The sheet is fed a distance equal to the diameter of the blank plus the width of the web for each stroke of the press (see Fig. 5), and after it has been started by the operator, who uses the handwheel feed illustrated, it is carried on automatically by the feed rolls located at both ends of the throat of the press. As the sheet from which the blanks have been sheared protrudes from the left-hand end of the machine, it passes through a shearing die, which in conjunction with a knife operated by a crank and connecting lever held on the extreme end of the crankshaft, cuts off the scrap, enabling it to be packed in boxes. The chief reason for cutting up the stock in this manner is to avoid having it pile up around the machine and also to enable it to be more easily removed.

The manner in which the dies and punches are laid out in order to economize in stock is shown in Fig. 5. By referring to the upper diagram in this illustration it will be seen that

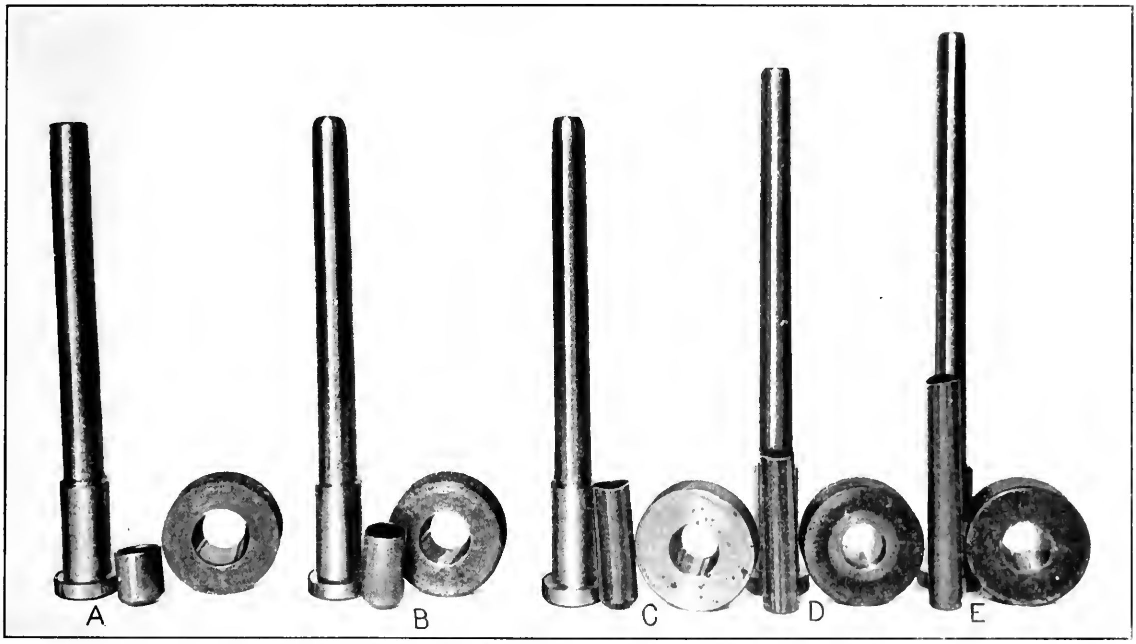

Fig. 1. Sequence of Redrawing Operations on a 0.30-caliber Cartridge Case and Tools used

* For articles on cartridge making previously published in MACHINERY, see the series on "Cartridge Making," in the March, April and May, 1911, numbers, and articles there referred to.
†Associate Editor of MACHINERY.

the centers of the four dies are located in a "diamond" shape, thus reducing the width of the sheet required and securing the most satisfactory layout for the punches and dies. The condition of the sheet after the press has made four strokes is shown in the lower portion of the illustration, which indicates the progression followed in cutting out the blanks.

Setting Drawing Punches and Dies

To set drawing punches and dies properly, requires considerable experience, as this is a difficult task under the most favorable conditions. The dies and punches are usually aligned with each other by setting them in the approximately correct position, then running through a few cups and noting the results. In the type of die-holder shown in Fig. 4, it is not necessary, of course, to reset the dies when they have been removed for grinding, if proper attention has been paid when they were first set up. This is not the case, however, with redrawing dies, as will be explained later. One peculiar point in making cups that causes considerable trouble is that it is practically impossible to produce a cup with a straight top; that is, one in which the metal is drawn to the same extent on one side as it is on the other.

The reason for a cup drawing irregularly in this manner is not due in all cases to inaccurate setting of the punches and dies, but generally to a variation in the thickness of the sheet from which the blank is cut out. It is a peculiar fact, but nevertheless true, that it is practically impossible to roll sheet metal uniform in thickness; that is to say, the sheet is thicker in the center than it is at the outer edges. The reason given for this is that the rolls, even though they be 8 or 10 inches in diameter, spring to a slight extent in the center—where they are unsupported except by their inherent strength—and thus produce a sheet of varying thickness throughout its width. Another difficulty experienced in making cups is the striking of hard spots in the metal. It is obvious, of course, that if the stock is not of a uniform hardness, the softest spot or portion will draw much more than the harder portion, and hence, a cup having one side longer than the other will be obtained. Not only will the top edge be irregular, but the walls will also be of uneven thickness. It is claimed by those who have had experience in this work that it is impossible to rectify any defect of this kind in the succeeding redrawing operations. When a cup is once started with a wall of unequal thickness, this condition prevails until the final drawing operation, so that it will easily be seen that great care must be exercised in making the walls of the cup of uniform thickness if a satisfactory product is to be obtained.

Annealing and Redrawing Operations

After the cups are made it is the general practice to anneal, wash and dry them as was described in an article on this subject in the March, 1911, number of MACHINERY. Then they are ready for the first redrawing, or second drawing operation. The temperature to which the cup is heated for annealing varies from 1200 to 1220 degrees F. The manner of handling the cups after they have been annealed, washed and dried, is to carry them in trucks, which are lifted from the floor of the annealing room to a track located above the drawing presses. These trucks are provided with false bottoms and are run along the track until they are directly over the hopper which feeds the cups to the punch press. The false bottom is then removed, allowing the cups to drop from the chute into the hopper *A* of the drawing press, Fig. 6, from which they are removed by a feeding device consisting of a wheel in which pins *B* are set at an angle of about 45 degrees with its horizontal axis. These pins are pointed, enabling the shell to be located on them, mouth first. The pins are rotated inside the hopper so that they catch the cups and deposit them in close-wound spring tubes *C*.

These tubes pass from the hopper down to the feeding slides of the drawing press (see Fig. 6) and as the shells drop out of the tubes they are caught by fingers held on the slides and carried over into line with the dies and punches. When the slides have advanced to their extreme forward positions, the punches descend and force the cups through the drawing dies, depositing them in a box located under the press. The slides are operated from the crankshaft through bevel gears and a connecting-rod that transmits power down to a horizontal shaft carrying a series of four cams. These cams contact with rollers held in the feeding slides and thus transmit the desired movement to them. The rolls are held in contact with the cams by coil springs. The machine shown in Fig. 6 operates at 100 revolutions per minute, and as four cups are drawn per stroke, it is evident that this machine has a productive capacity of 24,000 cups per hour. The drawing press shown in this illustration is used for performing the second and third redrawing operations, shown with the die and punch used at *B* and *C* in Fig. 1.

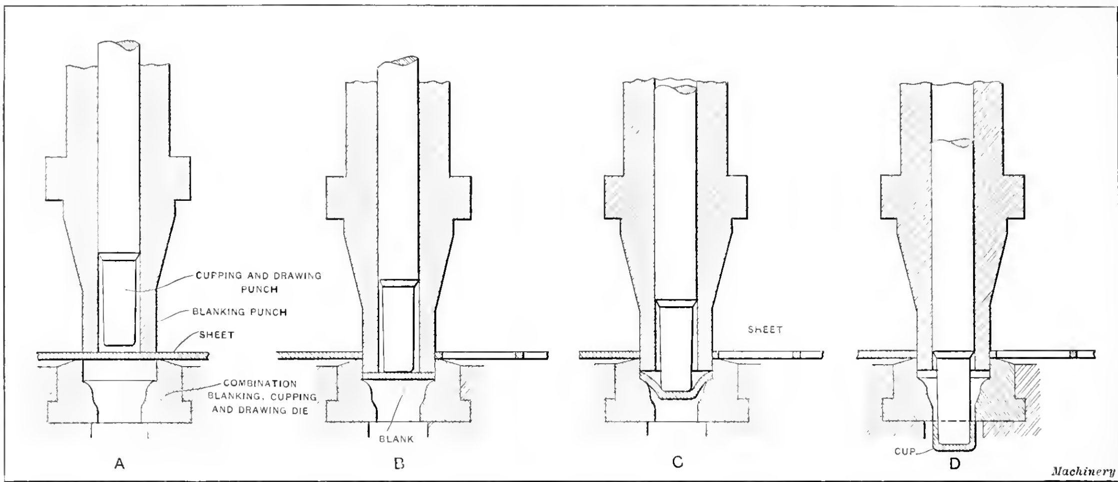

Fig. 2. Progressive Steps in the Blanking, Cupping and First Drawing Operations on the Cartridge Case

First, Fourth and Fifth Redrawing Operations

The first, fourth and fifth redrawing operations are handled in machines of a type similar to that shown in Fig. 7, which are provided with only two punches and dies instead of four, as was the case with the machine shown in Fig. 6. The feeding of the shells to the slide that carries them to the dies is practically identical with that shown in Fig. 6, but the slide is operated in a different manner. In this particular machine the slides *A* which serve as a means for carrying the cups from the feeding tubes *B* over into line with the drawing dies are actuated in their movement by means of a bellcrank lever receiving power from a cam held on the crankshaft *C* of the press.

While the shells are fed to the punch with the mouth up, it sometimes happens that one will pass down the feeding tubes to the slide the wrong way, that is with the bottom up. Now should such a shell be allowed to pass over into

line with the die, it would mean that the punch would be broken and the die either broken or damaged to such an extent that it would be unfitted for use. It is not uncommon also to have shells pass down to the slide that are dented or otherwise defective which would prevent them from feeding into the die properly. Should such a shell pass down the feeding tubes and stick in one of the slides, it would mean that the punch would come down on the slide and break, not only putting the machine out of commission for a time, but perhaps causing serious damage to the attendant as well.

In order to provide against such accidents, Mr. August A. Plate, general foreman, invented an ingenious tripping device

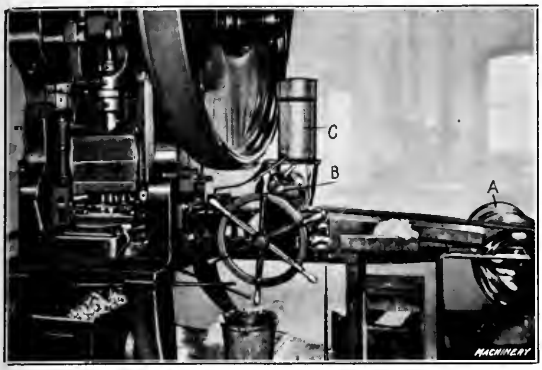

Fig. 3. Making the Cups, Four at one Stroke of the Press, at the Rate of 24,000 per Hour

that is applied to this machine and works very satisfactorily. This device, while comparatively simple in construction, is positive in its action, and has been the means of saving a lot of money in the cost of dies and tools. It also enables one attendant to run four instead of two machines. Essentially, this device consists of a projecting stud held in the crankshaft of the press, and which when the feeding slide is operating normally passes through a slot cut in a lever that is connected with the bellcrank lever operating the slide.

Now, if for any reason the slide should be prevented from making a complete forward or backward stroke, this projecting pin would not pass through the slot in the lever mentioned, but would force the lever out, knocking out the lever *D*, which transmits a movement through the links *E* and *F* and bellcrank *G* down to the tripping lever *H*. This knocks the clutch operating lever *I* off the catch—throwing in the clutch and stopping the operation of the press. It can therefore be seen that this tripping device is of simple construction, but is effective, owing to the fact that when the slide does not complete its movement the clutch is thrown in before the ram of the press reaches the top of the stroke so that the machine is stopped before it has a chance to complete another stroke.

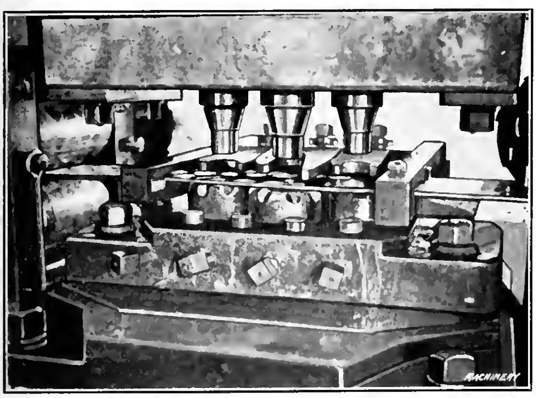

Fig. 4. A Closer View of the Machine shown in Fig. 3

Final Redrawing Operation

The fifth redrawing operation is accomplished in a press similarly equipped to that shown in Fig. 7. These presses operate at 100 revolutions per minute, and turn out 12,000 cups per hour. Several annealing operations take place between the time when the cup leaves the first redrawing operation and the time when it is ready for trimming, but as these have been described in the article mentioned no reference need be made to them here. Before the fourth redrawing operation is accomplished the shells are taken to a heading machine of the horizontal type where they are "bumped." This operation is accomplished in order that in the successive redrawing operations the head of the shell will not be reduced too much in thickness.

The 0.30 caliber cartridge case has what is known as a solid head; that is, the top portion of the shell that contains the primer is not indented to form a pocket for the primer, the pocket itself being simply a hole forced into the head. This type of cartridge has been found necessary for use with smokeless powders. The former method used in making 0.30 caliber cartridge cases was to form the pocket by forcing in the head which was very little thicker than the sides of the shell near the head. This construction, however, was found to be too weak for smokeless powders, as the head would blow off. The "bumping" is a very simple operation and is somewhat similar to heading except that the punch is perfectly flat and simply gives the shell a blow, upsetting it slightly and flattening it so that in the two final

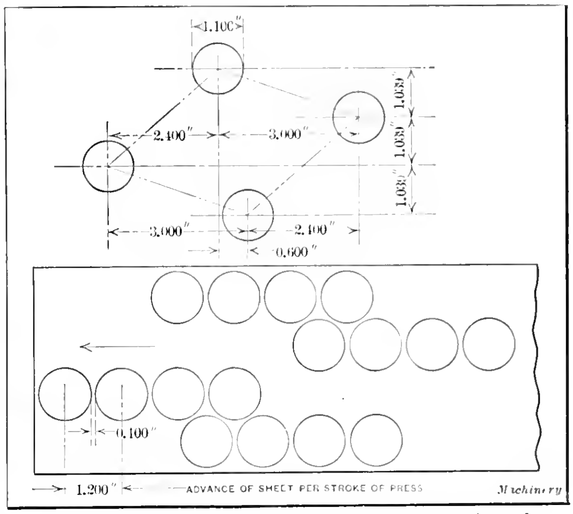

Fig. 5. Manner of laying out Combination Blanking, Cupping and Drawing Dies in order to economize in Stock

redrawing operations—fourth and fifth—the metal at the head is not stretched to any appreciable extent.

Trimming a Cartridge Case to the Exact Length

As was previously mentioned, it is practically impossible to draw a shell that will not have an irregular top edge and also that will not become distorted or cracked to some extent. This makes it necessary to draw the case much longer than actually required and to trim off the surplus material. The removal of this excess amount of stock is accomplished in machines that are operated automatically. A battery of these trimming machines at work on 0.30 caliber cartridge cases is shown in Fig. 8, while Fig. 9 shows a closer view of one of the machines and gives a clear idea of its working mechanism. As will be seen upon reference to Fig. 8, these trimming machines are arranged in such a manner that the various hoppers can be filled from an overhead conveying system. This arrangement consists of a track similar to that used in the drawing press department previously referred to, and enables one man to attend to an entire line of presses. The track accommodates a truck in which the shells are carted along the line and from which they are ejected through a false bottom, dropping into the hoppers located over the machines. The feeding of the shells down to the trimmer is accomplished by the same type of hopper as previously described, but the subsequent handling is somewhat different. As the shell descends from the hopper it passes through a

locating cage *A* from which it is carried forward by a plunger *B* and is located on the cutting-off punch *C*. Here it is held by friction while a circular trimming tool *D* advances and trims off the surplus stock. The shell and trimming are then ejected from the cutting-off punch by a sleeve *E* operated from the left hand end of the machine, the shell being

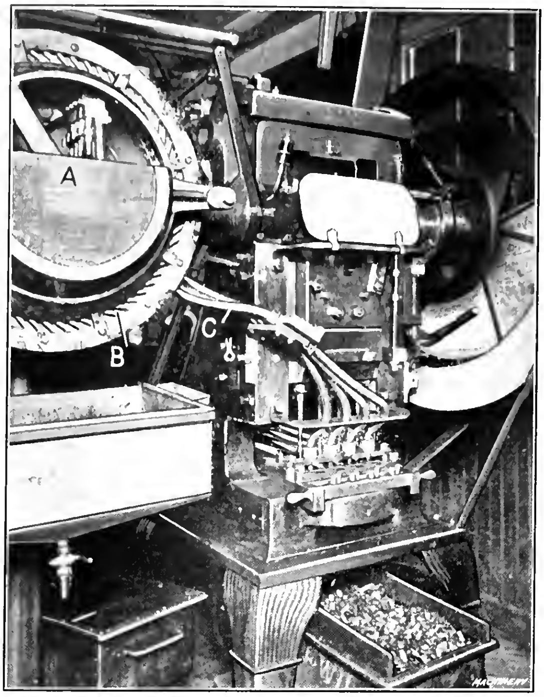

Fig. 6. Drawing Press used for Second and Third Redrawing Operations—Four Cups per Stroke at the Rate of 24,000 per Hour

deposited in one box and the trimming in another; two separate channels are provided as shown clearly in Fig. 9.

Making Combination Blanking, Cupping and Drawing Dies

While the making of combination blanking, cupping and drawing dies does not differ materially from ordinary tool making, there are a few points in connection with this work that it might be well to explain. The die blank is made from a special grade of Firth-Sterling steel containing from 1.11

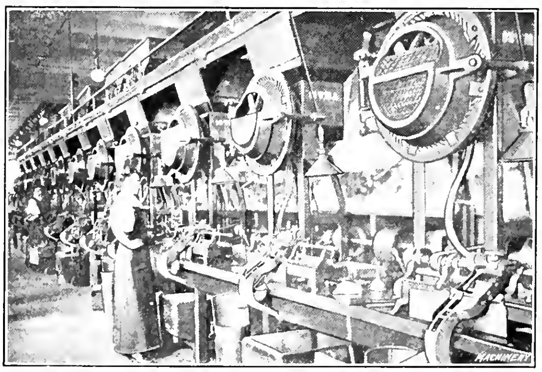

Fig. 8. A Battery of Automatic Trimming Machines at work on 0.30-caliber Cartridge Cases

to 1.30 per cent carbon. This is an extremely high carbon steel, but has been found satisfactory for this class of die owing to the great wear that it is subjected to when in use. The first step, of course, in making one of these dies is to cut off the blank from a bar of stock, and then by means of drills, reamers, etc., to shape the hole in the die to the correct form. Fig. 10 shows one of these dies at *C* together with a blank and a cup made from it, while *D* is the combination cupping and drawing punch and *E* the blanking punch.

Fig. 11 shows a toolmaker completing one of these dies, and Fig. 12 shows a close view of the chuck used for holding it. The manner in which the die is held while being drilled, counterbored and reamed is identical with that used when it is set up in the press, so that in this way the conditions in both cases are as nearly alike as possible. The chuck consists of a female center *A* in which a recess is provided that

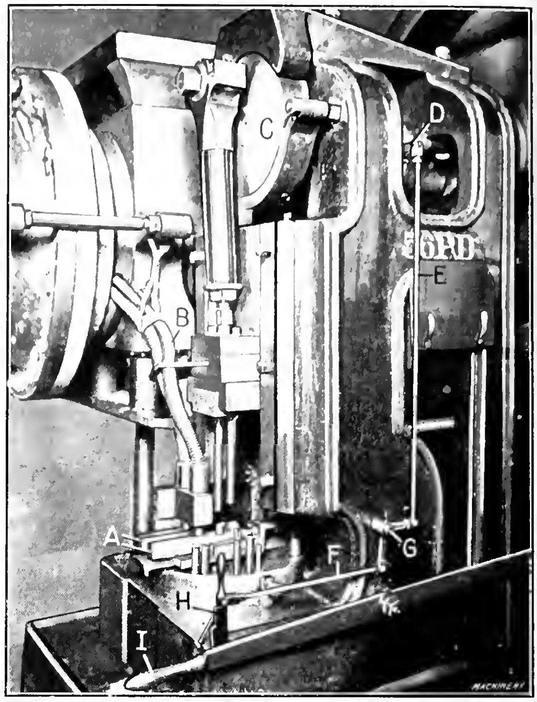

Fig. 7. Duplex Drawing Press performing Fourth Redrawing Operation and turning out 10,800 Cups per Hour

fits the external body of die *B*. The outer end of this center is turned and threaded to fit a cap *C* that is machined to correspond with the other end or smallest diameter of the die *B*. This cap holds the die rigidly in position while it is centered with the female member *A*. In addition to a drill, and, of course, a boring tool to true up the hole, two tools are used for finishing the hole in this die. The first or roughing tool *B*, Fig. 10, is of the flat type, having one cutting edge,

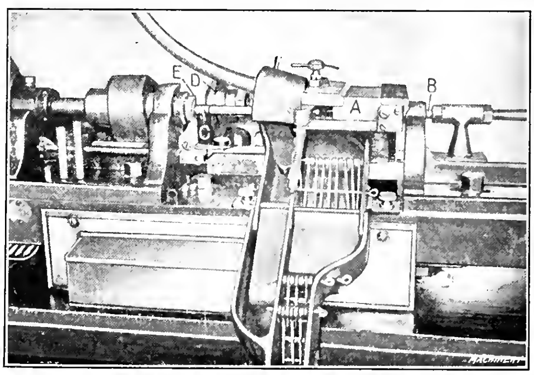

Fig. 9. Close View of One of the Automatic Trimming Machines shown in Fig. 8

while the finishing tool *A* is of somewhat similar shape but has considerably more circumference so that a rounder hole will be produced. The first tool is used merely for roughing out purposes and for bringing the hole to its approximate shape.

Making Redrawing Die Blanks

The blanks for redrawing dies are turned out in Cleveland automatic screw machines and are ready for the final reaming operation when they drop from the machine. This method is commendable in that it reduces the cost of the dies

o a minimum. The steel used for making these dies is a pecial grade of Firth-Sterling steel containing from 1.11 to .30 per cent carbon, and for the particular die G illustrated n Fig. 13 a bar 1¾ inch in diameter is used. This die is a econd redrawing operation die for a 0.30 caliber cartridge ase, and is 1 23/32 inch in diameter by 1/2 inch thick. In rder to have the hole true with the external diameter, great

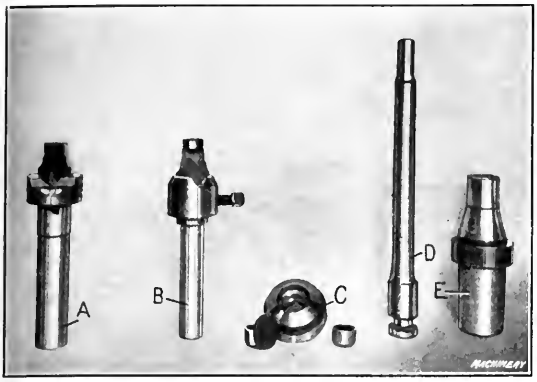

Fig. 10. Combination Blanking, Cupping and Drawing Punch and Die, and the Tools used for making the Die

are is taken in spotting the work and then removing the ole entirely from the next blank, using a fairly wide cut-off ool. The order of operations accomplished in the proper equence is as follows. First, feed stock to stop A; second, urn external diameter with box-tool B held in turret and pot with a drill C retained in the same holder; third, drill ith drill D; fourth, ream straight portion of hole with

Fig. 11. Making Comlination Blanking, Cupping and Drawing Dies

eamer E; fifth, bell-mouth with reamer F, and face with tool held on the rear cross-slide; sixth, cut-off with a tool eld on the front cross-slide.

The drawing dies, after being rough-formed in the manner llustrated, are then taken to the tool-room where they are eamed out to the exact diameter and bell-mouthed to the orrect shape, after which they are ready for hardening. For ardening, the dies are heated in a muffle furnace to a emperature varying from 1400 to 1450 degrees F., and are hen "spouted" as illustrated in Fig. 14. The spouting of the ie consists in directing a stream of water through the hole n order to harden it and at the same time leave the external iameter practically soft. The reason for this is that the ie, after hardening, is not drawn, and if the entire blank were hardened it would break very easily. Having the external diameter soft increases the strength to a considerable extent, and the dies wear much longer and do not break as easily.

When spouting, the die is held in a cage formed in the base of the bracket A and then the funnel B (which is similar in shape to an ordinary oil funnel except that the lower tapered tube is left off) is placed over it, the water being directed through this funnel and thence to the hole in the die. The funnel is provided with a handle to enable the operator to place it quickly in position over the die after the latter has reached the proper temperature, and has been placed in the fixture. The operator removes the die with a pair of tongs, holding the tongs in one hand and the funnel in the other.

Great care must be taken in heating this grade of steel because of its high carbon content. A variation of 10 degrees F. one way or the other from the temperature found most satisfactory will in many cases make the die defective for the operation that it is to accomplish. It has also been found necessary to heat the dies for various operations to different

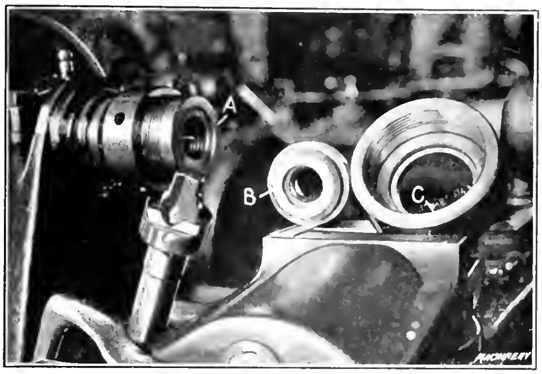

Fig. 12. Chuck used for holding Combination Blanking, Cupping and Drawing Die Blank when machining the Hole

temperatures; that is to say, the die that would be used for a first redrawing operation would be heated to a different temperature from one that would be used for the fifth redrawing or final drawing operation. The reason for this is that the pressure exerted on the die, by forcing the cup through it with the punch, on the first drawing operation, is much greater than that for the final drawing operation, and hence the die cannot be as hard and must have a more porous grain to withstand the additional pressure.

Lapping Redrawing Dies

After hardening, redrawing dies are lapped in the manner illustrated in Fig. 15. The die is held in a holder, resembl-

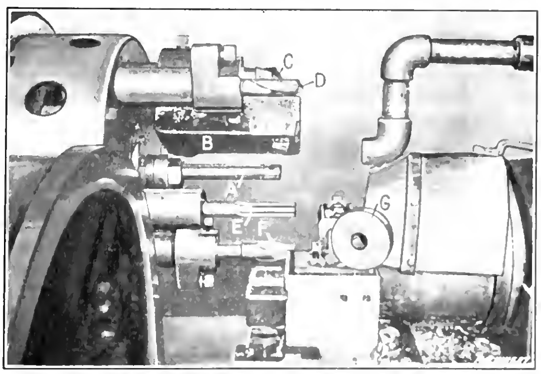

Fig. 13. Making Redrawing Die Blanks in a Cleveland Automatic Screw Machine

ing somewhat in shape that used in the drawing press, which is held in the chuck of the speed lathe. For lapping, a lead lap is used. This is held on a steel plug provided with a handle driven through it at right angles to the lapping portion, so that the operator can grip it with both hands and thus hold the plug in the proper position in relation to the

hole in the die. The speed lathe in which the die is held is operated at from 2000 to 2400 revolutions per minute, and the spindle is always kept a snug fit—also there must be no end play. A mixture of lard oil and No. 10 emery is used for lapping, this being found best for both the roughing and finishing operations. The mouth or bell-mouthed portion of the die is lapped with emery cloth of the same grade No. 10. The lapping of a drawing die is an operation that must

Fig. 14. "Spouting" a Redrawing Die—hardening the Hole and leaving the Exterior comparatively Soft

be very carefully handled. Not only must the hole be of the correct size, but the radii of the bell-mouthed portion must be exact. The correct lapping of the die is more a matter of experience than anything else, and it is practically impossible to give any definite information on the subject. One point, however, that should never be ignored is the fact that the lap should always be presented in a line parallel to the axis of the die. If it is tilted over the least bit to one side or the other a hole will be produced that will not only be out of round, but that will not be straight; that is, if the die were placed on the arbor it would be found to run untrue because the hole would not be exactly in the center of the blank on both sides.

After the dies are lapped to the correct size and shape, they are ready for use in the press and are then turned over

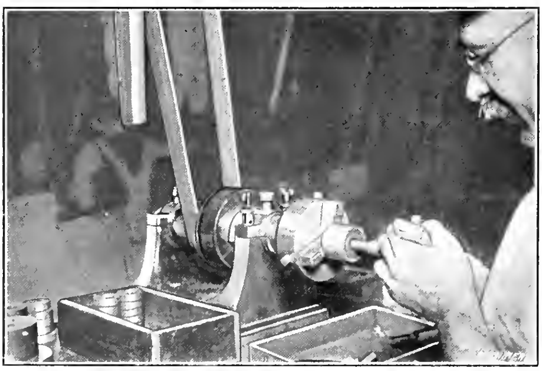

Fig. 15. Lapping a Redrawing Die

to the drawing press department. Drawing dies for all redrawing operations up to the final operation are used until they have worn approximately 0.0017 inch large. When they have become worn to a size this much greater than the actual diameter of the cup required, they are taken out of the press and annealed. The dies are then reamed out to the next size larger—that is for the previous redrawing operation than that for which they were originally made—and used over again. This is repeated until the dies have been used five times. Redrawing dies made from Firth-Sterling steel of the carbon content previously given are good for making 40,000 cups before they have become worn too large. The peculiar point about this steel is that it does not warp out of shape in hardening and also does not produce any scratches on the work. It is of extremely fine grain, hardens well and produces a shell free from scratches and other imperfections. The only thing that makes it unfit for use is when it becomes worn too large. Otherwise the condition of the hole in the die is as good at the completion of 40,000 cups as it was when first used.

Making Redrawing Punches

Redrawing punches are also made from Firth-Sterling steel, but the carbon content for the punch is considerably lower than that used for the die, and never should exceed over 0.60 per cent. There are a few points that require careful consideration in making drawing punches. In the first place, the stock should be centered as true as it is possible to get it. There is a good reason why this operation should be carefully done. If the piece of stock from which the punch is to be made has not been centered true, the finished drawing punch when hardening will be bent out of shape. The reason for this is that when a bar that has been incorrectly centered, so that it runs eccentric, is turned, more stock is removed from one side than the other, and the turning, instead of being parallel with the grain, cuts across it; hence the ability of the steel to resist deflection in hardening is not as great as it would be had the support not been removed from one side.

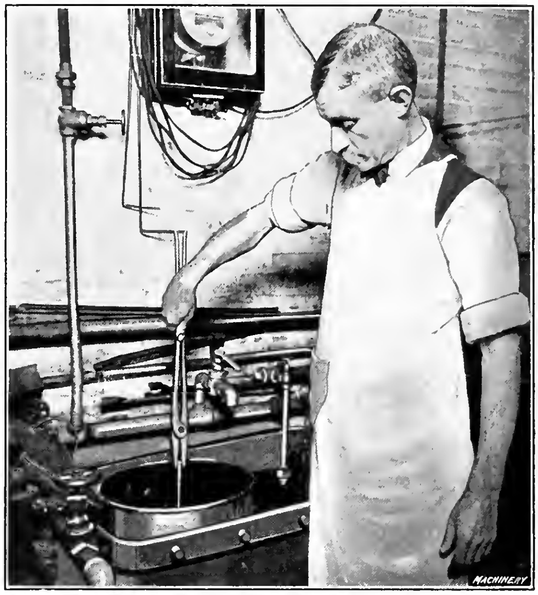

Fig. 16. Hardening a Redrawing Punch—Note Method of Dipping

The explanation given for this is that in rolling bar stock the fiber or grain of the metal is drawn out in practically a straight line and when this condition does not exist in the finished article distortion takes place, because, in cooling, the fibers of the stock revert to their original positions parallel with the axis of the bar.

Another point that is of considerable importance is that never less than 1/32 inch of material should be removed from the bars if the finished piece made from it is to be hardened. There is a certain decarbonizing portion surrounding a bar of stock that prevents the steel from hardening properly, and this decarbonizing portion should always be removed from those parts of the punch that must be hardened; if not, soft spots will be experienced.

The drawing punch should be heated in a muffle furnace very slowly until it has obtained the correct temperature, and while being heated it should be constantly rotated to prevent warping. The temperature to which drawing punches are heated varies from 1400 to 1425 degrees F. They are quenched in a bath consisting of 15 parts water and 1 part common potash, and are dipped in a vertical position as illustrated in Fig. 16.

METHODS OF CHUCKING BEVEL GEARS

ACCURATE AND EFFICIENT METHODS DEVELOPED BY THE HEALD MACHINE CO., WORCESTER, MASS.

The Heald Machine Co., Worcester, Mass., has given the problem of chucking both spur gears and bevel gears, preparatory to grinding, a great deal of study during the past few years, and has devised, at different times, what have been considered very accurate and efficient methods of chucking. There is a great diversity of opinion among the users of internal grinding machines in regard to what seems to be the most desirable method of holding or chucking gears for grinding; furthermore, a device that is very successful in one shop does not always appeal to the man in charge of another shop doing similar work. It seems to be very difficult, in many cases, to get the men responsible for results in different shops, to appreciate the advantages of a method which is different from what they have used in the past, or, in some instances, even to consider carefully the exact advantages of one scheme as compared with another, for securing the accurate results required in grinding operations.

Some of the successful methods of chucking gears which have been developed by the Heald Machine Co. are shown in the accompanying illustrations. Fig. 1 shows an excellent method of holding crown gears or ring gears such as are used in automobile transmissions. An unhardened master gear *A* is mounted on the faceplate so as to run true, and certain teeth are cut away at the inner ends as shown at *B*, leaving three sets of three or four teeth each as at *C*, which are longer than the others. When a gear to be ground is set into this master gear it will be centered with great accuracy and run true. The gear can be held in position very easily by two or three spring clips *D*. There is only one position that the gear to be ground can take with this method of holding, and as the master gear has contact points practically 120 degrees apart, the gear will not rock on its support, and extremely accurate work may be produced.

Fig. 2 shows a standard draw-in collet fitted with special jaws for holding bevel gears, these jaws being arranged to bear at the bottoms of the tooth spaces. Jaw *A*, as will be seen, has a slight projection *B* which extends over the outside of the gear to prevent it from sliding out as the jaws are closed; hence, by simply opening and closing the jaws of this collet the gear is clamped and released and no straps or yokes are necessary to hold the work in position. An objection to this design is that if the chuck teeth do not have a good bearing surface at the bottom of the tooth spaces, a chance of error will be introduced.

Fig. 3 shows a method of holding bevel gears by the use of taper rolls which enter between the teeth, giving a pitch-line control method of chucking. This illustration shows a chuck having six rolls arranged in three pairs. These rolls, for gears of other sizes, may have one or possibly two teeth between them, according to the number of teeth in the gear to be chucked. This gives practically a six-point contact, and yet the rolls are so disposed that the gear will be held solidly in the chuck with less tendency to rock than if they were evenly spaced around the circumference. The use of six rolls in three pairs, instead of three rolls evenly divided around the gear, gives superior results because the double rolls furnish a sort of check on each other in locating the gear. They also provide additional wearing surface, thus increasing their durability, and, according to the experience of the Heald Machine Co., gears that run very accurately are produced when this form of chuck is used.

The chuck has a faceplate *A* which screws onto the nose of the grinder spindle *B*. In front of the faceplate *A* there is a second plate *C* recessed to a suitable angle for receiving the gear *D* and rolls *E*. The rolls are held by triangular shaped plates *F* and cap-screws. These plates and the cap-screws hold the rolls back firmly against the chuck plate *C*, which prevents dirt from getting under the rolls, but allows a slight freedom for the rolls so that they can adjust themselves slightly with relation to the gear teeth. The gear is held in place by a yoke *G* and thumb-screw as shown. This yoke exerts a pressure in a line parallel with the axis of the gear, and assists in forcing the gear back to a solid and concentric location.

It will be noted that the surface on part *C* is marked "Finish for indicator," and it has been suggested that after the angular surface is accurately ground true as to size and position, this outer surface also be ground true; then if it should be necessary to remove the fixture from the machine or exchange it for another size, when the fixture was replaced it would be a simple matter to test its accuracy by applying an indicator to the finished surface previously referred to. If any error were observed, the clamping screws which hold parts *A* and *C* together would allow for whatever adjustment might be necessary to enable part *C* to run true, without going to the trouble of re-grinding the surface for locating the rolls. While it would cost a little more to make this division between parts *A* and *C*, this cost would be

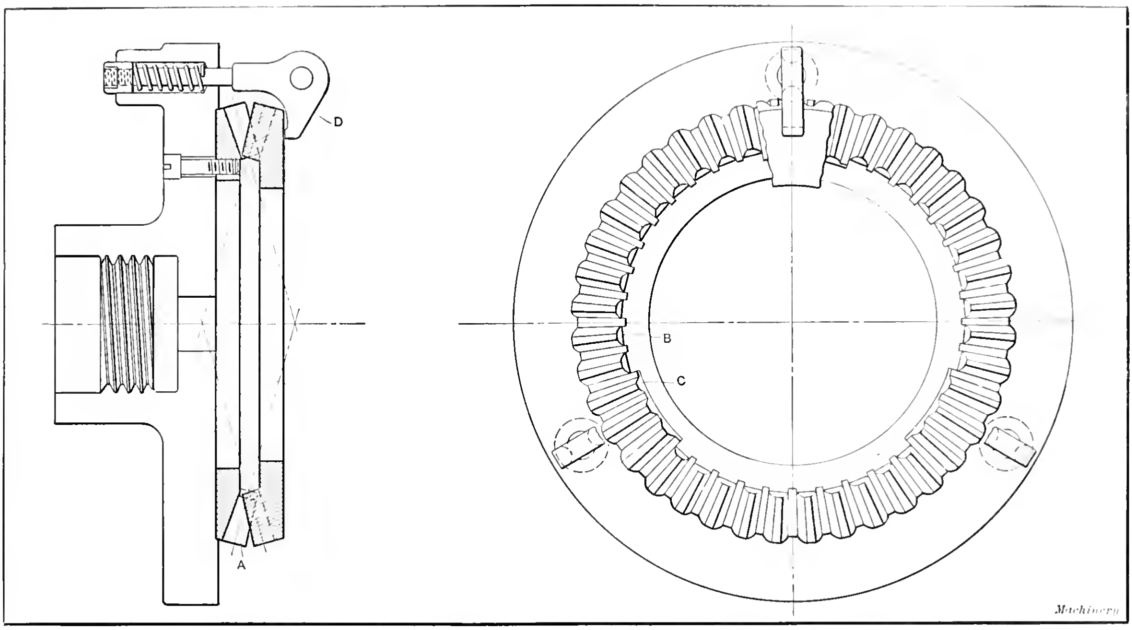

Fig. 1. Chuck for Bevel Gear having a Master Gear against which the Work is clamped

saved many times over because plate *A* could be arranged to receive many different types of chucking devices, if the user of the grinding machine had a variety of gears differing as regards the number of teeth and pitch.

According to the experience of the Heald Machine Co., the rolls used for chucking bevel gears should be tapering because they make contact with curved surfaces, the elements of which converge at a common vanishing point. Some mechanical men who stand high in the profession of making gears claim that cylindrical rolls are just as satisfactory as tapering rolls, although this company considers the tapering roll superior, and is inclined to believe that those who consider cylindrical rolls satisfactory, are using them in connection with gears having a face width that is small in proportion to the gear diameter, as, for example, ring gears used in automobile transmission. In such cases the error does not seem to be as pronounced, but with miter gears, especially when the face width is say one-quarter to one-fifth the gear diameter, there appears to be a most decided tendency for the gear to rock on a cylindrical roll at a point about midway of the face of the teeth.

The method of calculating the diameter and taper of the rolls is to select for the large end of the roll a diameter which will bring the surface of the roll about 1/16 inch above the outside diameter of the gear teeth. The taper of the roll should be approximately that which would cause the roll, if extended, to converge at the apex of the pitch cone. If these rolls are to make proper contact with the tooth surfaces, the points of contact must lie in a line running from the large end of the tooth to the vanishing point of the pitch cone, and if two elements in the surface of the roll meet in a common vanishing point, all other similar elements must apparently meet at the same point, indicating that these rolls should be part of a true cone. Experience seems to show this to be true, although the center of the roll is slightly outside the pitch circle of the gear. Working on this basis, it is not difficult to lay out, with considerable accuracy, the included angle of the rolls and obtain the angle of the surface in the chuck plate against which the rolls bear. In actual manufacturing, this angle can be checked easily by simply inserting the taper rolls between the teeth on opposite sides of the gear, thus forming a temporary gage.

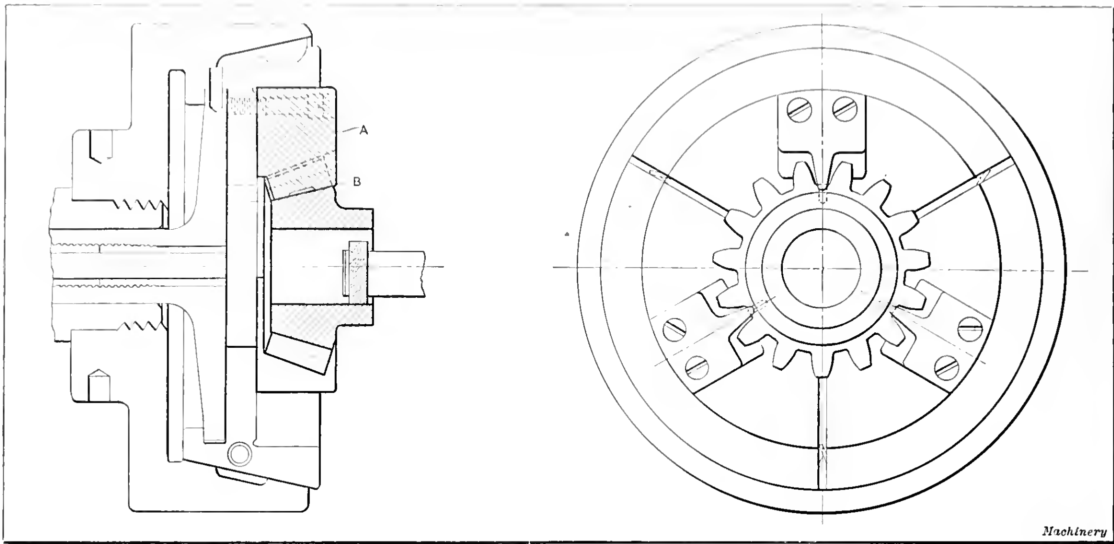

Fig. 2. Bevel Gear Chuck with Jaws which engage Bottoms of Tooth Spaces

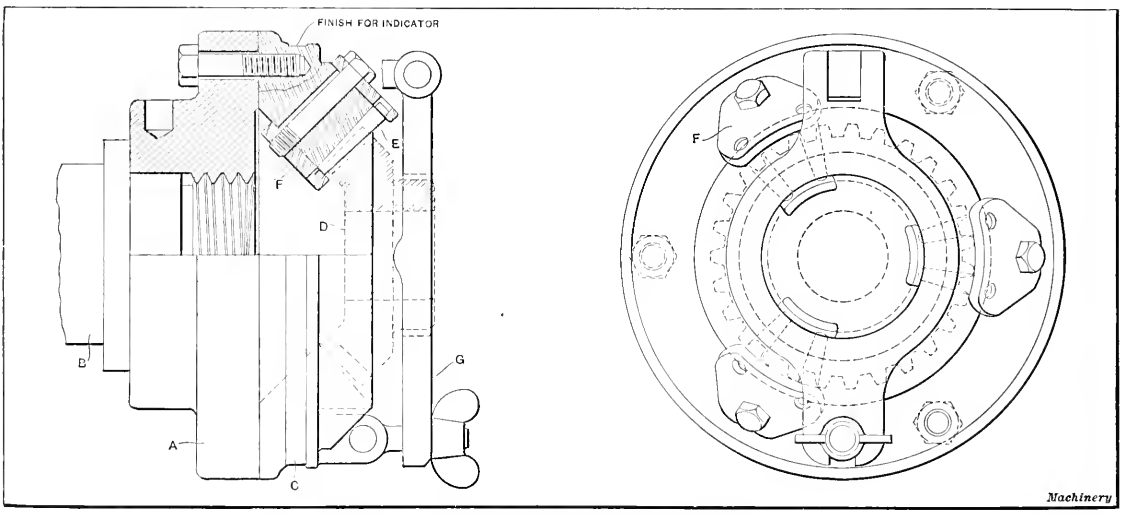

Fig. 3. Bevel Gear Chuck with Tapering Rolls which bear against Sides of Teeth

The best method of holding the rolls in place has proved to be more of a problem than would be supposed after the solution has been found. These rolls could, of course, be riveted to the conical surface, but the rivets would be quite small and rather frail for everyday service, and this arrangement would not provide the lateral adjustment that is desirable to compensate for minute variations in the gear teeth, due to cutting or hardening.

SOME SOURCES OF LEAKAGE IN THE ENGINEERING INDUSTRY

IMPORTANCE OF EFFICIENT TOOL EQUIPMENT, LAY-OUT OF PLANT, ADAPTABILITY OF DESIGN, AND AMOUNT OF STOCK

BY A. A. PEEBLES*

It is impossible in the scope of a brief survey of the subject to treat adequately all the different sources of leakage which may arise in the running of an engineering plant. Each individual case which is examined has its own leakages, some of which may be peculiar to itself, and due to an inherent fault of original planning or to a defect in the management or discipline of the organization. Yet there are some phases of the question under consideration so common, but so seldom emphasized, that a brief summary of the various leakages most frequently met with may not be out of place.

For the purposes of this article leakage may be defined as all unproductive expenditure of time or effort on the part of either the men or the machinery employed in an industrial undertaking, and may also embrace the unprofitable expenditure of capital. It is, moreover, one of the most prevalent and insidious diseases which attack efficiency—prevalent because there are so very few of even the most modern plants into which leakage in one form or another does not creep; insidious because those who suffer from it so rarely know of its presence. To become aware of a source of leakage is frequently to overcome that leakage. It is the loss which is unnoticed that eats into efficiency and consumes dividends.

There are not a few engineers—owners or managers of engineering plants of one kind or another—who blame competition for the loss of business and the decrease in profits which their organizations experience. To a certain extent this may be the cause, but only to a certain extent. If a business loses contracts because other firms underbid its quotations, or if it can secure contracts only by quoting prices which permit of no profit, it is a sure sign that other firms can do the work more cheaply. They are out for profit also, and under normal conditions will not quote prices that do not yield a fair return. Any firm which cannot compete with such prices is operating inefficiently. In other words, the aggregate of its leakages is high, for efficiency is merely the absence of leakage.

It is, perhaps, no exaggeration to say that of the total money expended in the engineering workshops of the world, one-fourth is wasted on unproductive effort of one kind or another, and that of this fourth at least a half is conservable. Such items as loss of time and power, and the wear and tear of machinery involved in the return stroke of slotting, planing and shaping machines are examples of wastage which cannot well be eliminated at the present stage of machine tool development, although the day is not far distant, to judge from present indications, when even such losses as these will be avoidable. It is our aim, however, to deal here only with such of the more common leakages as are at the present moment wholly or partially remediable.

Unsuitable and Poor Equipment

One of the most prevalent sources of leakage in the engineering works is poor equipment. Too much stress cannot be placed upon the importance of up-to-date machine tool equipment. Any efficiency expert in the engineering field will endorse the statement that old or unsuitable tools are responsible for more inefficiency than is any other cause. Factory managers and owners seem to be reluctant to invest in a new plant while the old can, by any means, be made to suffice. When a machine is worn out they will scrap it, but very few will scrap a comparatively new tool merely to make room for a more efficient one. Yet, in deciding when to throw out an existing machine to make room for a new one, the question of the condition of the former should not be the determining factor. The question should be looked on purely as one of business. The operating cost of the existing machine should be computed, and also the operating cost of the proposed new one. The output of each should be carefully estimated, and the final decision based purely upon the results thus obtained. If the installation of the new tool is going to return a reasonable interest on the capital invested, the new tool should be put in. In estimating operating expenses, such items as a percentage of rental and rates proportional to the floor space occupied by the tool, and also a percentage of the interest on the capital invested in the building and of the depreciation thereof, should be considered in addition to such items as interest on capital invested in the tool itself, depreciation, operator's wages, and power used.

* Address: Box 1514, Winnipeg, Manitoba, Canada.

The only occasion upon which there is room to question the advisability of installing a more efficient machine tool in place of one of smaller capacity is when the demands of the plant are such that they can be conveniently coped with by the existing machine. In such a case the only saving effected by a change is in the operator's time, the overhead charges of interest, depreciation and floor-space, rental being the same in each case. Such instances are, however, rare, and in most cases the progressive policy of scrapping out-of-date equipment for that of a more modern nature will be found to pay.

The writer recalls one instance which illustrates the effects of wholesale scrapping. In the north of England there is a small general engineering and millwrighting shop which, until a few years ago, was still operating an equipment composed of old, slow-speed tools. It was a busy shop, and in order to do all the work considerable overtime was necessary. It never paid. Work had to be taken at prices that would not permit of the extra cost of overtime in addition to the high cost of production due to inefficient equipment.

A change of management, however, put things on an entirely different basis. The new man raised money and put in a practically new equipment consisting of powerful high-speed tools. He also installed a new power plant with electrical distribution, and speeded things up all around. The result was that the capacity of the plant was augmented to such an extent that its output was materially increased without the necessity of any overtime, and the cost of production was so reduced that the firm was able to quote lower prices than formerly and realize a useful profit in the bargain.

Instances parallel to the foregoing could be multiplied at will. There are many shops operating at a low efficiency simply because the management is reluctant to throw out machines until they are worn out. It is comparatively rare to find an instance where the reverse is the case. That such a contingency is possible, however, will be illustrated by another experience. In this case the shop (also a small one) specialized in valves and steam fittings. Among other machinery was a battery of three hollow spindle capstan lathes which were employed in turning out spindles for a patent valve from the bar. These machines were quite capable of meeting current requirements and were rarely required to do overtime work. It happened, however, that while visiting a machinery exhibition the manager saw some new machines of the same type, but of a more powerful and improved design, and was so impressed by them that he ordered three and had them put in place of the old ones. The approximate net cost of the change was $3500. The saving effected was the money previously paid in overtime, which rarely exceeded $10 a month, and was usually less. This represents a saving of considerably less than 3½ per cent—a poor investment from a business point of view. Yet against this it must not be forgotten that the maximum output of the plant had been increased against possible future demands.

Inefficient Power Generation

Apart from the machine tool equipment of an engineering works, considerable loss may arise from inefficient power generation and distribution. It has been estimated that the average cost of power in the different industries amounts to only 5 per cent of the total cost of production, and for this reason it is sometimes regarded as immaterial. Yet in these days of keen competition, even the smallest source of leakage is of importance, and in the progressive shop, obsolete and inefficient power arrangements are no more to be tolerated than obsolete machine tools. The writer knows of

two cases which show what can be done in the way of improving power facilities. Both are extreme, perhaps, and consist in replacing a plant of exceedingly wasteful nature by the most efficient available. In one instance the saving in power paid the whole cost of the work of installing the new plant in three years. In the other all the machinery of the factory was driven, and the building lighted with electricity, for a cost approximately equal to that of lighting the place with town gas, as had been done previously.

The lay-out of a plant is a very important factor in the equation of efficiency. This should be carried out on lines calculated to reduce the amount of handling to a minimum. Repeated and unnecessary handling of material during the process of manufacture is a potent cause of costly production and one which is very frequently found. Material should be made to pass, in so far as is possible, through the different departments in order. The disposition of traveling cranes is an important consideration, as is also the method in which the different classes of machines are grouped according to their purposes and in relation to the other parts of the plant.

Where an engineering works has been originally laid out along lines which are not the best, it may not always be advisable to go to the heavy expense of entirely remodeling the whole plant. Yet much can be done in many directions to reduce the unnecessary handling, if a little thought be given to the matter, without undue expense. An example of this is afforded by a large Tyne-side shipyard in the "old country." Two cupolas were operated in connection with the foundry and were kept constantly busy. At one time these cupolas were fed by means of hydraulic lifts. Fuel and pig iron were loaded from the cars on a neighboring siding onto the lifts and were then fed to the cupola—two handlings only being required, but when the quantity of material is considered the second handling constitutes an item of some importance. By building a trestle incline from grade level to that of the charging platform, and running the cars up directly to the latter, the second handling was obviated at a relatively small expense. The direct saving effected in laborers' wages was considerable and, in addition to this, the time saved in charging increased the efficiency of the whole foundry.

Up-to-date equipment in the way of machine tool fixtures and accessories, special tools, jigs and small tools, is scarcely less important than the efficiency of the tools themselves. A good tool-room foreman and staff are among the most valuable assets of the modern engineering works. To have a complete and well kept stock of tools and accessories stored in such a way that any particular one can be found at the shortest notice is to increase the efficiency of the whole plant. Good store-keeping is also an important factor and the reverse a prolific source of small leakage. When men have to wait several minutes while the storekeeper is looking for a certain tool or some stock material, there may be a considerable waste of time, particularly when such waiting is a general thing. It is important that material, both in the tool and stock stores, should be so disposed that anything asked for can be produced without delay.

Accumulation of Scrap

There is another source of leakage which, though usually small, is found in a large number of engineering establishments and is rarely reckoned with. The accumulation of scrap is a source of small leakage in nine out of every ten shops and it is one which is most easily overcome. Scrap in a shop or in a yard takes up valuable space; it is in the way and is generally a nuisance. It also represents so much capital lying absolutely idle. It has a cash value and its value, if realized, might be used to advantage. In the majority of engineering works, far too much scrap is allowed to accumulate before it is disposed of or put to useful purposes in the cupola. The writer was once called on to make a valuation of the entire plant of one of the largest ship-building concerns in the north of England. The estimated weight of the scrap which littered the yards and the different departments was 1000 tons, much of which had obviously been lying around for years. Cast iron, steel and wrought iron were all piled together, with a considerable proportion of brass and gun metal in the form of bearing bushes, stuffing-boxes and the cylinders of old feed pumps. Our estimated value of the whole of the scrap was $21,000, which sum, invested at the rate of five per cent, would give an annual income of $1050. A small item, perhaps, in view of the size of the plant, but one which counted. It was a dead and unnecessary loss, and in addition to this, the scrap was in the way and was occupying valuable space.

The leakages previously dealt with have been those most commonly met with in the operation of the works department of an engineering firm. There are others which have their origin in the offices, and which are not without their importance in the matter of efficiency. Among the chief of these is the matter of adaptability in the designing department. Let us consider a firm that manufactures steam fittings on a large scale as an example. In such a firm it will often be found that every valve or other fitting is designed with no regard for existing types, or for types undergoing contemporaneous design. The result is that for every type of valve or other fitting, an entirely new set of details has to be made. By a little adaptability in design it would be possible very often to utilize, in new designs, existing patterns for the main castings and existing types of spindles, seating and other details. The saving effected in manufacture would be considerable if in the new design the same patterns used in an existing design could be employed. This principle applies with more or less force in many other lines of manufacture. The secret of the success of the manufacturers of the Ford automobile has been duplication—the making of all their engines alike. This has rendered possible the production of an efficient car at a price unheard of previously.

There is still one other point to touch on in connection with the executive end of the engineering business before this cursory review of the matter of leakage is brought to a conclusion. That is concerning the matter of stock. From the engineer's point of view stock can be divided into raw material and finished product, and a careful adjustment of both these divisions is essential to efficiency. In buying raw material, under which head may be included pig and bar iron, and often studs, bolts and other material not produced in the works, the markets must be carefully watched, and purchases made in so far as is possible when the market is favorable. Sufficient stock must be carried in all lines to avoid the possibility of running short unexpectedly, with its attendant holding up of work and waste of time; on the other hand, too much stock should not be purchased. Stock in the shop is capital idle, and it takes up space, which is also true of finished stock. A sufficient quantity should be kept on hand to meet possible demands, and to guard against loss of business on account of inability to give early delivery, but an excess of stock above this quantity is inadvisable. It represents an unprofitable investment of capital, and there is the risk that some of it may become out-of-date before it is disposed of. This adjustment of stock, both in regard to raw material and finished product, is one which demands nice judgment. In quiet times manufacturers not infrequently continue to run their plants at or near capacity, with the result that a surplus stock is accumulated which is difficult to dispose of. Stock should be kept within reasonable limits even if it means a shut-down for a time. It is the best policy in the end.

* * *

An interesting application of the vacuum cleaner as a foundry tool is told by a contributor to *Foundry*. When making a three-part mold, six spikes were inserted to secure the sand, but one spike passed through the sand into the pattern, and after rolling over and drawing the main part of the pattern it pulled through the core and about a handful of sand dropped down underneath. In this case, either the mold had to be destroyed or the loose sand had to be removed. The only feasible manner in which the latter could be done was by the use of a vacuum cleaner, by means of which the loose sand was readily sucked from underneath the core. The resulting casting was sound, which showed that a device of this kind may be utilized to advantage in foundry work.

DESIGN AND CONSTRUCTION OF BORING TOOLS

VARIOUS TYPES OF BORING TOOLS FOR ENGINE LATHES, HORIZONTAL AND VERTICAL TURRET LATHES OR BORING MILLS

BY ALBERT A. DOWD*

A boring tool or boring-bar is, in itself, a very simple tool and yet, in its various applications, it may require considerable forethought in order to obtain a tool which will be exactly the right one for the job. In order to properly design any kind of a cutting tool, an intimate knowledge of the actual working conditions which are met with in using the tool is a valuable asset. There are a number of factors which influence the design of boring tools and there are also many types of machinery to which boring tools may be applied. In some cases the bar revolves with the spindle of the machine, while in others it is held rigidly and the work revolves around it. These things affect the design and must be considered. The work naturally controls the size of the bar and also its shape, while the material which is to be cut makes a difference in the shape of the tool and determines the amount of "chip clearance" necessary.

The tools described and illustrated in this article must be considered as representative types of the many varieties to be met with in the general course of manufacturing. Points in design and construction will be noted and faulty tools will be discussed and criticised.

General Points in Boring Tool Design

Some of the important points in the design and construction of tools for single-point boring are here given, and while some of these may seem obvious, they may be of assistance in calling attention to matters which would otherwise be overlooked.

1. Chip clearance must be very carefully looked after when the tool is to be used for cutting steel, as an accumulation of chips caused by insufficient clearance is very annoying to the operator and also injures the work by tearing or scratching it, and finally ruins the bar itself unless it is hardened. The amount of clearance between the bar and the work should be as great as possible without sacrificing strength, and in this connection it should be noted that in addition to the necessary chip clearance at the point where the cutting action takes place, provision must also be made to get rid of the chips themselves. For this reason the portion of the bar beyond the cutting tool should be so proportioned that chips will not wedge. In cutting materials other than steel the clearance is not so important, as the chips are short and do not curl up or cling to the bar, so that they practically take care of themselves.

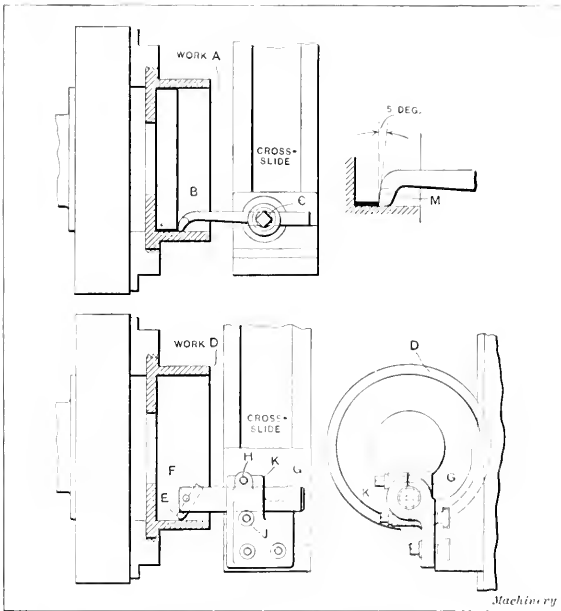

Fig. 1. (Upper View) Forged Type of Boring Tool; (Lower View) Boring Tool with Inserted Cutter

2. The method of holding or clamping the tool in position should be such that the thrust of the cut comes against the solid body of the bar and not against the set-screws or clamps. It is advisable to use square-head set-screws instead of the headless type whenever possible.

3. Boring-bars should be provided with some means of adjusting the tools for diameters, by the use of "backing-up" screws or wedges. The so-called "sledge hammer adjustment" type of bar should never be used when there is room enough to put in adjusting screws.

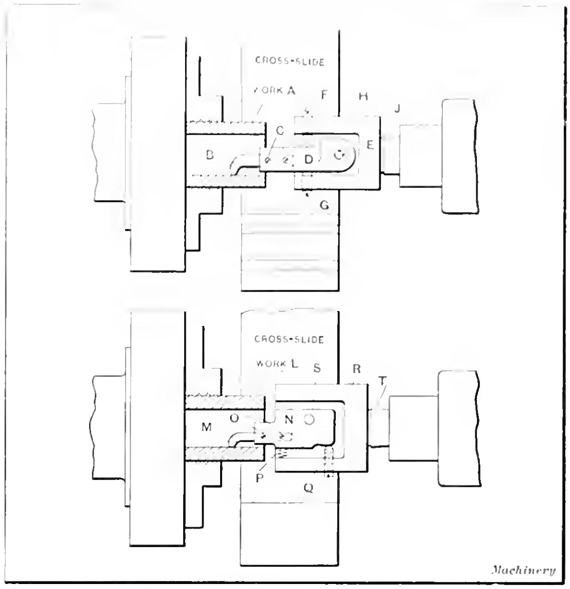

Fig. 2. Two Types of Adjustable Boring Tools for Tool-room Work

4. Boring-bar tools should be made as large as the diameter of the bar will permit without sacrificing strength, in order to assist in carrying away the heat generated by the cutting action, and to permit the use of heavier feeds without burning the tool. The rake of the tool should be such that it will turn the chips to the best advantage.

5. The bar should be so designed that micrometers can be used over the bar and tool in order that the operator may be able to set his diameters closely without resorting to the usual "cut-and-try" method used by our forefathers.

6. In the design of multiple boring-bars which are to be used to bore up to a shoulder, it is not good practice to set the tools in the bar at an angle. They should be located in a plane perpendicular to the axis of the bar. If set at an angle it will be found a very difficult matter to grind the tools so that diameters and shoulder distances will remain constant.

7. Bars designed for use on turret lathes should have the tools set in a plane perpendicular to the rotation of the turret. By this means variations in the indexing of the turret are minimized in their relation to the cutting tools, so that diameters can be held much closer to size than if the tools are arranged in a plane parallel to the turret rotation.

8. When the work is of such a nature that a cutting lubricant is required, provision should be made so that an ample supply of the fluid can be carried directly onto the face of the cutting tool. This result can be accomplished either by means of a hole in the bar with outlets at the proper places, or oil grooves covered with a strip of sheet brass. In either case a good connection must be made with the cutting lubri-

* Address: 81 Washington Terrace, Bridgeport, Conn.

cant system on the machine. This may be arranged by a distributing collar on the turret or by means of a special oiling device through the spindle.

Boring Tools for the Engine Lathe

Boring tools which are designed for use in the engine lathe are generally of a very simple kind, adapted only to light cutting and seldom used for more than one or two pieces of

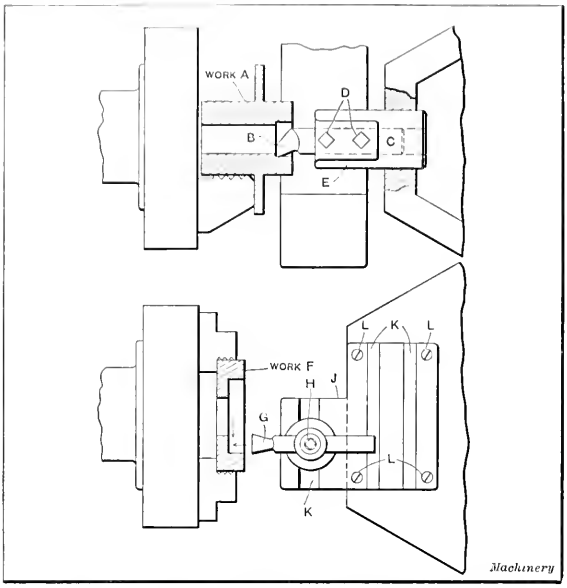

Fig. 3. (Upper View) Single-point Starting Tool; (Lower View) Boring and Facing Tool

work of the same size at the same time. Several varieties are to be found in the average tool-room, although forged tools will be noted in greater numbers than any of the others. Tools of this kind of almost every conceivable shape and size, from a small round "hook tool" for cutting an inside recess, to a a large bar of tool steel bent over at the end for boring some long pieces of work, will be found in abundance. There are

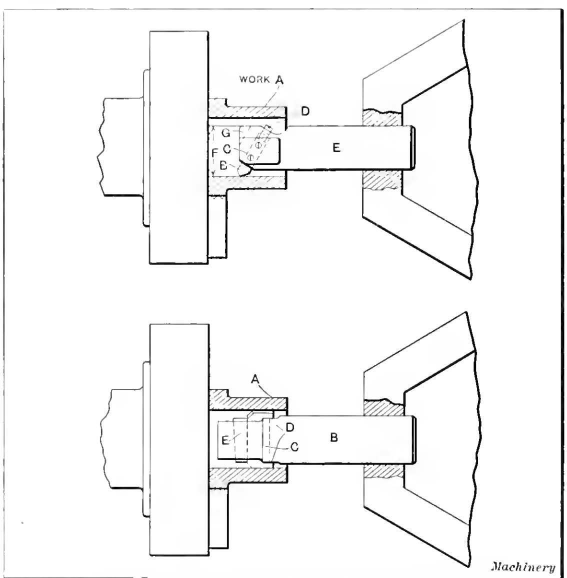

Fig. 4. (Upper View) Boring-bar with Adjustable Cutter; (Lower View) Boring-bar with Double-ended Cutter

square bars and round bars with inserted tools, and, in addition to these, each toolmaker has a special boring tool of his own make which he uses for jig work. These special tools occasionally show considerable ingenuity in their construction, and are usually made in such a way that very fine adjustments can be attained.

The upper part of Fig. 1 shows a piece of work *A* held by the outside in chuck jaws, the machine on which the work is to be done being an engine lathe. A plain forged tool *B* is held in the toolpost *C* on the cross-slide of the lathe. This type of tool is the simplest of all tools used for boring and consists of a rectangular piece of tool steel of suitable size to fit the toolpost. The tool is drawn out and bent over at the cutting end by the blacksmith and is then ground to a cutting edge by the workman using it. Hundreds of tools of this variety can be found in every machine shop and factory in this country. They are suitable only for light cutting and there is a tendency toward "chatter" even when the cut is light; this is due partly to the shape of the cutting end and partly to the overhang of the entire tool. It will be found that less chatter will result if a slight land or flat is stoned on the tool immediately below the cutting edge. The tool should also be set slightly above the center. For casting work where scale is encountered, there is a decided tendency for the tool to ride up on the scale and ruin very rapidly if it is ground as shown at *B*. The enlarged view *M* shows another method of grinding which is useful in cases of this sort. It will be noted that there is a slight back taper to the end of the tool and this assists in preventing any riding up on the scale, as its tendency is to make the cutting point draw in slightly and thus keep under the scale. Care must

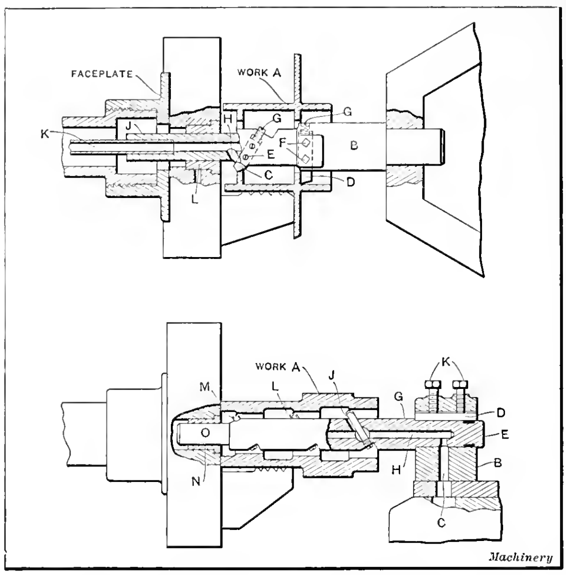

Fig. 5. Boring-bars arranged for lubricating Cutters

be taken not to make the angle too great—5 degrees is ample, and much less than this can be used if desired.

The lower part of Fig. 1 shows the same piece of work *D* with another type of boring tool in action. A cast-iron body *K* is held down on the cross-slide of the lathe by means of the three bolts *J*. A steel bar *G* is longitudinally adjustable in the cylindrical portion of the holder and is clamped in position by means of the binder screw *H*. A round cutting tool *E* is held in place by the taper pin *F*, in a manner familiar to all. A holder of this type will be found a very useful adjunct to any toolroom, and is adaptable to a variety of conditions. A series of bushings can be made to take different diameters of round stock, and tools may be quickly made to suit almost any case. Obviously, adjustment for diameters is made by the cross-slide. Rigidity and adaptability are points in favor of this device.

Adjustable Boring Tools for Jig Work

Fig. 2 represents two styles of adjustable boring tools used mostly for boring small shallow holes or jig bushings. These tools are capable of fine adjustments but are not suited for any kind of heavy cutting. The upper part of the illustration shows how tool *B* is used for boring a part of the bushing *A*, which is held in chuck jaws. The body of the toolholder *H* is made of steel and is turned down and tapered at

J to fit the tailstock spindle. The adjustable swivel *D* is pivoted on the shouldered screw *E*, and is adjusted by the two headless set-screws *F* and *G*. The tool *B* is of round section and fits the end of the swivel, where it is held in place by the two screws *C*. The end of the tool is bent over for the purpose of clearance. A tool of this kind is very convenient and is easily adjusted for diameters within its capacity. It is not adapted to deep holes, but can be made up in several sizes so that it will handle fairly large work.

The lower part of the illustration shows another tool of somewhat similar construction, which is designed for the same purpose as the other. The body is of steel and the shank *T* is turned taper to fit the tailstock spindle. The forward portion of the body *R* is cut out to receive the swivel *N*, which pivots on the screw *S*. The tool *M* is of round section, bent over at the end, and it is held in place by the two screws *O*. One adjusting screw *Q* is all that is required in this tool, as the coil spring *P* takes up lost motion and prevents drawing in. This tool is not as rigid as the one previously referred to, but the spring makes adjusting much quicker, as only one screw is needed. A number of tools of this type, and of various sizes, were made for tool-room use in a large automobile factory and were used on the greater part of the jig work.

Boring Tools for the Horizontal Turret Lathe

Boring tools which are required for use on the horizontal turret lathe are of many forms and their design is somewhat dependent on the type of machine to which they are to be attached. On machines having no transverse movement to the turret slide, the tools are nearly always designed for straight boring, while on the other types of machines, *i. e.*, those having transverse movement, the design is frequently made in such a way that the tools can also be used for facing operations. The form of the turret itself also influences the design to a certain extent, for it is evident that a flat turret would require a different type of tool-holder than one of the vertical face variety.

Single-point Starting Tool for Taper Holes

The work *A* shown in Fig. 3 is a malleable iron automobile hub with a cored taper hole which runs out of truth very badly. Therefore it was necessary to design a starting tool of the single-point variety in order to generate a true running hole, so that the subsequent tool would start properly without being influenced by the wobble of the core. This tool and tool-holder are very simple, the tool itself being a piece of round high-speed steel bent over on the end and ground to cut a diameter a trifle smaller than the large end of the tapered hole. The holder *E* is a piece of machine steel of cylindrical shape, which is ground on the outside to fit the turret hole and on the inside to fit the shank of the tool *B*. Two set-screws *D* are used to hold the tool in position. It will be noted that the end of the cutting point is ground very nearly square so that it will not ride up on the scale. The tool is not made for continuous boring but is merely used to generate a true hole for a short distance into the cored portion of the hub.

Boring and Facing Tool for a Flat Turret

An example of a boring tool which is also used for facing out a pocket on a turret lathe having a flat turret is shown in the lower part of Fig. 3. This tool is of the "shovel nose" type and its cutting action is rather hard on account of the bluntness of the nose and the amount of stock which it removes. The work *F* is a machine steel forging and the shoulder is not recessed at all in the blank. The tool *G* is of rectangular section and it is forged and ground on the cutting end to the shape shown. The tool-holder *H* is supported by the steel bracket *J* which is fastened down on the turret face by screws *L*. The slots *K* are T-shaped and permit various settings and combinations of tools to be made.

Fig. 4 shows a very simple type of single-point adjustable boring-bar for machining the bushing *A* (see upper part of the illustration). Although this bar is simple in its construction, there are several important points in design which should be carefully noted. The bar *E* is of a low grade of tool steel and is hardened and ground to fit the turret hole. The reason for making the bar of tool steel is simply to obtain all the rigidity possible and thereby obviate chatter. The tool *B* is of round section and is put through the bar at a slight angle, being held in position by the two screws *C*. A backing-up screw *D* permits careful adjustment to be made. The bar is cut away where the tool comes through to provide chip clearance, but it is cylindrical on the end except in this one place. By making it this way, it is found an easy matter to use micrometer calipers across the bar and tool as indicated at *F*, so that accurate settings may be readily made without resorting to "cut-and-try" methods. It is very bad practice to bevel the end of the bar at *G* and put the holding screws through at this point, because a calipering point is sacrificed by so doing. A simple formula is here given for setting tools of this type for turning a given diameter:

Let F = required calipering distance for a given size hole;
X = diameter of the bar at the end where the tool is;
Y = diameter of the hole to be bored.

Then

$$F = \frac{X + Y}{2}$$

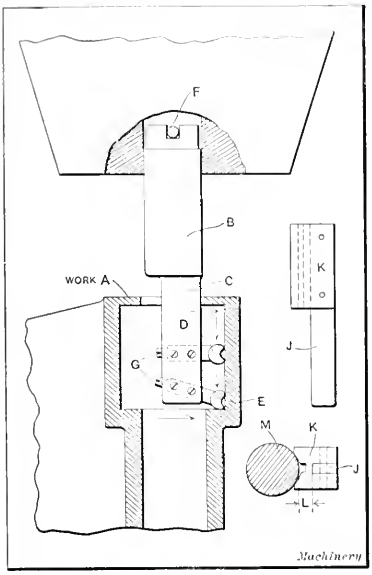

Fig. 6. Bar for Undercutting, Facing and Boring in the Vertical Turret Lathe and Gage used in setting Tools

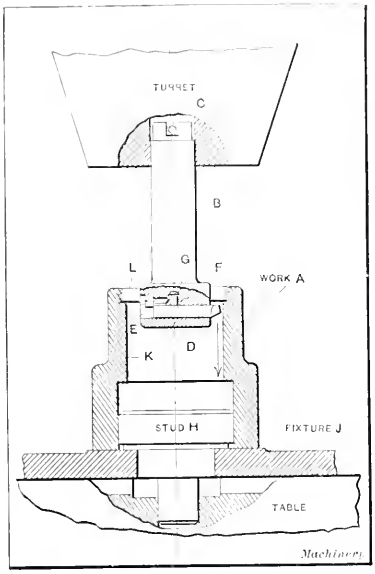

Fig. 7. Bar equipped with a Set of Interchangeable Cutters for Boring and Reaming

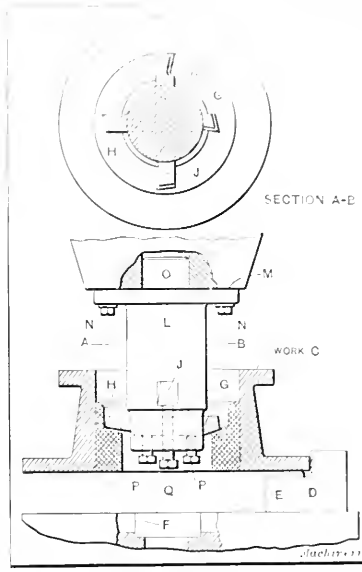

Fig. 8. Bar with Four Cutters set at Different Radii for removing Considerable Stock in One Cut

This formula will be found useful for setting tools very close to the desired diameter, although the spring of the bar will cause slight variations and the amount of stock which is to be removed also makes some difference.

The lower part of Fig. 4 shows a boring tool of an entirely different type. The cutter is double-ended, and a bar of this sort is often used for removing stock rapidly. Although it is a faster cutting tool than a bar having only a single tool or cutting point, it cannot be depended upon to produce a hole which is absolutely concentric with other surfaces machined at the same setting. The work *A* is the same as in the upper part of the illustration, and the bar *B* fits the turret hole. It is flattened slightly on two sides at points *D*, and a rectangular slot contains the cutter *C* and the wedge *E*. It will be noted that the cutter is shouldered so that it is a close fit at the points *D*. Tools of this type cannot be ground radially without changing their diameters, but this is seldom necessary as the cutting edge is at the forward end. A land of about 1/8 inch is usually left just back of the bevel, and the cutter can be ground back to this point without changing the diameter. Beyond this, however, there is a slight back taper for the sake of clearance, so that the life of the cutter does not extend beyond it.

Boring-bar with Provision for Cutting Lubricant

On certain classes of work it is very difficult to supply the cutting points of the tools with sufficient lubrication to make them thoroughly efficient, when the regular supply system is used. Some method must be devised, therefore, to direct the flow to the point or points where the cutting action takes place. An example of a bar arranged to carry the lubricant to inaccessible tools is shown in the upper part of Fig. 5. The work *A* in the chuck jaws is an automobile hub of malleable iron. It will be noted that the portion bored by the forward tool *C* is in such a position that it cannot be reached for lubricating purposes in the ordinary way, but the rear tool *D* can easily be taken care of. The boring-bar *B* is of a low grade of tool steel and fits the turret hole at the rear end; the forward end *J* is a running fit in the chuck bushing *L*. A telescoping oil supply tube *K* enters this end of the bar and is supplied with lubricant from the rear end of the spindle. The hole in the bar at *H* leads the fluid directly onto the face of the cutting tool *C*, thus insuring constant lubrication at this point. The two tools are held in place by the screws *E* and *F*, and they are provided with means of adjustment in the backing-up screws *G*. The writer has used bars of this type in a number of cases with very gratifying results.

Fig. 5 (lower illustration) shows a very different condition, in a multi-cutting boring-bar for generating a series of true holes in the bronze artillery hub *A*. The finished hole is tapered but a starting bar was used in order to prepare the hole properly for the taper tools which followed it, so that they would not be influenced by the irregularities of the cored hole. In this case the turret lathe was one of the flat-turret variety, and provision was made for lubrication through the hole *C* in the turret face. As the turret indexed to the proper position, this hole came directly over another in the slide, which, in turn, was connected with the lubricant pressure supply system, thus allowing the liquid to pass up into the body of the tool-holder. The boring-bar *G* is turned down at the rear end to fit the tool-holder *B*, and has an annular groove *E* which is packed with felt to prevent the escape of lubricant. A shoe *D* is forced down on the bar by the two screws *K* and prevents the bar from turning. The hole *H* in the bar is drilled from the forward end and is tightly plugged so that this end remains closed to prevent the lubricant from passing through. A groove is cut in front of the tools *J*, *M* and *L*, as shown at *J*, and this allows the fluid to flow directly onto the faces of the tools. The end of the bar is piloted at *O* in the bushing *N* which is fixed in the chuck body. An arrangement of this sort has also proved successful in a number of instances.

Bar for Undercutting, Facing and Boring in the Vertical Turret Lathe

A very difficult condition for which to design tools is shown in Fig. 6, as the work itself requires rapidity of handling and is a steel casting weighing about 300 pounds. Only a part of the piece is shown at *A*, but it will readily be seen that it is necessary to make the bar in such a way that the tools can be used to do all the cutting indicated by the arrows; *i. e.*, undercut the upper flange, double-bore the interior, and face the lower shoulder. As the fixture on which the work was held was of the indexing variety and was very much off center, it was not expedient to run at high speed. Therefore, the double boring was of assistance in increasing the production. It will be noted that the hole through which the tools pass is of small diameter, which makes the problem still more difficult. The shank of the bar *B* fits the turret hole at its upper end and is slotted so that the pin *F* in the turret will act as a driver. (This feature is patented by the Bullard Machine Tool Co.) The lower part of the bar is eccentric to the shank in order to obtain the necessary clearance when the tools are in action. Even the tools themselves are considerably out of the ordinary in that they will cut in two directions. The upper tool *D* is used for undercutting the flange and also for boring, while the lower tool *E* is used for facing the lower shoulder and partially boring the interior. Both these tools have backing-up screws *G* and are held in place by the headless set-screws.

As it was necessary to set these two tools so that they would cut approximately the same diameter, the gage shown at the right of the figure was made to assist in the setting. The V-block *K* was slotted to receive the steel strip *J* so that distance *L* would measure the correct distance from the bar shown in section at *M*. It is obvious that the gage could be placed against the bar so that tools could be set out the right amount by means of the backing-up screws. This bar gave fairly satisfactory results although some trouble was experienced with chips, as there was considerable stock to remove. There was likewise a slight tendency to chatter when using a heavy feed, but this was remedied by careful grinding to make the cut as easy as possible. It must be remembered that the conditions were about as awkward as they could be, and the lack of room made it necessary to cut down the bar to such an extent that it was hardly heavy enough for the work. Taken as a whole, however, the action was satisfactory for a roughing tool. It was not used for finishing cuts.

Slip-cutter Bar for the Vertical Turret Lathe

The steel hub shown at *A* in Fig. 7 is held on a special fixture, located by the previously bored and reamed hole which fits the stud *H*. The hole *K* has been rough-bored in the first operation, but enough stock has been left for the final finishing so that it may be finish-bored and reamed and part *L* threaded at the same setting. This type of bar is the product of the Bullard Machine Tool Co., and is designed especially for use in their machines. It is a combination boring- and reaming-bar, and the cutters are of the "slip" variety. One bar can be furnished with a set of cutters for the various sizes of holes within its capacity. A full set of cutters for any one size of hole consists of chamfering, rough-boring, finish-boring, rough-reaming and finish-reaming tools. The first three of these are of square section, carefully ground to fit the broached hole *D*. The rear ends of these tools bring up against the shoulder of the screw *E*, which acts as a stop. The fit in the hole is such that tools can easily be put in and taken out with the fingers.

The two reaming cutters are used in the rectangular hole *F* which is at right angles to the other hole; these tools are allowed to float so that they follow the hole generated by the boring tools. The action against the reaming cutters is in an upward direction, and comes against the hardened steel plug *G* which is inserted in the bar. The bar *B* is of special steel and is slotted at the upper end to fit the driving pin *C* which is located in the turret. Bars of this type have a number of advantages, one of which is that only one turret hole is occupied; other advantages are the cost of maintenance, and the adaptability of the bar with its series of cutters to handle a number of different sized holes. The cost of large sizes of reamers of the fluted type is considerable, while a flat reamer such as that used in this bar is inexpensive. It may be noted that the pressure or thrust of the cut is all

that holds the boring tools in place, so that trouble would be experienced if a cored pocket were to be encountered. This is provided for by a detent screw in the end of the bar, which prevents the tools from coming out. This screw can be put in any time if it is found necessary.

Multi-cutting Bar for the Vertical Turret Lathe

An example of a bar designed to remove a large amount of stock in a very short time is given in Fig. 8. The work shown at *C* is a steel boiler nozzle which is forged, and a 5-inch hole punched in it before it is machined by the vertical turret lathe. The finished hole is 8 inches in diameter and it was desired to remove the surplus stock as rapidly as possible. Accuracy in the diameter of the hole was not essential. The bar *L* is a steel forging which fits the turret face at *M* and is held to it by the screws *N*. The stem *O* is used to center the bar in the turret. Two rectangular holes are broached through the body of the bar, at right angles to each other, and these receive the high-speed steel cutters shown. It will be noted that these cutters are so proportioned that they remove the stock in a series of steps, each tool extending beyond the preceding one and also above it about 1/8 inch.

The section taken at *A*—*B* shows the manner in which the tools extend beyond each other, and the lower view illustrates the cutting action of the tools. One end of the first tool *G* makes the first step, while the other end *H* makes the second. In like manner one end of the upper tool *J* makes the third step while the other end *K* takes out the remainder. The two screws *P* hold the first tool in place, while the other is secured by the screws *Q*. It will be noted that the work is held in jaws *D* and is supported on buttons at *E*; the height above the table is great enough to allow the end of the bar and the set-screws to go through far enough to finish the cut. Regarding the upkeep of these tools, attention is called to the fact that they may be pushed backward or forward to compensate for wear and distribute the cut. For roughing purposes requiring rapid removal of stock and rapid cutting, a bar of this sort has proved very successful, but it is not recommended for work requiring great accuracy.

Other Types of Boring-bars

There are several bars on the market which are adjustable for various diameters by means of micrometer screws and taper wedges. These are useful for many purposes but space will not permit a detailed description nor has it been the writer's purpose to deal with the many varieties but rather with representative types. Special bars for many purposes, porcupine bars and cutter heads of various kinds, I have not

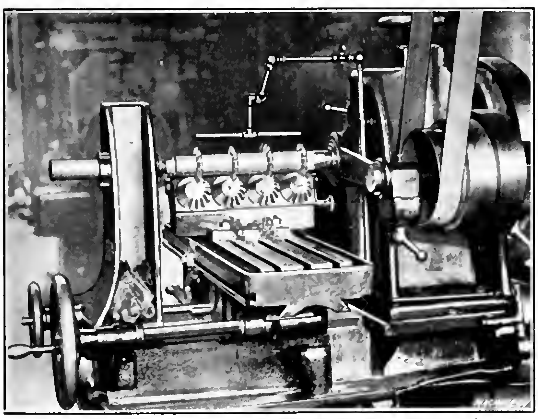

Fig. 1. Multiple Fixture for roughing Teeth of Bevel Pinions, applied to Horizontal Milling Machine

attempted to describe, for these are not single-point boring tools. Neither has mention been made of boring tools such as are used in fixture work on the horizontal boring machine, for these are found in every tool-room, in all shapes and sizes.

In several of the illustrations it may be noted that the tools are shown in a plane parallel with the rotation of the turret. This has been done simply because the details are more clearly apparent when shown in this way. Greater accuracy is obtained by setting the tools in a plane perpendicular to the turret rotation, as previously stated.

MULTIPLE FIXTURE FOR ROUGHING THE TEETH OF BEVEL PINIONS

BY C. BOELLA*

A great many small bevel gear pinions are used as "satellites" in the manufacture of differential gearing for motor cars. In order to increase the production of these pinions and lower the cost, the device shown applied to a horizontal milling machine in Fig. 1 was designed. By using this fixture, gear blanks can be roughed out at a single cut; they are then finished more rapidly by a second operation in a regular bevel gear cutting machine.

The cutter arbor is fitted with four properly spaced cutters. The fixture, which is securely bolted to the milling machine

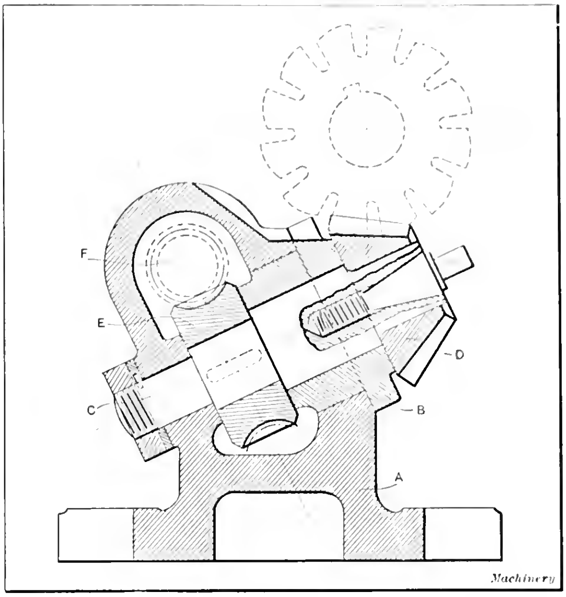

Fig. 2. Cross-section of Multiple Fixture

table, has four small spindles, each holding a bevel pinion at such an angle that the cutters will rough out the teeth at the depth required. When a tooth has been milled in each blank, the table is withdrawn and, by a complete turn of the handle seen on the right side of the fixture, the four pinions are indexed simultaneously one tooth. Then another cut is taken and this operation is repeated until all the teeth are roughed out.

Fig. 2 is a section of the device. There is a hollow base *A* having four plates *B* each fitted with a spindle *C*. The spindles have expansion collets to hold blanks and they are indexed by the worm-wheels *E* which mesh with worms *F* that are turned by the handle previously referred to. The worm-wheels have twenty-eight teeth and the worm is double threaded so that each complete revolution of the worm causes the pinions to rotate 1/14 turn, as they must have fourteen teeth of five diametral pitch. The indexing handle is fitted with a spring knob, the end of which can engage a hole located in the base, thus insuring an exact division. These pinions are made from 5 per cent nickel steel. The time required for each cut is one minute ten seconds, four pinions being completely roughed out in about sixteen minutes. The machine is operated by the same man who runs the gear shaper used for finishing the teeth.

* * *

For an anti-friction metal that can be subjected to pressures up to about 400 pounds per square inch, the *Foundry* recommends the following composition: Lead, 85 per cent; antimony, 10 per cent; and tin, 5 per cent. For pressures exceeding 400 pounds per square inch, the following alloy will prove satisfactory: Tin, 85 per cent; copper, 5 per cent; and antimony, 10 per cent. This alloy can be used safely for pressures up to 1000 pounds per square inch.

ENGINEERING QUALIFICATIONS

In three months the engineering colleges of the country will be turning out a few thousand graduates to find places for themselves in the industrial world, and many of them with no practical experience are likely to believe that the mere act of graduation opens the road to success for them. We believe that no greater service could be rendered young men fitting themselves for industrial work than for their teachers to impress them, while at college, with the fact that many other qualities are necessary for success in the engineering field besides mere ability to pass their "exams" successfully. The knowledge and training obtained at school and college are important, but there are other qualifications that count for more in later years. Two of these are reliability and thoroughness; another is tact; others of the greatest value are executive ability, push and initiative; while still another is real enthusiasm and love for the work in hand; and, last but not least, health—moral, mental and physical. One engineer, in stating his requirements for subordinates in terms of percentages, said that he would be satisfied with fifty per cent of technical knowledge and analytical ability, provided the remaining fifty per cent was divided into twenty per cent tact and ability to cooperate, and thirty per cent push, initiative and originality. This combination makes for a well balanced personality, to whom success in the engineering field is well-nigh certain.

Reliability in an engineer should not be confused with what is commonly called "honesty," which is merely the inclination to do one's best. Reliability is a faculty which requires constant training, until mere inclination has been developed into ability to get out of oneself the very best possible from one's mental and physical qualifications. One phase of reliability is the ability to carry out definite instructions. This cannot be done without continual training of the mind, and the lack of such training is shown by the inability or unwillingness of many people to carry out a given piece of work according to given instructions. Another evidence of reliability is a willingness to acknowledge promptly one's inability to carry out a certain piece of work in a prescribed way or within a specified time limit. Paradoxical as it may seem, a definite statement of what he *cannot* do may often be the first thing to attract favorable attention to a young man.

GETTING IN TOUCH WITH THE FOREMAN

Some time ago a manufacturing concern made for stock a number of parts consisting of steel castings bushed with a well-known bearing alloy. The shafts were required to make but a short oscillatory movement in the bearings, and the foreman instructed the fitters to give them a clearance of 0.001 to 0.0025 inch, the diameter being 1½ inch. The parts were ordered out for a repair job a few months after and the workmen discovered that the shafts would not enter the bearings. An investigation showed that the diameter of the holes was 0.005 inch less than the shaft diameters.

The foreman was called to account, and while he was positive that the parts had been fitted with sufficient clearance, he was unable to explain satisfactorily why the change had taken place. A letter to the editor describing the case brought an explanation clearing the foreman of blame and saved his job.

The cause of the trouble was that the alloy bushings had been assembled in the steel parts by pressure. The alloy used is one having excellent characteristics as a bearing metal, but though very strong, it "flows" slightly when subjected for a long time to heavy pressure. The result was that the bushings contracted in diameter, causing the closing of the holes and thus making them too small for the shafts that were originally fitted in them.

The makers of the alloy are fully aware of this characteristic, and issue directions to the effect that when used for bushings it should not be assembled by pressure. Instead, it should be made a close shove fit and held in place by non-bottoming set-screws. When properly fitted according to directions, it gives perfect satisfaction.

This brings us to the practical difficulty met with by some concerns in getting their products treated as they must be treated in order to yield the best results. They deal with purchasing agents who, in some cases, having little appreciation of technical matters, are careless in transmitting important specifications to the men in the shop. Manufacturing concerns should find it to advantage to encourage free intercourse between the representatives of concerns furnishing them supplies and the men responsible for results, especially when the treatment is out of the ordinary. The free circulation of catalogues and circulars among the men has been found advantageous. In some places this literature forms part of a regular circulating library. MACHINERY will gladly publish important details of practice pertaining to new products in its field and invites all manufacturers to use its columns freely as an educational means to reach the foremen and machinists handling them.

* * *

THE OBJECT OF TEMPERING STEEL

In examining recently a great number of books and articles on the subject of tempering steel, we found that almost invariably the authors stated that the object of tempering was the softening of the steel. They said that steel, when heated to the required hardening temperature and quenched, became too hard, and that therefore it was necessary to draw the temper in order to soften the steel so that it could be used for the purpose for which it was intended. This is an erroneous statement which seems to be accepted by the majority of mechanics, because they fail to distinguish between hardness and brittleness, two entirely different qualities. Hardened steel is tempered in order to make it less brittle, but unfortunately the tempering process also softens the steel to some extent. If it were possible to temper steel so as to produce greater toughness and at the same time retain the extreme hardness, the ideal condition would be obtained. That hardness and brittleness are not necessarily synonymous may be seen in the case of cast iron, which is very brittle but not very hard. On the other hand, there are some alloy steels that may be made very hard and at the same time very tough. The object of tempering steel is to reduce the brittleness; the hardness is simultaneously reduced, but this unfortunately cannot be avoided.

PUNCH AND SHEAR FRAMES

The article "Punching Machine Frames," to be found in another part of this number, is one of the most interesting contributions of a practical nature that has ever been published on this important subject. The author shows the danger of using the commonly accepted method for calculating the design of machine frames of the curved type, and gives a method which can be used without difficulty by any one familiar with the rudiments of the use of formulas. In the deduction of the formulas, the author has made use of calculus, but it is by no means necessary to be versed in calculus in order to appreciate the important facts brought out and profit by the results of the calculations.

Probably many readers of technical journals are deterred from reading certain articles because they find that they contain mathematical treatment of a kind with which they are not familiar. As a rule, this is a mistaken idea, because even if the reader is not able to follow the writer's mathematical proof of his theories, he can nevertheless profit by digesting the results obtained, taking for granted the accuracy of the writer's deductions. Of course the value is still greater to the man who can follow the author through the mathematical treatment, but this is not necessary to understand the article.

In the specific case referred to, the fact that the stresses in machine frames, when calculated according to the more modern theories evolved, may be from two to three times the stresses found by the older methods of calculation, is sufficient to indicate the importance of the subject. It is true that accurate analytical methods that can be easily applied have not as yet been developed, but the method explained in the article referred to is so nearly correct in the light of modern investigations that it might well be adopted as a standard for curved machine frame calculations until a better and simpler method giving the same accuracy is proposed.

* * *

THE SMALL POWER PLANT

The power problem confronts every factory manager in one form or another. Small shops in cities can *sometimes* buy electric power cheaper than it can be generated with small power units, but unfortunately this is not always true. The fact that the large power companies cannot or will not uniformly furnish electric power at rates cheaper than it can be supplied by small private plants is a standing reproach to the good sense and business management of these so-called public utilities. Manifestly, the large power plant managed on scientific principles, generating steam in boilers fired with the cheapest coal and utilizing it in turbines of great size and high efficiency, can produce a kilowatt at the plant at a far lower price than can the small concern. The overhead charges are less proportionately and the efficiency of production much higher. Many manufacturing plants have in self-defence put in power plants in order to get reasonable rates from the electric companies. It becomes an idle investment but a necessary one, if reasonable rates are to be had.

But aside from urban conditions are those where power must be generated at the shop with small units. What shall the prime mover be? The steam engine and boiler is expensive to maintain. A fireman and engineer must be in constant attendance. A gas engine using illuminating gas is likely to make big gas bills. Small gas producers are successful, but require more technical knowledge to operate satisfactorily than is available many times. The gasoline engine is out of the question now with gasoline at twenty to twenty-five cents a gallon. The kerosene engine is far more economical, but of yet greater economy is the Diesel engine. This motor burns fuel oil, distillates and other cheap liquid fuels. The engine is simple in construction, but must be well built to give long service. It is highly economical, the thermal efficiency running above twenty-five per cent and the fuel consumption being as low as one-half pound of oil per indicated horsepower. The high compression necessary in the Diesel engine is the greatest disadvantage. It makes necessary a power starting device for even the smallest units, but compressed air furnishes the means for it without serious complications.

THE ADVANTAGES OF MANUAL TRAINING HIGH SCHOOLS

BY FRANCIS L. BAIN*

The demand for the teaching of manual arts in the high school is founded upon the need of the pupil. It has grown out of the dissatisfaction of the people with the narrow, one-sided curriculum of the secondary school. The old measure of culture, training in the classics, has given way to broader lines of development. Today that man is considered cultured who can ably utilize the forces of civilization of his own time, not of a few centuries back.

We have come to realize that the disciplinary value of work which makes for vocational training may be greater than that which comes from the so-called cultural studies. The skilled artisan contributes more to the prosperity of the country and the uplift of his community than the college graduate without the adaption to any line of work. The one goes straight to the mark; the other flounders hopelessly in trying to find himself and his work. The world never needed leaders more than now—leaders of education, of skill, of honesty and of courage, and real leadership is as necessary in the trades as in any department of commercial activity.

The study of the manual arts in the high school has four distinct values:

1. It helps the student to find himself. Nearly two-thirds of the pupils in our public schools leave school at the age of sixteen or earlier. This is due to lack of inclination to study further or the necessity of bread-winning. They usually enter and remain in the ranks of unskilled labor, at the lowest wages and in most unstable positions. These pupils need the stimulus of courses that lead to quick or greater efficiency in wage earning. Many students have no definite aim at entrance to or even at graduation from high school. Chance determines their vocation, and usually chance makes a mistake. Manual arts help the uncertain boy to determine his bent and to choose more intelligently his vocation.

2. It enables the high school to adapt itself to the needs of the community. That high school is best that best meets the needs of its immediate locality. Communities may be divided into commercial, manufacturing and agricultural, and vocational courses may be so shaped as to meet the needs of any or all.

3. It vitalizes the teaching of mathematics and science by showing and using their practical application. Algebra and geometry, physics and chemistry no longer appear simply as studies in a course, but they become a means to an end; as useful tools, they provide studies of living interest.

4. It furnishes direct vocational training. A high school course in manual arts does not aim to make a foreman or a journeyman workman of a boy. Such work must be left to the shop. The school should be able, however, to turn out a student who ranks with advanced apprentices, and whose academic and technical training has been such that, if he has otherwise the right qualities, he can forge rapidly to the front in his chosen trade.

Work in the manual arts, undertaken for vocational training, should not be undertaken without well equipped shops and skilled special teachers. To play with manual arts is to invite contempt for them at the start. It may not be necessary or advisable to attempt many lines of work, but what is undertaken should be done thoroughly and as nearly as possible under shop conditions. Every stroke should count toward definite construction. There is more mental discipline, more technical skill, and far greater interest, in making something of mechanical value, than in the doing of "exercises" or in playing with tools. Work must be the key-note of all the arts.

Technical courses should have all the time possible given to their distinctive work. A few hours per week will not develop skill, vocational or otherwise; all the time that can be given will not develop much; that must come from the experience of the work-shop.

All the attendant academic studies, English, mathematics,

* Director, Department of Technical and Manual Training, Everett High School, Everett, Mass.

science and drawing can be made to bear directly upon this technical work, and so be vitalized, because the pupil appreciates their use and application.

In all the manual arts courses the work should be so arranged as to give each student in junior and senior years opportunity to choose between additional shop and academic work and to specialize along chosen lines. This allows the student to fit himself for higher technical schools, if he so desires, or to gain additional skill in wood-working, forging or machine-shop practice.

Manual arts is not an educational cure-all. It will not revolutionize the work of high schools. Pupils will not all flock to its study. It will be subject to many of the same defects and limitations as other courses and it will have additional limitations of its own; but it will spell opportunity, educationally and vocationally, to a large class of students who have hitherto received too little attention.

TAP DRILL SIZES

BY F. W. GATES*

In the January number of MACHINERY, Albert A. Dowd gives an interesting formula for determining the size of drill to use before tapping. Boiled down, he advocates 80 per cent depth of thread in the nut for machine tapping and 90 per cent for hand tapping. In this connection, some of the results obtained in the Wells Brothers Co.'s experimental laboratory may, perhaps, prove of interest.

Using U. S. standard threads, an ordinary cold-punched nut even, reamed out until it has but 50 per cent depth of thread, will not strip. Neither will it strip the tops off the bolt thread—*the bolt always breaks.* In fact, we have never found a metal tough enough to strip a nut thread having 50 per cent of full depth. If, in tapping, we produce nut threads which are stronger than the bolt, with a reasonable margin of safety, nothing is gained by attempting to make fuller or deeper nut threads. Such attempts only make unnecessary waste in tapping operations. We have demonstrated that a full depth of thread in a nut is *practically* no stronger than 75 per cent depth of thread. We have also demonstrated that 75 per cent depth of thread is only 20 per cent stronger than 50 per cent depth of thread. (Theoretically it might seem to be 50 per cent stronger.) From 75 per cent depth of thread, the power required to tap rapidly increases as a full depth of thread is approached.

The breaking strain of the average ½-inch, 13 U. S. standard commercial tap as found on the market is approximately 700 inch-pounds. Tapping common cold-punched nuts with *new* taps, the *average* power required is as follows, using mineralized lard oil as a lubricant:

75 per cent depth of thread...... 199 inch-pounds
90 per cent depth of thread...... 365 inch-pounds
100 per cent depth of thread...... 575 inch-pounds

Therefore, in attempting to tap out a full depth thread, the strain is too close to the breaking strain of the tap to be advisable. As the tap wears and becomes dulled, the power required fully equals the breaking strain, and "away goes the tap." There is practically no margin of safety. But in tapping 75 per cent depth of thread there is a factor of safety of practically 3.

On a ½-inch tap the difference in cut between 75 per cent and 90 per cent depth of thread is only 0.0075 inch; yet, under the favorable conditions given, the power required to make the deeper thread is nearly double. Tapping dry, or using machine oil, the ratio of increase in power is very much greater than that given above.

Inasmuch as with 75 per cent depth of thread the nut is stronger than the bolt—so much stronger as to break the bolt without even "starting" the nut threads—and, inasmuch as 75 per cent depth of thread possesses practically all the strength of a full depth thread, one can readily see that the 75 per cent depth is much preferable to the full depth. For instance, grit or dirt, in the case of 75 per cent depth, works down to the root of the bolt threads and gives no trouble. In a full depth thread it is forced into the walls, creating unnecessary friction and destroying the smoothness of the threads.

For these and many other reasons, we have for some time been advocating drill sizes for taps which yield 75 per cent depth of thread in the nut or tapped hole. However, as commercial drills do not exactly meet these figures, by using the next larger commercial size, good results are obtained. The use of these sizes of drills is proving a revelation in tapping economy to many shops.

TABLE OF TAP DRILL SIZES

Nominal Size, U. S. S.	Root Diameter, U. S. S.	Drill Sizes Recommended		
		For 75 Per Cent Thread, Exact	Next Largest Commercial Size: In Decimals of an Inch	Next Largest Commercial Size: Commercial Designation
1/4	0.1850	0.201	0.201	No. 7
5/16	0.2403	0.258	0.261	G
3/8	0.2936	0.314	0.316	O
7/16	0.3147	0.368	0.368	U
1/2	0.4001	0.425	0 4330	11 mm.
9/16	0.4542	0.481	0.4843	31/64 inch
5/8	0.5069	0.536	0.5468	35/64 inch
11/16	0.5700	0.599	0.6093	39/64 inch
3/4	0.6201	0.652	0.6562	21/32 inch
13/16	0.6831	0.715	0.7187	23/32 inch
7/8	0.7307	0.767	0.7677	19½ mm.
15/16	0.7929	0.829	0.8437	27/32 inch
1	0.8376	0.878	0.8858	22½ mm.
1 1/8	0.9394	0.986	1.0000	1 inch
1 1/4	1.0644	1.111	1.1220	28½ mm.
1 3/8	1.1585	1.213	1.2187	1 7/32 inch
1 1/2	1.2835	1.338	1.3386	34 mm.

Machinery

It is a fact, readily demonstrated, that 90 per cent of commercial taps break before they have been used long enough to require sharpening. This tremendous breakage is seldom the fault of the taps. Strains are often brought to bear upon taps which no metal can possibly withstand. The most important cause is the use of too small holes. It is not by any means uncommon to find taps used in holes which are smaller than the root diameter of the tap.

It would be a good thing if the manufacturers of both taps and drills would get together and publish uniform tables of drill sizes for tapping. At present there is no agreement, and the sizes recommended vary all the way from 75 to 101 per cent depth of thread. For instance, in one very commonly used table the drill size recommended for ½ inch, 13 U. S. standard, yields 94 per cent depth of thread. On 9/16 inch, the next larger tap, a size is recommended which yields 101 per cent depth of thread. "Somebody" started it, and custom continues it without questioning its advisability.

Just by way of confirming the conclusions we had reached through our own tests, we recently took a poll of leading manufacturing concerns throughout the country, from makers of very fine machine work to farm implements, including electrical fixtures, calculating machines, commercial bolts and nuts, harvesting machinery, etc. With one exception, their practice is to use drills which yield 75 per cent depth of thread in the nut, or less; one very prominent shop uses 50 per cent depth of thread in tool steel with good results. We therefore earnestly advocate 75 per cent depth of thread in the nut as a maximum where standard thread systems are used (such as U. S., S. A. E. and A. S. M. E.), because it gives all the strength of a deeper thread and brings about a much needed economy in tapping operations.

* * *

HIGH-GRADE BEARING METAL

A high-class bearing metal is prepared as follows: Melt 7 parts copper at as low a heat as possible, then add 25 parts antimony and 200 parts tin. This mixture is cast in iron ingot molds. It is then re-melted and to each five pounds of the ingots is added eight pounds of tin. This second alloy is cast in bars to suit the requirements.

* Advertising Manager, Wells Brothers Co., Greenfield, Mass.

THE VALVE PROBLEM ON GASOLINE ENGINES*

UNDESIRABLE EFFECTS OF GRINDING THE VALVES AND DESIGNS THAT ELIMINATE THE DIFFICULTY

BY M. TERRY†

What is the proper size of valves for a gasoline engine of a given bore and stroke? What is their proper lift? These, perhaps, are among the most puzzling questions which confront both mechanics and designers, but the vast majority do not even understand the principles underlying the correct solution of the problem. Not knowing what end to begin with, they invariably fall back on "common practice." Just what common practice is and how it works might be illustrated by an incident which occurred a few months ago. A fellow draftsman who was laying out a new gasoline engine came to consult the writer in regard to several details connected with its design; valve lift was one of them.

"And what would you suggest for the valve lift?" he asked.

"Well," I replied, "that is no easy question to answer offhand; it requires a close study of your engine and, perhaps, considerable figuring." Close study and considerable figuring never did appeal to this gentleman; so, entirely ignoring my reply, he continued:

"Jones Motor Works, on their Model X engine, which is 1/4 inch smaller in bore and 1/2 inch longer in stroke than mine, use 1/4 inch lift; and the Smith engine, which is practically identical with mine except that the stroke is 3/4 inch longer, use 5/16 inch lift. I am going to make my lift 9/32 inch; do you think that will be all right?"

"Well, it ought to be," I replied dryly, fully realizing the uselessness of further argument.

In selecting 9/32 inch for his valve lift he apparently showed excellent judgment, for the chief draftsman heartily approved of his method of procedure. "That's fine," he declared, "but how do you know that Smith and Jones are right?" While the question struck the nail squarely on the head, it was asked more with the object of teasing the man than to seriously question his method.

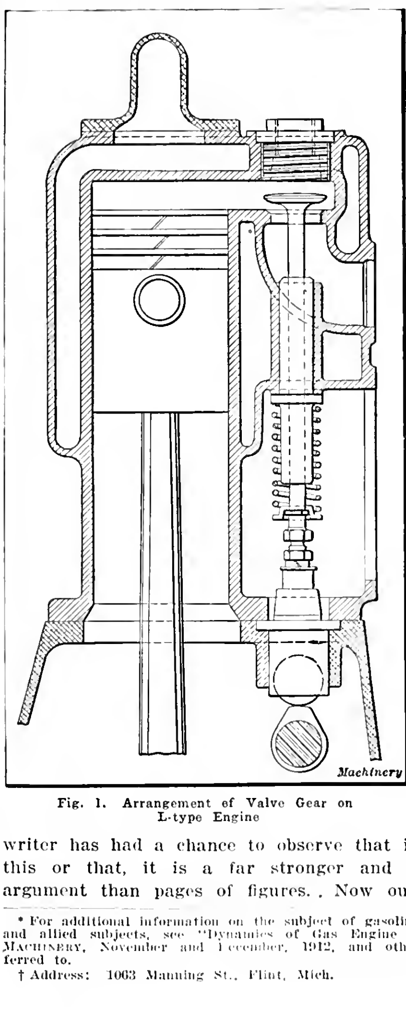

Fig. 1. Arrangement of Valve Gear on L-type Engine

"I do not know whether they are right or wrong," was the reply, "but I do know that their cars sell like hot-cakes."

Time and again the writer has had a chance to observe that if So-and-So does this or that, it is a far stronger and more convincing argument than pages of figures. Now our own firm was by no means a "second-rater," and both the Jones Motor Works and the Smith Motor Car Co. were undoubtedly doing the very same thing with our valve lift.

"Our design follows common practice," said the chief engineer to the general manager in an effort to convince the latter that he had in him a man of safe ideas. This was really a mis-statement; the right name for this sort of thing is the "common practice of designing" and not "designing along the lines of common practice."

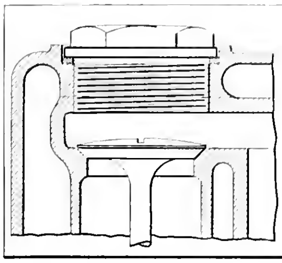

Fig. 2. Enlarged View of Valve Head on its Seat

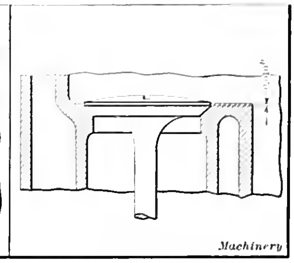

Fig. 3. Result of grinding Valve Seats

Proper Design of Valve Head and Valve Seat

Neglecting for the present the question of valve size and of valve lift, we shall turn our attention to the problem of properly proportioning the valve head and its seat. There is absolutely no theory in connection with this important point; it all hinges on a few practical considerations, and can be easily understood by any man with a mechanical mind. Fig. 1 shows the general arrangement of the valve gear on what is known as the L-type engine, and Fig. 2 shows an enlarged view of the valve head on its seat. The design is wrong. As long as the motor is new, no trouble will be experienced, but as soon as the valve seats pit and wear, the owner of the motor is compelled to grind them, and in doing so the state of things shown in Fig. 3 will result. Assuming that the valves now seat 0.010 inch lower than they did when the motor was new, that the valve lift is 0.250 inch and clearance is 0.005 inch, let us see what happens. The total valve lift, of course, is not changed, as it is governed entirely by the shape of the cam. The effective valve lift, *i. e.*, that part of the total lift during which the gases are free to pass in and out of the cylinder, is now only 0.235 inch—a reduction of 4 per cent. When the motor was new the effective lift was 0.245 inch. This loss of 4 per cent, appreciable as it is, is by no means the end of the story. It will be observed that the exhaust commences later and ends sooner in the stroke; and the incoming fresh charge is similarly affected. The extent of this change of original timing, which is seldom appreciated, will be presently shown.

Let the original timing be as shown in Fig. 4. The base circle of the cam is 1.000 inch in diameter; the roller diameter is 1.000 inch; and the clearance between the valve stem and the valve lifter is 0.005 inch. The writer is assuming a certain amount of knowledge on the part of his readers in regard to the construction and operation of gas engine valve gears. Those who are unfamiliar with it are referred to another article entitled "Dynamics of Gas Engine Cams" published in the engineering edition of MACHINERY for November and December, 1912, where the problem was thoroughly discussed and the relation between the clearance and the clearance angle was fully explained. In Fig. 5, the cam and its roller are shown in position where the latter is just on the point of rising. Therefore:

$$oc = 1.000 \text{ inch.}$$

At c_1 the backlash is closed and the valve is just on the point of rising. Therefore:

$$oc_1 = oc + \text{backlash} = 1.000 + 0.005 = 1.005 \text{ inch.}$$

c_2 is the point where the effective lift of the valve commences, *i. e.*, where the gases are first commencing to leave

* For additional information on the subject of gasoline engine valve gears and allied subjects, see "Dynamics of Gas Engine Cams," published in MACHINERY, November and December, 1912, and other articles there referred to.

† Address: 1063 Manning St., Flint, Mich.

or enter the cylinder, as the case may be. According to our assumption:

$$oc_2 = oc_1 + 0.010 = 1.005 + 0.010 = 1.015 \text{ inch.}$$

$$\text{Now } \cos\alpha = \frac{1.000}{1.005} = 0.995$$

$$\alpha = 5 \text{ degrees } 45 \text{ minutes}$$

$$\cos\beta = \frac{1.000}{1.015} = 0.985$$

$$\beta = 9 \text{ degrees } 45 \text{ minutes}$$

$$\beta - \alpha = 9 \text{ degrees } 45 \text{ minutes} - 5 \text{ degrees } 45 \text{ minutes} = 4 \text{ degrees.}$$

Thus the inlet and exhaust valves start 4 degrees later and close 4 degrees earlier than they did when the engine was new. This loss, of course, is doubled on the crank circle, since the crankshaft of a four-cycle engine revolves twice as fast as its camshaft. The loss, then, amounts to 8 degrees at opening and 8 degrees at closing of the valves, and the modified timing diagram is as shown in Fig. 6. It will be observed

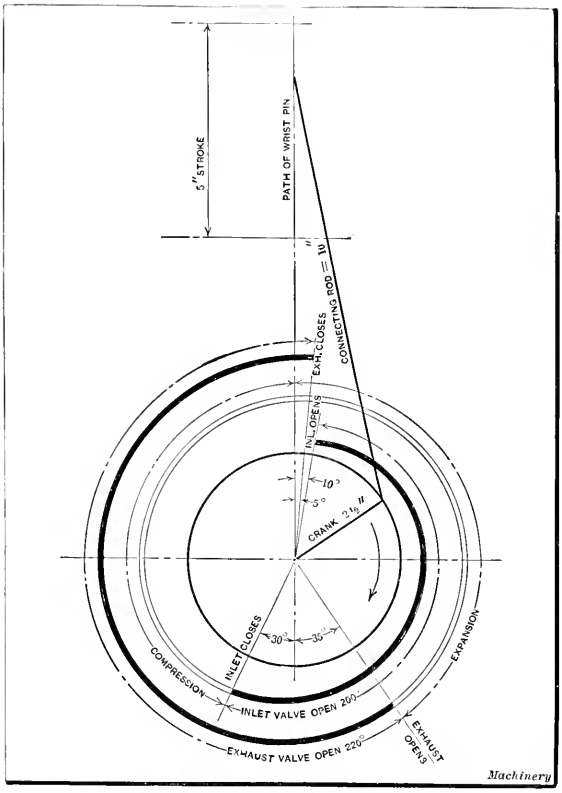

Fig. 4. Diagram showing Original Timing of Engine

that the loss is appreciable, amounting, as it does to $\frac{16 \text{ degrees}}{200 \text{ degrees}}$ or 8 per cent for the inlet valves, and $\frac{16 \text{ degrees}}{220 \text{ degrees}}$ or 7.27 per cent for the exhaust valves. The combined loss due to the shorter effective valve lift and shortened duration of the period of valve opening is shown very strikingly in Fig. 8, which is the time-lift curve of the inlet valve. The area bounded by the curve and the clearance line can be taken to represent the charge admitted to the cylinder when the engine was new, as explained in the article previously referred to. Similarly the area bounded by the curve and the effective lift line represents the charge admitted after the wear of 0.010 inch has taken place. The shaded area represents the volumetric loss which amounts to about 7.65 per cent for the exhaust and 8.5 per cent for the inlet valve; these results were obtained by means of a planimeter. The volumetric loss, as the term is ordinarily understood, occurs only on the inlet or suction stroke; a similar loss, however, which may be termed loss in scavenging action, takes place on the exhaust stroke. Either loss is undesirable, as it results in a falling off of the power developed by the engine.

The preceding discussion will probably account in many cases for the oft-heard complaint that the horsepower of certain automobile engines seems to drop off with their age, in spite of replacing the old, worn piston rings by new ones, and thereby restoring the compression pressure to its original value. The valve seat being comparatively inaccessible, an average repair man is not likely to notice the little ridge formed around it, and of those who would notice it not one in a hundred would realize its significance and attempt to remedy the trouble. As a matter of fact, the trouble in most cases is not very easily remedied, and the reason for it is not far to seek. The plug above the valve (Figs. 1 and 2) is only a plug; it is simply put there to close the hole formed in order to permit machining the valve seat and assembling the valve. Since the performance of any gasoline engine depends

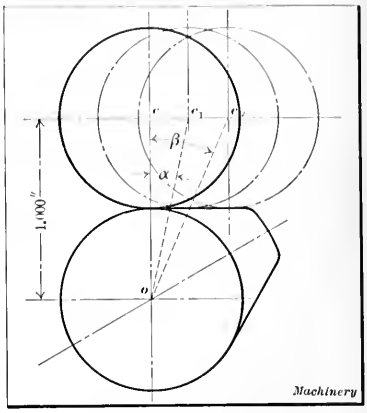

Fig. 5. Valve Lifting Cam with Roller ready to rise

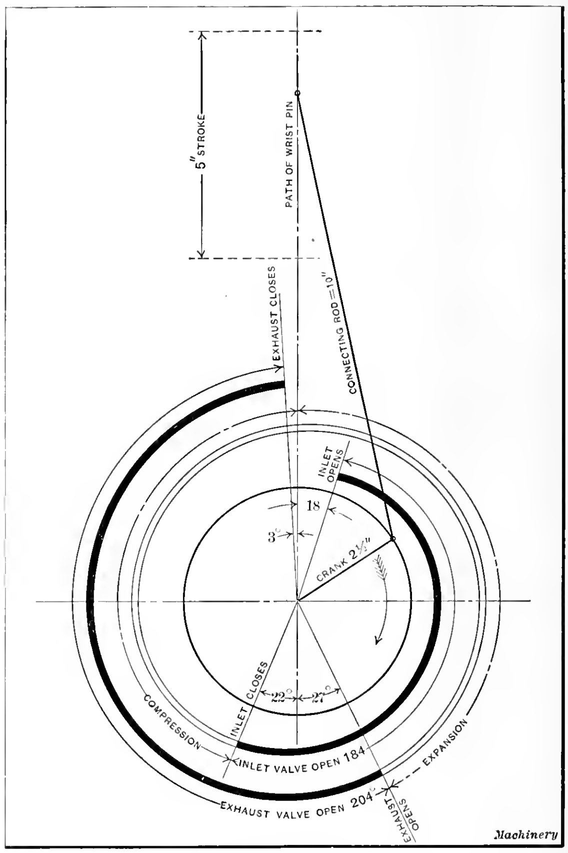

Fig. 6. Modified Timing Diagram showing Result of grinding Valve Seats

to a great extent upon the size of its valves, the latter are invariably made as large as possible, and in the construction shown in Fig. 2 the valve head is made only a few thousandths inch smaller than the threaded hole above it. Evidently the tool for chamfering the valve seat cannot be made any larger

than the valve head, and hence the difficulty which must inevitably face the repair man, should he take it into his head to remove the ridge. There is only one way—so far as the writer knows—of remedying the trouble, and that is by means of a fly-cutter. Care must be taken, however, to center the shank of the cutter properly by means of some special fixture; otherwise the valve seat and the valve stem guide hole will not be concentric, and gas leakage and poor compression are sure to follow. It will be seen from the foregoing that small and insignificant as the question of proper proportioning of the valve head and its seat at first appeared to be, it is far-reaching in its results, and surely deserves some consideration on the part of designers. The trouble we have just been investigating is very easily remedied—if it is recognized—on engines equipped with removable valve cages as shown in Fig. 7, which is the Buick design, and on the L-type engines having a detachable cylinder head like the Ford.

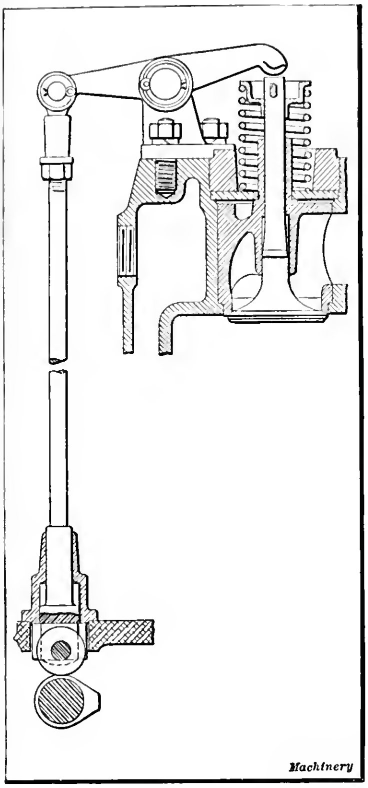

Fig. 7. Removable Valve Cage used on Buick Engine

A correct design is shown in Fig. 9, where the outside diameter of the valve D is made from 1/16 to 3/32 inch larger than D_1—the outside of the bevel seat. The width of the seat W generally varies from 3/32 to 3/16 inch. The diameter at the lower edge of the valve head is made equal to the bore of the throat; occasionally it is from 1/64 to 1/32 inch smaller. This is all right; but under no circumstances should it be made larger than the bore of the throat, for a flat seat will eventually be formed at the inner edge of the bevel seat, thus resulting in a tortuous path for the gases—a condition admittedly undesirable on any gas engine. In addition to this, the contact between the valve head and its seat will take place in two planes with the probability of being far less perfect than it was before.

The Bore of the Cylinder vs. the Bore of the Throat

Any mechanically inclined person surely recognizes the fact that there must be a certain direct relation between the size of any given engine and the size of its valves; the larger the cylinder, the larger the valves. But what is the exact relation between the two? As stated before, the valves are invariably made as large as a given design will permit. This, however, does not settle the problem; on the contrary, the important test of any given design is the size of its valves, and should calculations show the latter to be too small, the design must be changed to permit the use of larger valves. In the absence of extensive experimental data on the subject or even of a simple and plausible theory which would take into account several important factors, the designers of today reduce the whole question of proper size of valves to a simple numerical relation between the bore of the cylinder and the bore of the throat. Let:

D = diameter of cylinder bore in inches;
S_p = average piston speed in feet per minute;
L = length of piston stroke in inches;
t = duration of piston stroke in minutes;
V = piston displacement in cubic inches;
d = diameter of bore of throat in inches;
S_g = average velocity of gases at the throat in feet per minute;

$$V = \frac{\pi D^2}{4} \times L = \frac{\pi D^2}{4} \times 12 S_p \times t \qquad (1)$$

Since the same volume V has passed through the valve throat and neglecting the reduction of the passage area due to the presence of valve stem:

$$V = \frac{\pi d^2}{4} \times 12 S_g \times t \qquad (2)$$

Therefore

$$\frac{\pi d^2}{4} \times 12 S_g \times t = \frac{\pi D^2}{4} \times 12 S_p \times t \qquad (3)$$

$$D^2 S_p t = d^2 S_g t \qquad (4)$$

$$\frac{D^2}{d^2} = \frac{S_g}{S_p} \qquad (5)$$

It is common practice among designers to so proportion D and d that S_g shall not exceed the value of 6000 feet per minute at the time the average piston speed S_p is 1000 feet per minute.

Formula (5) then reduces to the form:

$$\frac{D^2}{d^2} = \frac{S_g}{S_p} = \frac{6000}{1000} = 6$$

$$6\,d^2 = D^2$$

$$d = \frac{D}{\sqrt{6}} = \frac{D}{2.45} \qquad (6)$$

For example, if $D = 3$ inches, $d = \frac{3}{2.45} = 1.225$ inch.

The bore of the throat should not be less than 1¼ inch diameter and this determines the size of the valves. Almost any multiple-cylinder engine may be redesigned to accommodate larger valves, but if this advantage is secured at the expense of spacing the cylinders farther apart, thereby increasing the overall length of the engine and making a corresponding increase in its weight, as well, the procedure is not worth while. This is especially true in the case of automobile engines, where weight is a question of prime importance. It must not be supposed, however, that if an engine with a 3-inch cylinder bore and 1¼-inch valves has its piston moving

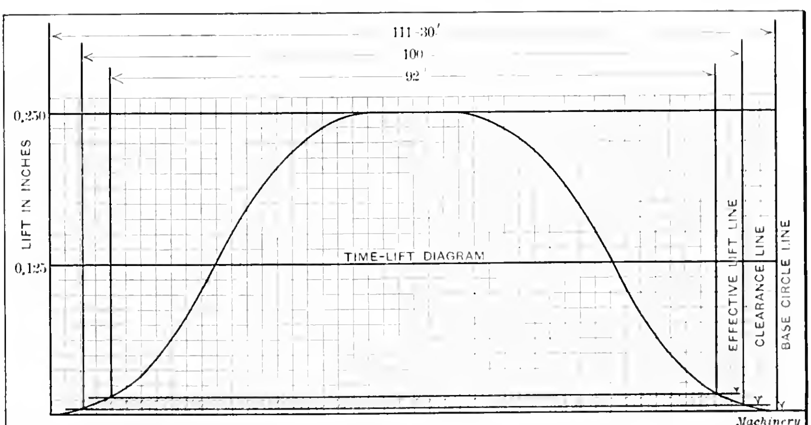

Fig. 8. Time-lift Diagram showing Combined Loss due to Shorter Effective Valve Lift and Shorter Period of Valve Opening

at the rate of 1000 feet per minute the average velocity of gases is actually 6000 feet per minute. It is very unlikely that it is anywhere near this figure. In the first place, Equation (4) is not strictly true, because the suction stroke of the piston lasts through 180 degrees, while the inlet valve, according to Fig. 4 in our case, is open through 200 degrees of the crank circle. In the second place, the statement that the volume V, which is equal to $\frac{\pi D^2}{4} \times L$ = piston displacement, passes through the valve throat, is far from being true. The weight of the gases drawn into the cylinder is equal to the weight of the gases passing through the valve throat, but their volumes are not equal. This inequality in volume arises from two causes: first, the temperature of gases at the instant they fill the cylinder must be considerably higher than at the time of their passage through the throat; second, from the analogy between aero- and hydro-dynamics, we know that, neglecting frictional losses, the total energy of a given weight of moving gas in the cylinder is equal to the total energy of the same weight of gas at the throat. The total energy is the algebraic sum of the velocity and pressure energies; and as the velocities of the gases in the cylinder and at the throat are different, it is clear that the gas pressures cannot be the same. As the gases are in a different state as regards their pressure and temperature, their volumes are more than likely to be different.

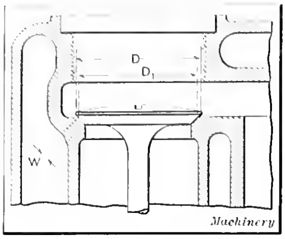

Fig. 9. Design of Valve with Seat that can be properly ground

There is yet another cause which tends to make the actual velocity of gases different from that allowed in the derivation of Formula (6), but its discussion will be postponed for the present. The natural conclusion is that Formula (6) is based on assumptions which are far from actual working conditions. Nevertheless, on account of being simple, it serves the purposes of design as well as any empirical formula. With the accumulation of experimental data in the years to come, this formula will undoubtedly be considerably revised and extended. As an empirical formula, $d = \frac{D}{2.45}$ falls short of meeting the requirements of a thoughtful designer. Let us consider, for example, a 3 by 4 and a 3 by 6 engine; according to our formula the throat opening on both engines should be $1\frac{1}{4}$ inch in diameter. Now, let the pistons of both engines be moving at precisely the same speed, say 1000 feet per minute. Since the stroke of the first engine is 4 inches, its piston will cover 1000 feet in 1500 revolutions of the crankshaft. The piston of the second engine will cover the same distance in 1000 revolutions of its crankshaft. Since the Otto cycle is completed in two revolutions of the crankshaft, there will be 750 cycles per minute on the 3 by 4 and only 500 on the 3 by 6 motor. The column of fresh gases must be started and stopped 750 and 500 times per minute, respectively, on the two engines; the same applies to exhaust gases. Also, the duration of valve opening, and, hence, the duration of gas flow is 50 per cent greater on the 3 by 6 than it is on the 3 by 4 motor. The result is that at the

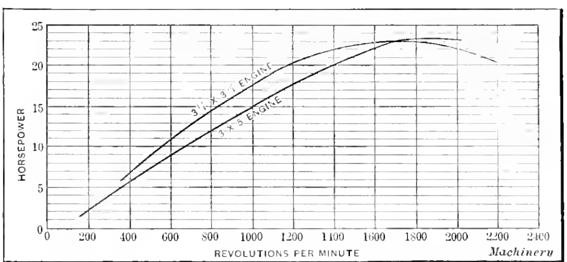

Fig. 10. Power Curves of Engines subjected to a Commercial Test

same piston speed, the former engine is bound to excel the latter. This is one of the causes of the recent remarkable performances of certain long-stroke racing motors, both here and abroad, and of the increasing popularity of the long-stroke engine for pleasure cars. Our formula $d = \frac{D}{2.45}$, failing as it does to take into account the stroke of the engine, cannot give entire satisfaction.

Again, the constant 2.45 in the preceding formula and the gas velocity of 6000 feet per minute on which this formula is based, are not applicable to all engines. Certain types of engines can accommodate valves that will easily permit as low a gas velocity as 5000 and even 4000 feet per minute, while others necessitate a velocity closely approaching 10,000 feet per minute. Yet, in spite of this great disadvantage, an engine with valves in the head having 10,000 feet per minute for its gas velocity, may show a better economy than an L- or T-head engine with 5000 feet per minute for its gas velocity. This phenomenon is generally accounted for by the fact that the combustion chamber of the valves-in-the-head engine has less radiation area per unit volume than that of the L- or T-head engine, and consequently more heat units are converted into useful work and fewer lost by radiation. Whether this generally accepted explanation of the phenomenon is correct or not, the fact remains, and hence, the apparent necessity of having a distinct constant or permissible rate of gas flow, for each type of engine. No better proof of this necessity of differentiating between engines of distinct types can be given than by making a comparison of an L-head and a valves-in-the-head engine, and studying their power curves as obtained from an actual test. The curves as shown in Fig. 10 are the result of an ordinary commercial and not a scientific test; they also represent the brake and

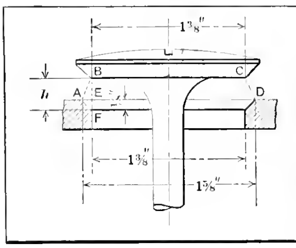

Fig. 11. Diagram showing Method of determining Valve Lift

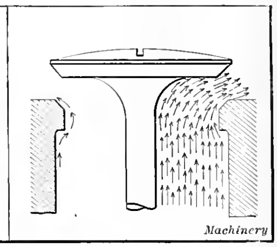

Fig. 12. Diagram showing Effect of "Vena Contracta"

not the indicated horsepower. Strictly speaking, the latter is preferable for our purpose. Also, the two engines happen to have somewhat different piston displacements, this circumstance slightly favoring the larger engine for no other reason than that large engines invariably show better economy or generate more power, displacement for displacement, than the smaller ones. These minor shortcomings, however, detract but little from the value of our comparison. The principal dimensions of the two engines are tabulated in Table I. From a study of this table, particularly items 8, 9 and 14, one would be led to expect greater output, displacement for displacement, from the 3 by 5 rather than from the 3¾ by 3¾ engine. Such, however, is not the case, as can be seen from their power curves (Fig. 10) and Table II which is derived from them.

A more recent test of the two engines conducted with the same size and make of carbureter has brought out a still better performance, displacement for displacement, of the 3¾ by 3¾ engine, which maintained the lead on the 3 by 5 engine up to 1800 revolutions per minute, at which speed their performance curves crossed. By making a comparison on the basis of the same rotary speed we eliminate the factor of cycles and duration of valve opening, thus leaving only two main factors unbalanced, namely: rate of gas flow and horsepower per unit displacement. In engines of the same type, lower rates of gas flow are invariably accompanied by greater horsepower per unit displacement. Referring to Table II and the statement made in regard to it, it will be observed that at low, moderate and even high speed, the

valves-in-the-head engine shows an equal and even better performance than the L-head engine, in spite of its almost 50 per cent greater rate of gas flow. This proves it to be a fallacy to prescribe the same rate of flow, i. e., 6000 feet per minute at the piston speed of 1000 feet per minute for engines of all types.

Valve Lift

Last, but not least, comes the problem of valve lift. Assuming that our valve throat is properly proportioned, it remains—as a matter of common sense—not to lose the advantage thus gained by restricting the passage and thereby choking the gases anywhere along the line—something that can be very easily accomplished by providing an insufficient valve lift. The problem consists of so proportioning the lift (h in Fig. 11) that the area of the frustum of the cone of revolution $ABCD$ be made equal to the net area of the throat.

TABLE I. DIMENSIONS OF L-HEAD AND VALVES-IN-THE-HEAD TYPES OF ENGINES SUBJECTED TO TEST

	Valves-in the-head	L-head
1. Type of engine	Valves-in the-head	L-head
2. Number of cylinders	4	4
3. Bore = D inches	$3\frac{3}{4}$	3
4. Stroke = L inches	$3\frac{3}{4}$	5
5. Area of cylinder bore $= \dfrac{\pi D^2}{4}$ square inches	11.045	7.069
6. Total piston displacement $= 4 \times \dfrac{\pi D^2}{4} \times L$ cubic inches	166	141
7. Revolutions per minute corresponding to piston speed of 1000 feet per min.	1600	1200
8. Number of cycles per minute at piston speed of 1000 feet per minute	800	600
9. Duration of valve opening in per cent assuming same timing	100	133
10. Bore of valve throat in inches	$1\frac{1}{4}$	$1\frac{3}{8}$
11. Diameter of valve stem in inches	$\frac{3}{8}$	$\frac{3}{8}$
12. Net area of valve throat in square inches	1.117	1.375
13. Area of cylnder bore ÷ net area of valve throat	9.9	5.14
14. Rate of gas flow in feet at a piston speed of 1000 feet per minute	9900	5140

Machinery

Net area of throat $= \dfrac{\pi}{4}(1.375^2 - 0.375^2) = 1.375$ square inch.

Area of the frustum $ABCD = AB \times \pi \times \dfrac{1\frac{3}{8} + 1\frac{5}{8}}{2} = 4.71\ AB$.

$AB = \dfrac{1.375}{4.71} = 0.292$ inch.

$BE = \sqrt{AB^2 - AE^2} = \sqrt{0.292^2 - 0.125^2} = 0.264$ inch.

Valve lift $= h = BE + EF = 0.389$ inch.

The valve shown in Fig. 11 was used on the 3 by 5 engine previously described. The lift as actually employed was only 7/32 inch or about 56 per cent of the calculated amount. It may seem absurd, but this dwarfing of the lift is being done on a wholesale scale—in most cases unconsciously—by the followers of the "common practice" theory, who have no sounder arguments to advance than that "they all do it." The true reason for the dwarfing of the valve lift, whenever it is done knowingly, of course, and not in the act of merely copying someone else, lies in the fact that high lifts are invariably associated with increased stresses on the parts comprising the valve gear and their rapid wear. This consideration is of so serious a nature that it cannot be ignored. But apart from this purely mechanical reason there is yet another reason, seldom recognized, but which nevertheless exists. The writer is referring to the presence of what is known in hydraulics as *vena contracta* in the throat passage (Fig. 12) which materially reduces the net area of the throat. Thus, in the case under discussion, the theoretical lift of 0.389 inch is excessive, since our theory did not take cognizance of the existence of vena contracta. But there is also a possibility of increasing the lift from 7/32 to 9/32 or even 5/16 inch and securing better output from the engine without incurring excessive wear of the valve gear. The actual amount of vena contracta, as well as the maximum useful valve lift, can be determined only by experimental means. The existence of vena contracta is the third reason alluded to in the early part of this article when it was stated that the actual gas velocity at the throat differs from the calculated one.

There is one more thing in connection with valve lifts which the writer feels is worthy of mention. Let us take, for example, an engine having $1\frac{1}{2}$-inch valves, with a lift of $\frac{3}{8}$ inch. Now, suppose we desire to redesign this engine and increase its valves to 2 inches. The increase of area at the throat is proportional to the square of its diameter; and, in order to maintain the same advantage at the valve seat, the valve lift must be increased roughly to $\frac{1}{2}$ inch. If the latter expedient be considered undesirable, the lift need not be changed, but the net gain, then, will be proportional only to the increase of the throat diameter. Now, the same engine can be redesigned along somewhat different lines. Suppose that quieter running and reduction of wear on the valve gear is the end aimed at, the power performance being entirely satisfactory. This can be secured, as before, by increasing the valve diameter from $1\frac{1}{2}$ inch to 2 inches, and reducing the lift from $\frac{3}{8}$ to 9/32 inch, thus leaving the passage area at the valve seat practically unaltered.

Judging by the ratio of the cylinder bore to the valve throat alone, as outlined in the earlier part of this article, the performance of the two engines should be identical—something that is very unlikely to happen owing to the great difference in passage areas at their valve seats. It will thus be seen that the valve throat alone does not form a good criterion of the probable engine performance. Indeed, the practice of comparing and designing engines on the basis of the ratio of the two bores alone may be considered as misleading and unfortunate. It should rather be based on the passage area at the valve seat, the exact amount of which depends both on the diameter of valve throat and the valve lift, the latter being so limited by practical considerations that there is absolutely no danger of its being made too large at the expense of the throat. When the usual method of computation is followed, the valve throat might be, and generally is, made too large at the expense of the lift.

In conclusion, the writer wishes to say that, while the formulas cited are somewhat unsatisfactory, they serve as a guide for one's analysis of gasoline motors. Like all inefficient tools and methods, they cannot be discarded until better ones are found to take their places. The use of formulas alone is practically worthless, unless it is accompanied by the two most important elements in all branches of design: a painstaking analysis and a trained judgment.

* * *

The post office department estimates that the gross receipts from the parcel post business during 1914 will amount to $80,000,000, of which $30,000,000 will be profit. This is a conservative estimate based on the results of the past year. The railroads claim that out of the profits $15,000,000 ought to be paid them in addition to the payments now made for carrying the parcel post mail, but even if that were done the profit realized is a fair one, and not at all in agreement with the opinions of leading business men engaged in the express service who claimed that the government could not carry on the parcel post except at a loss.

TABLE II. COMPARATIVE TESTS OF GASOLINE ENGINES

	800 R. P. M.		1200 R. P. M.		1600 R. P. M.

THE TESTING OF MATERIALS*

The ever-increasing intensity of the stresses which the materials of engineering, and especially of metals used in machine construction and structural designs, are expected to withstand, or the energy they are required to transmit, has during recent years necessitated a more and more intimate knowledge of the properties of the materials employed. At the present time, also, a great deal of study is given to the laws which determine the distribution of the stresses in the elements of the mechanical details or structures themselves. It is, however, impossible to deny that the architects of the past, who conceived and carried out such designs as are found in Greece and Italy and in the great Gothic cathedrals, possessed a considerable knowledge of the materials they employed and a keen sense of the stresses to which they submitted them; so did also the engineers and builders who launched upon the ocean the war-ships and merchantmen of the eighteenth century. They did not, however, for the most part, possess a knowledge of accurate calculation, nor of the definite laws necessary for the determination of the elastic properties of their materials. They took for guidance structures of a similar nature that had already proved successful, and when it was a question of undertaking entirely new work, either as regards size or shape, the designer was guided by the sense of fitness which practice is so capable of conferring, although it may sometimes be a mistaken one. Thus the designer was frequently led to over-emphasize the strength, or, if this proved inadequate, to employ means of strengthening his structures by making such means contribute to their ornamentation, as, for example, in the flying buttresses of the Gothic architecture.

The First Definite Investigations into the Strength of Materials

It was not until the seventeenth century, in the era of Galileo, that we find the first attempt made by this great scientist to solve the problem of the resistance of materials. Shortly afterward, Hooke enunciated the fundamental law of stability, which has ever since found application. In the eighteenth century renowned scientists and skillful engineers, such as Bernouilli, Euler, Duhamel, Gauthey, Rondelet, Young, Coulomb and Lagrange, ultimately developed the theoretical investigations which fostered the progress of the mathematical analysis and rational mechanics of the elastic properties of materials. The movement once initiated was never allowed to halt. It was, however, especially toward the improvement of the mathematical theory that the early investigators directed their efforts, but experiments were not lacking during this period. Among those who based their researches on experimental results may be mentioned Morin, Hodgkinson, Stephenson, Fairbairn and Napier.

The early development of the railways gave considerable impulse to the investigations into the strength of materials. The steam railways involved bridges of great length, capable of supporting rolling loads at high speeds. Work of this kind had nothing similar in any previous experience, and new methods and new elements of computation were required; besides the question of cost and maintenance came to the front as never before. Although a great deal was done during this period, it may be said that it was mainly during the course of the last thirty years that the activity in experimental work has become accentuated, owing, on the one hand, to the extraordinary increase in the dimensions of the structures themselves and the loads they are expected to carry, and on the other, to the introduction of new methods of testing and of refinements hitherto unknown. In this connection may be mentioned not only the erection of immense bridges, but of roofs of great span, steamships of immense size, the introduction of reinforced concrete, and the development of the automobile and of aerial navigation. It has therefore been necessary to improve experimental methods, to create more powerful and more accurate testing machines, and to study properties to which no regard was previously paid, such as, for instance, the resistance to shock and to rapidly repeated stresses. It has been necessary to look more deeply into the actual study of the structure of materials and to investigate the various forms of treatment to which metals are subjected before being put into use. A new science, metallography, has arisen, which, although of recent birth, has already been the object of a great deal of research which has endowed the metal industries with a fund of valuable knowledge.

Testing Methods

The most conclusive test, from the point of view of the strength of a structure, is obviously that which consists in subjecting the structure to the maximum stresses it is required to undergo, or even to still greater stresses, so as to insure complete security against all possible accidents. This has been done, for example, in the case of ropes, in boilers, and in bridges. Such tests are of extreme interest from the point of view of the confirmation of the accuracy of the formulas employed in the calculations of the dimensions and of the assumptions that it is often necessary to introduce into these calculations; these tests may often be made to yield valuable information for the completing of similar structures. An attempt has been made to introduce such tests into general practice, and methods and apparatus for same have been developed by Mr. Rabut and applied in France; Mr. James Howard has also developed the methods and apparatus adopted by the Bureau of Standards in Washington. These methods permit of measuring with considerable accuracy the deformation in a structural part; or of the plotting of a diagram showing the deflection in a bridge under the influence of moving loads; or of measuring the angular deviation in structures submitted to wind pressure, or in parts submitted to torsion.

Other investigations have made it possible, in many cases, to substitute hardness tests for tensile tests in iron and steel. Such tests, which may be termed "indirect," often justify their adoption by reason of the simplicity of the appliances required, or their small initial cost, and may often play an important part in practice, even if the information obtained is less accurate than that obtained by direct tests. The latter, however, are the most important and are always adopted when it is necessary to ascertain with the greatest accuracy the elastic properties of a metal, apart from the mode in which it is to be employed. These properties are, in particular, the elastic limit, the ultimate breaking stress, the coefficient of elasticity, the elongation, and the percentage of reduction of area at the breaking point. These tests are carried out on test pieces, that is, on samples cut from the materials to be investigated and specially prepared so as to display the properties under investigation. Experience has shown that this very preparation, as well as the methods of carrying out the tests, considerably influences the results obtained. It has therefore been necessary to fix international standards for uniform methods of testing for each class of material, and in particular for iron and steel. This work of standardization has been carried out by the International Association for Testing Materials, which was formed in 1895. The original aim of this association was to introduce uniform methods for the testing of materials, but while this has only been partly accomplished, the meetings of the association have become occasions of learning new facts and of investigating new methods for testing, rather than classifying those already known throughout the engineering world. When these new methods have been thoroughly established, it will be possible to establish standards which will rest on a scientific basis and yield more exact indications as to the nature of the materials than has been possible in the past.

The Work of the International Association for Testing Materials

As the work of the International Association for Testing Materials is, in a measure, a record of what has been done in recent years throughout the engineering field along these lines, a brief review of the work of the association will afford a comprehensive idea of the present status of the testing of materials. In 1906, at the meeting at Brussels, the association adopted and published a set of methods for the testing

* Abstract of a paper read by Prof. H. Hubert of Liege, Belgium, before the Iron and Steel Institute at Brussels.

of iron, steel, cast iron, copper, metal alloys, hydraulic cement, wood and clay, stoneware and cement pipes. The degree of accuracy in measuring permanent elongation should be 0.001 per cent. The "apparent elastic limit" has been reached when there is a permanent elongation varying between 0.2 and 0.5 per cent and the "proportional elastic limit" has been exceeded when the elongation on increasing the load by 100 kilograms per square centimeter (1422 pounds per square inch) differs by more than 0.0005 per cent from the proportional elongation. The association has also fixed rules for the determination of shock-fractures and resilience.

Metals are subjected to three different classes of tests: chemical, physical and mechanical. The chemical tests are more especially carried out during the process of manufacture in order to ascertain the composition and purity of the products. They are also carried out by the purchaser as a check on the specifications.

Physical tests consist of the examination of the exterior of the products and noting their fracture. The superficial examination may yield a general idea to the expert, but it is the examination of the fracture, especially when the surface can be projected under strong illumination on a screen suitably enlarged, that yields definite indications as to the quality of the steel and cast iron, and the defects that may be present. Of late, this method has been improved by polishing the surface of the fracture and etching it with a dilute solution of acid or preferably with a ten-per-cent ammoniacal copper solution, which allows of a micrographic examination being made immediately. This mode of testing often affords the metallurgist and engineer means for ascertaining the cause of discrepancies manifested in mechanical tests. Micrographical research is a branch of the science of testing in which, more than any other, progress has been made in the past few years, and it has become a trustworthy guide in the manufacture if iron, steel and metal alloys. It has been introduced particularly in works engaged in the construction of automobiles.

The variations in the properties of metals, under the influence of changes of temperature, hardening, tempering and annealing, and the study of magnetic and electric properties, all form branches of the physical testing and have given rise to many investigations.

Mechanical Tests

Mechanical tests were, for a long time, the only ones to which recourse was to be had in the study of metals. They still remain among the most important. These are classified into resistance tests on subjection to tensile, compressive, shearing, bending and torsional stresses, either applied gradually or suddenly, and workshop tests, consisting of bending, hammering down, upsetting and punching. The necessity of using, for the resistance tests, accurate and very costly machines, and of subjecting the test piece to the most careful and therefore the most expensive, preliminary treatment, and entrusting the experiments themselves to an expert staff, renders the time and expense for such tests relatively large, and many investigators have sought to supersede them by more rapid and cheaper treatments, even at the expense of accuracy. Among such methods may be mentioned the Frémont punch-test and the various hardness tests. The Brinell hardness test gives a fairly definite relation between the breaking stress and the hardness number and has the advantage of being capable of application to finished parts without injuring them. Many investigators claim that the relationship between hardness, as measured by the Brinell method, and tensile strength is so close that a coefficient may be determined by which the hardness numeral may be multiplied to obtain the tensile strength. Other observers claim that the results sometimes are very erroneous, and the Brussels congress, in 1906, would not consent to the substitution of the ball hardness test for the tensile test in specifications, but it recognized the value of the process by recommending its use in testing supplies. Later investigators, however, have credited the method with close accuracy. At the meeting of the International Testing Association in New York, 1912, the subject was again discussed, but no definite conclusions were arrived at.

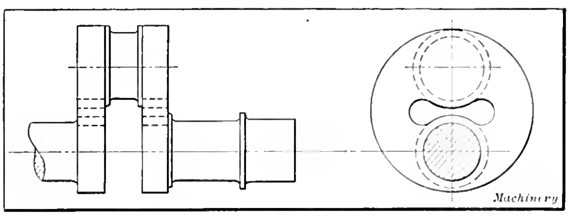
An interesting subject of investigation, relating to the testing of materials, is that of "fatigue" in metals, that is, the giving away of structural parts after they have been in use for a long time under a stress not exceeding that to which they have been continuously exposed. The earliest investigations of this subject were those made by Wöhler between 1857 and 1870. Many methods have been developed for carrying out these tests. It is claimed that 80 per cent of the fractures that actually occur in structural designs are due not to over-stresses, but to fatigue, and much importance, therefore, should be paid to methods of testing metals for continued stresses. The ability of a metal to resist fatigue may be denoted by a "factor of quality" which would indicate not its absolute strength, but the relative number of times that the material could be subjected to a given stress before it would actually break under that stress.

The brief review in the foregoing gives a general outline of the present status of the science of testing materials, for such it might well be termed. The great importance of the work of the International Association for Testing Materials to the engineering field is evidenced by the fact that the association now has about 2700 members from some twenty-five different nations, and that ten governments officially give financial aid to the work of the association. In the United States alone there are nearly 500 members and about as many in Germany. These two countries apparently lead in the interest taken in this important subject.

* * *

IMPROVEMENT IN CRANK AXLES

The illustration shows an improvement which has been applied to crank axles having circular webs, by M. C. Frémont, a French engineer. The stresses in these circular webs are most severe at the center, where the ingot from which the axle is forged is the weakest, and therefore cracks often start at this point, continuing to the periphery. In order to obviate this difficulty, the metal in the center is cut away in the form of the figure 8, thus preventing the starting of cracks. Axles made according to the Frémont



The Fremont Crank Axle with Portion at Center of Web removed

system have been in use in France for four or five years and have given entire satisfaction. In fact, crank axles which showed cracks in the center and were condemned have had the faulty portion cut away and then been put back into service, and have given no further trouble. Axles with circular crank webs have been tested to destruction and have been found to resist greater stress when the webs are cut away in the center, as described, than when the webs are solid.

* * *

An analysis by the *Railway Age Gazette* of the statistics of locomotives ordered during 1913 indicates that the superheater is being applied to nearly all locomotives, except those of the smaller size, and that engines of very large size are much in demand. Specifically stated, 79 per cent of all new steam locomotives of moderate and large size are equipped with superheaters, while in 1912 the percentage was 63. Nearly 63 per cent of the total number of locomotives ordered during 1913 were of the consolidation, Mikado or Pacific type, the consolidation being in the lead of all other types, forming 23 per cent of the total. The Pennsylvania R. R. leads in the use of these engines, 435 having been built for this railroad alone.

THE DIESEL ENGINE*

PRINCIPLE OF OPERATION—CHARACTERISTICS—EFFICIENCY—FUEL

The development of the internal combustion engine has made tremendous strides in the last few years. This is especially true of one type in particular, the Diesel engine. The unparalleled progress of this prime mover, due primarily to the expiration of the basic Diesel patents, has created a wave of enthusiasm. To the careful observer, however, signs of an ebbing of this wave are apparent, and more sober views are rapidly gaining ground. The application of the engine to marine work, especially to vessels of certain classes, has been especially noticeable, and the marine interests of the country have been watching closely the work of the Diesel engines. Other applications of the engine are common, and the Diesel engine of today is likely to be found in almost any line of work.

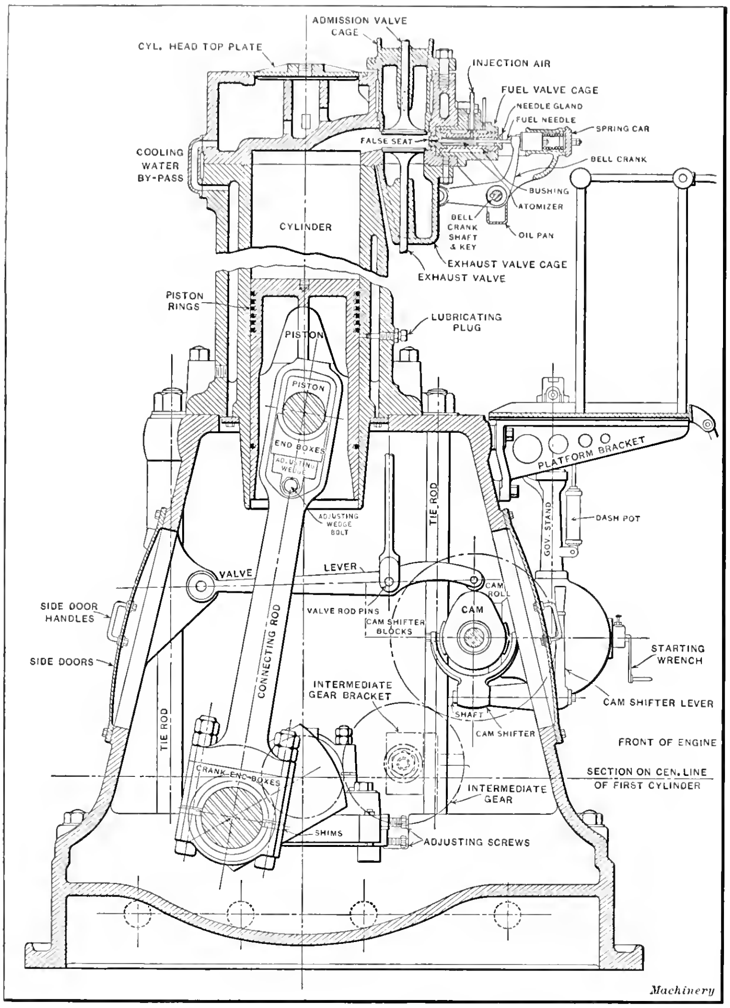


Fig. 1. Sectional View of Typical Diesel Oil Engine

In spite of the fact that the name Diesel has spread over the entire world, but few engineers in fields other than combustion engineering have ever taken the time to thoroughly study the movement of the engine and to learn of its proved practical application and use to the engineering world. The purpose of this article is, therefore, to present an idea of what the Diesel engine is, and to show in what fields the greater possibilities of the engine lie.

This type of engine may be defined in a few words as follows: An internal combustion engine which takes its fuel—crude, lowest grade fuel oil, or the residues from oil refining—into the cylinders, raw, without any previous transforming, and there converts it into energy, exerting that energy directly on the crankshaft through pressure on the piston head, without any intermediaries, thus producing the simplest, most direct and economical operation.

Principle of Operation

The cycle of operations of the Diesel engine operating on the "four-stroke cycle," comprising the Diesel ignition compression is as follows:

Stroke 1. Admission. The piston travels down or out, allowing the cylinder to fill with pure, fresh air from the inlet valves.

Stroke 2. Compression. The piston travels up or in, compressing air in the cylinder. The compression heats the air so much that the oil discharged into it will ignite and burn.

Stroke 3. Combustion. The piston travels down or out. At the beginning of this stroke, when the crank is on dead center, the fuel valve opens and the fuel charge of oil is sprayed into the heated air of the cylinder by a jet of air separately compressed by a small compressor. The spraying extends over 12 per cent of the working stroke of the piston and the combustion is gradual, the resulting pressures being even and sustained and not explosive.

Stroke 4. Exhausting. When the piston reaches the lower or outer end of the cylinder on stroke 3, the exhaust valve is opened, the pressure relieved and the piston travels up or in, driving out the exhaust gases of combustion.

Large Diesel Engines

Owing to the steady application of its power, the lack of vibration, comparative noiselessness, reliability, and to the small space which it occupies, the Diesel engine has become an almost ideal engine for marine work where oil may be had at nominal prices. An idea of the ease with which a Diesel engine may be controlled may be had from experiments run with the British motor ship *Eavestone*. This vessel is a ship of 4310 tons displacement recently built by Sir Raylton Dixon Co., Ltd. The 800 horsepower Diesel engine was largely built and installed by Richardsons, Westgarth & Co., Ltd., of Harthpool. She was capable of doing somewhat over nine knots. The action of the engines was very remarkable; they were reversed from full ahead to actually running astern in from nine to ten seconds, and this without any haste; in fact, with intentional deliberation. It was stated that the reversal had actually been completed in the remarkable time of six seconds. Observations showed that it only took about three seconds from the ringing of the telegraph till the engine was actually running ahead, the gear being already in the "ahead" position. Units of this character have been built for marine service up to about 2000 horsepower, single-acting type. The double-acting types are as yet but in the experimental stage.

Established Popularity of the Small Diesel Engine

The small and medium Diesel engine in sizes of from 40 or 50 horsepower in single-cylinder units, up to about 600 horsepower in four-cylinder units plays a vastly more important part in the commercial world than do the larger units; it has unquestionably come to stay, and has reached a high

* Abstract of an article in the January number of the Sibley "Journal of Engineering."

degree of perfection which places it right in line with the corresponding steam or gas engine plant as far as reliability and cost of operation are concerned, and far ahead of its competitors when considered from the standpoint of fuel economy. It is amazing to note how many manufacturers of gas and steam engines have taken up the manufacture of Diesel engines, because they found that the sale of suction-gas producer plants and smaller steam engines has fallen off alarmingly within the last few years.

The reason is plain. The single-acting four-cycle, single or multi-cylinder Diesel engine, but particularly the former, is comparatively simple in construction and operation. It does not require upkeep and attendance of boilers or gas

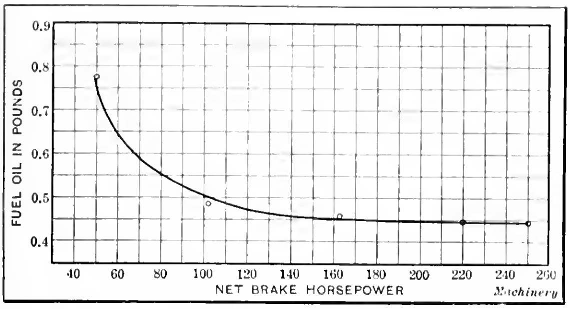

Fig. 2. Diagram showing Fuel Consumption of Diesel Engine

producers, and its cost, compared with that of a steam or gas plant, is reasonable. It can be installed in the basements of buildings below occupied dwellings. One of the greatest advantages, however, is the fact that the actual fuel consumption of Diesel engines taken over long periods of operation does not materially exceed the guaranteed figures; whereas, in gas producer and steam plants this excess is quite considerable. In a Diesel plant the human element—the skill of the operator—has much less influence upon the fuel economy than in a steam or producer gas plant, where everything depends upon the efficiency and intelligence of fireman and producer attendant.

On account of its low cost and great simplicity and variety of fuels which can be utilized the engines are being used and installed for various purposes, as for power transmissions, for operating flour mills, for lighting factories, office buildings, department stores, and for electrical works, etc. Lately they have been applied to the production of power where new and additional equipment is found necessary. It has been found that this engine can be very economically maintained as a reserve for relieving the original units of the peaks of the load and for like purposes.

Efficiency of the Diesel Engine

The efficiency of this type of engine and its characteristics may be readily obtained from the results of a test on a typical Diesel engine doing actual work. This test was conducted by A. C. Scott at the Scott Engineering Co., Dallas, Texas, on a 225 horsepower Diesel engine; the following data have been obtained which will give an excellent idea of the applicability of this engine to the generation of power.

The engine tested operates on the four-stroke cycle Diesel principle. It is a vertical three-cylinder unit, rated at 225 net brake horsepower, with allowance for power necessary to drive auxiliaries. It is directly connected to a Fort Wayne 200 K. V. A., three-phase, sixty-cycle, 2300-volt generator of 164 R. P. M. The auxiliaries consist of one belt-driven three-stage air compressor; one motor for driving compressor, 25 horsepower; and one exciter, 10 K. W., speed 850 R. P. M., belt-driven from the engine.

In many cases the air compressors for the starting and injection of air for Diesel engines are belted from the crankshaft of the engine; or when the compressor is motor driven, the power is supplied from the generator. During the series of tests, the power for the compressor was furnished from an outside source. Therefore, in order to obtain the net available power developed by the engine, readings were taken of the power consumption of the motor driving the compressor and a deduction made from the kilowatt output of the generator. No allowance was made for the efficiency of the motor; so that with the compressor belted to the engine shaft, the fuel consumption per brake horsepower hour would have been less than shown in the results given.

Fuel Oil Used

To obtain the amount of fuel oil consumed by the engine, it was only necessary to weigh the oil fed to the fuel pump, where the amount of oil actually fed to the engine cylinders is automatically controlled by the governor, and varied according to load requirements. For weighing the oil a 15-gallon tank and platform scale were used, and readings were taken at ten-minute intervals. A funnel of sufficient capacity was installed in order that a small amount of oil might be stored ahead of the governor, and the weighing tank properly re-filled with oil.

The oil used for these tests was taken from regular stock in ordinary use in this engine. Samples of oil were taken periodically, and the analysis made upon the total combined samples. The analysis of the fuel oil is given below:

British Thermal Units	18,986 per pound of oil
Specific Gravity, 25.5 degrees C. to 27 degrees C. (78 degrees F. to 81 degrees F.)	0.8531
Viscosity, 33.3 degrees C. (92 degrees F.)	1.63
Flash Point	143.6 degrees F.
Burning (Fire) Point	181.4 degrees F.
Sulphur	0.2 per cent
Water	Trace
Free Acid	None

The cost of this oil was $1.22 per barrel of 42 gallons, delivered; or practically 2.9 cents per gallon.

The instruments used in making the tests were all calibrated before using and due corrections made in the figures obtained. A water rheostat was found entirely satisfactory for the adjustment of all loads.

Tests

Six tests, each of three hours duration, were made with load changed for each hour period as follows:

Test Nos.	1	2	3	4	5	6
Net B. H. P.	2.25	49.7	111.39	162.97	219.63	245.62

Fuel Consumption

The fuel consumption for these various loads was in each instance obtained from an average of the readings taken at ten-minute intervals on the generator and the motor, and the records of oil used also taken every ten minutes. Fig. 2 is a curve showing in pounds the fuel oil consumed per net B. H. P. hour at the various loads. Test No. 1 is not included in this curve, as it was practically a no-load test. This curve was plotted by taking the average readings of output of the generator at the switchboard, corrected for the previously ascertained generator efficiency at the given load. From this was subtracted the actual kilowatt in-put to the motor and the resulting figure reduced to brake horsepower. It will be noted from the above curve, that the consumption of oil per brake horsepower hour increases but very little when the output is decreased from full load to about half load. At full load the fuel consumed was 0.441 pound per brake horsepower hour, or about 6.2 gallons per hundred net brake horsepower hours. When running at practically half load, the fuel consumed was 0.482 pound per brake horsepower hour, or about 6.8 gallons per hundred net brake horsepower hours. At quarter load the engine consumed 10.8 gallons of oil per hundred net brake horsepower hours.

* * *

The largest double-acting pile driver ever built was used for driving concrete piles for the Intercolonial Railway's new pier and shed at Halifax, Nova Scotia. The combined weight of the hammer with follower and follower guide is 24,000 pounds; weight of the ram only, 4000 pounds. The diameter of the cylinder is 14 inches and stroke 36 inches. The hammer drove 1800 reinforced concrete piles 24 by 24 inches square and 37 to 77 feet long.

RATIONAL METHODS IN ENGINEERING EDUCATION*

The work in machine design and construction at the Michigan Agricultural College is under one head. This permits of a superior selection and correlation of subjects. In this way the student, during the last three years of his course in mechanical engineering, has presented to him the fullest possible variety of subjects for design, and the work in the shops and the methods in design are more successfully correlated.

Many men, among others Mr. F. W. Taylor, have objected to the ordinary engineering graduate because of his lack of responsibility, perception and individuality. The endeavor at the college, the work of which is to be described, is to link good commercial practice with theory. The object is to put more seriousness into the teaching of engineering. School terms, such as "plate," are not used in the designation of drawings. The drafting-rooms are real drafting-rooms carried on along lines obtaining in good commercial practice. The main effort is concentrated on making the students more responsible men, and developing individuality and judgment. An endeavor is made to create a more businesslike atmosphere in the college, but the object is not to make engineering less rigid, but more interesting, fascinating and hence more understandable and better assimilated.

These things are done by applying principles as soon as possible after they have been enunciated. The examples are made real, doing away almost entirely with exercise pieces as such, both in the shops and in the drafting-rooms, and designing and building real machines in real ways for real uses. The great variety of machines and tools now being made in the shops permits of selecting in pedagogical order the proper sequence of exercises.

A need on the part of the students is created in exciting their desires by presenting subjects to them, first functionally and then following this by the pure theory underlying the subject at hand. They are led by means of that which is familiar to them, to that which to them has been unknown. The methods of making machines and tools follow the best practice; both processes, that of "building," and that of "manufacturing" in lots and by the use of special tools, jigs, etc., are used. The work differs from the condition in commercial shops only in the time required to produce a machine. The pedagogical order of selection of exercises does not permit of finishing a machine within a definite period. Of course, all of the equipment is not made at the college. The policy is to buy the very best machinery required for very accurate work, as for example, universal milling machines, and to make the general equipment.

In general, seniors and sometimes juniors design the machinery made. The details for the most part are worked out by sophomores. This follows the order in which work is done in the commercial drafting-rooms and it correlates well with the sophomore work in empirical machine design. The problems are attacked just as they would be in the commercial drafting-office. The need is first considered; a general specification sheet is then prepared by the instructor; the specifications are then elaborated by the student in accordance with his individual ideas, after which the final specification is checked and approved. As far as possible the students, in the senior year especially, work on different problems or on the same problem with different specifications. Drafting-room standards have been adopted which are rigidly followed during the three years that the students are engaged in the machine design. This follows good commercial practice.

In connection with the courses in machine design, the shop courses and the course in works management, a series of what may be termed "specialized inspection trips," has been adopted. These are not entertainment trips; nor are the students bewildered by examining all the processes occurring in any one factory. A need is first established such as, for instance, in machine tool design; after the students have endeavored to complete their specifications for, say, a radial drill by reference to a rather complete catalogue file, they find themselves somewhat shaky regarding some of the details. A trip to Lansing is then taken and radial drills, nothing else, are inspected, several different shops being visited.

A course is given in jig and fixture design, not with the idea of making tool designers of the graduates, but to acquaint them with the principles of this most important feature of manufacture. In this course especial emphasis is laid upon working hand in hand with the shop, conferences being held by the student with the machine shop foreman after the student has carefully studied his problem and has formed an opinion as to the best design, but before the work is done on paper. The jigs and fixtures designed are constructed in the shops and used in making the machinery. The courses in design and that in the construction of jigs are carried on simultaneously. The course in works management is also given during the same term, thus correlating three courses that go well together.

The course in works management includes such subjects as location and design of works, organization, costs, wages, labor, etc. The principles are given first and this is followed by a series of lectures on their application in the different departments of a factory. One advantage in giving these applications is to show to the student the relations, duties and limits of these several departments toward one another and to better enable him to fit himself into a commercial plant after graduation. In this course modern methods of production are carefully considered, and the course has enabled a number of the graduates to accept and hold positions along this line.

Efficiency is not only preached but also practiced. Indeed, the great variety and considerable number of machines and fixtures now going through the shops requires some system of checking and following up work, and this is done along approved commercial lines, using order blanks, etc., as in a first-class machine manufacturing plant.

Let us consider a hypothetical case: All orders for machines or tools that are to be made in the shops are issued, in triplicate, from the office of machine design and construction. The drawing numbers are also given here, following a standard system. The order is first issued to the pattern shops, two copies of the orders being sent with the blueprint, and the original being filed in the office under the head of "Orders issued." If the order is urgent, the pattern, when finished, is delivered to the foundry, otherwise to the pattern storage. The pattern number is given by the foreman of the pattern shop, who also has charge of the pattern storage department. The numbering system adopted at once locates the piece on its shelf. The pattern number is marked in red pencil in its proper place on the bill of material by the foreman of the pattern shop and the blueprint returned to the office with the one copy of the production order which has received the signature of the one to whom the pattern was delivered and filed under the head of "Orders filled." The second copy of the order is retained by the pattern shop. The pattern number is then put on the tracing and the casting production order is issued.

A "work order" card is also used, by means of which the shop can keep a record of the students' work, waste and efficiency, and the student is able to compare his time with that of a mechanic under similar conditions in a commercial shop. He can also obtain the shop cost of the work done, and thus have an idea of production values. The cost value of an automatic machine or special tool, such as a jig, and the rate at which the pieces to be machined could be turned out with the refined equipment, the time cost of the operation, etc., are studied. The student is thus enabled to study production while producing, and without expenditure of time.

Some of the machines now under construction are: six 14-inch engine lathes; a number of pattern lathes; a planer; a keyway slotter; two one-ton pneumatic hoists; a triplex power pump; a disk grinder; a steam hammer; a punch and shear; a star feed for a boring mill; and a vertical slotting attachment for the universal milling machine, and a great number of jigs, tools, and fixtures.

* Abstract of a paper read by Prof. Edward J. Kunze, assistant professor of mechanical engineering, Michigan Agricultural College, East Lansing, Mich., before the Michigan Engineering Society.

INVENTING MACHINES TO MAKE INVENTIONS MARKETABLE

SOME INTERESTING FACTS ABOUT INVENTIONS AND A FEW POINTS THAT THE INVENTOR USUALLY OVERLOOKS

BY E. R. MINER*

Probably ninety-eight out of every hundred men have, at times, dreams of becoming great inventors. Such dreams are usually colored by visions of some epoch-making discovery which will bring both fame and fortune. As a matter of fact, and according to history, the epoch-making discoveries have made comparatively few fortunes for the inventors. The fortunes have come to others after a long period of improvement, elimination and practical trial. Where there is one Alexander Graham Bell or Thomas Alva Edison, there are a thousand unknown and unremembered inventors. Inventors, as the old saying has it, may be born, but successful inventions are matters of pure business, the gradual evolution of new dresses for old ideas, the working out of new methods, new goods, and new applications to meet recognized trade requirements.

Whereas the large fortunes which have been made by some great and timely discovery or invention can be counted on the fingers, the moderate fortunes which have been made by inventing some small article of practical and everyday use are not only numerous, but are well represented in all sections of the country. To merely invent something is not nearly as hard as knowing what to invent. Nearly any mechanic, if turned loose in a shop, could manage to invent things, but it would only be the occasional and exceptional man who would invent things which had a money value. The really new things or the radical changes are often the ideas of persons who have but a surface knowledge of the business to which their invention applies. Not being bound by custom or by recognized methods or previous experience, they draw upon their imagination or inventive faculty. Lack of practical knowledge often does give that twist to the imagination which results in the new idea, but usually there must be a long period of experiment and the bringing into play of practical knowledge to make the idea successful.

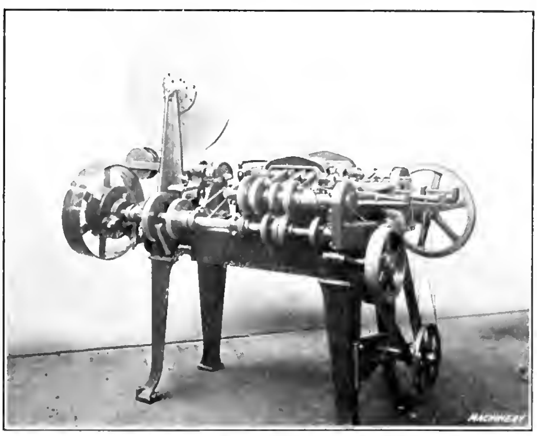

Fig. 2. A Pin Ticket Machine which prints the Ticket and makes and attaches the Pin for Tickets used on Clothing, etc., in Stores

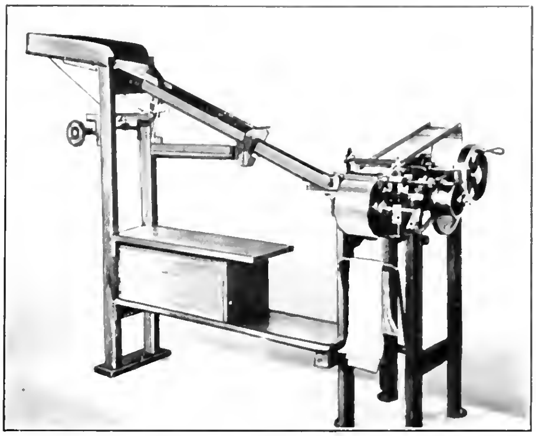

Fig. 3. Pin-sticking Machine which counts the Pins and sticks them into Papers

An electric lineman might be employed for twenty years in stringing heavy electric cable, yet his duties seem so commonplace that he never suspects or thinks that a large business could be created in making the clips or hooks which fasten the heavy cable to the supporting wire. The stranger, or possibly the young engineer who has charge of the line gang, being more or less unfamiliar with the work, notices the great number of clips or supports used. He also notices that the lineman cuts off a section of wire for making these clips, and immediately the idea is born as to why these pieces could not be manufactured more cheaply, more uniformly, or better, by machinery.

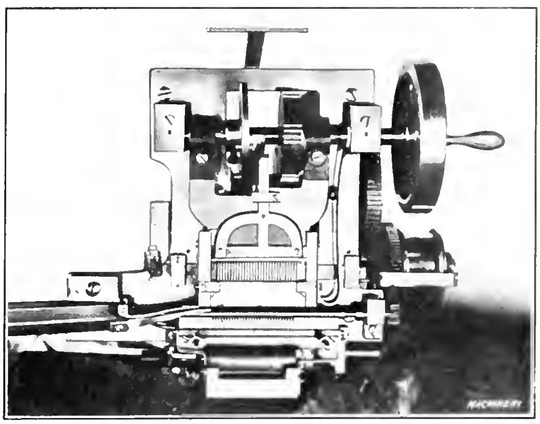

Fig. 4. Top View of the Principal Part of the Pin-sticking Machine shown in Fig. 3

To successfully follow out such an idea, it is important to understand trade conditions, to know what the possible market would be, what price they would have to be sold at, what saving in labor or cost such article would represent, and after designing a clip which would meet all requirements, to know that a machine could be made for manufacturing such a clip both rapidly and cheaply. The failures in the invention business have been mostly by reason of the inventor going ahead on some idea which appealed to him personally, but on which his actual information was very small.

So apparently insignificant a product as the hairpin illus-

* Address: Box 315, Bridgeport, Conn.

trates in a simple manner the development of an idea into an industry. Wild thorns, sharpened sticks and shaped pieces of bone or shell were the original hairpins. Later on, the goldsmiths turned out by hand various devices in the way of bands and pins for holding the hair. The inventor of the wire hairpin is unknown, but the original hairpin was probably a piece of wire bent over in the center to form two straight legs of equal length.

The practical man stepped in, and understanding the various deficiencies of the hairpin as it existed, began to make improvements until today there are dozens of patents covering the point on the pin, the crimping or waving of the wires, the general shape, and other features which presumably make the hairpin better for the purpose intended. From this development, there proceeded the development of machines for manufacturing them. A hairpin made by hand or one requiring considerable manual labor would be a hairpin of rather high cost. As a consequence, the sales would be restricted. With automatic machinery, the hairpin becomes an article where cost is reduced to a mere trifle over the cost of the raw material, and as a consequence, it becomes an article of everyday necessity. A modern hairpin machine, depending upon the size and kind of the pin, will turn out from 75 to 200 per minute. At least one modern hairpin manufacturing company making nothing but hairpins keeps 75 machines running continuously with a general average of 100 per minute or 6000 per hour for each machine.

The improvements, the attachments, and the small changes that make a thing practical, make it conform to the requirements of the trade, and generally whip it into shape, are made by those who are thoroughly familiar with the business in hand and know what will be required by trade usage. There are very few inventions that ever have or ever can immediately revolutionize conditions, trade, methods, or things in general. A design or invention that is different beyond a certain point is held up to ridicule as a freak, and regardless of actual merit, it may be years before the public will accept such a design or invention at its true worth.

Wise manufacturers seldom put out freaks, but rather keep to their general design, making small changes here, and others there, until the trade is led to accept a freak as an outgrowth of gradual improvement. Few inventors see the reasonableness or business policy in this. The true inventor would immediately revolutionize business. He forgets the interests of those who have money tied up in a competing article, and would stuff his invention into the hands of every member of the trade. Admitting that an invention had real and superior merit, this, without previous education, is not a selling point. One shotgun might be so superior to another shotgun that there would be no comparison, and yet there would be no argument that would influence the man whose knowledge of shotgun requirements could not grasp the technical difference. To him they would both be shotguns.

To the general public, inventions that are radically new are things to let the other fellow fool with. This characteristic of the public will account for about one-half of the failures of inventors to put a really meritorious article on the market. The inventor, therefore, to be successful in a financial way, should be a business man. He should be broad in mind, and willing to see things as they exist, and not as he would have them. He must recognize that all things must be manufactured, and to be of any pecuniary benefit, they must be sold. To be sold, a product must adhere more or less to certain well defined standards. Such standards can be gradually altered, but they cannot be rushed at and immediately overthrown. In addition, to be manufactured at a cost which will admit of selling at a price which will be acceptable to the public and yet admit of a profit, special machinery or special applications of standard machinery may be necessary.

Successful invention (and by successful invention we mean invention which brings financial return to the inventor) is a business which requires close study of trade conditions and the possible demand brought about by modern improvement. The man who invents a garter clasp or a new type of hairpin, and can get them on the market in a proper manner, stands a better chance of being adequately rewarded than he who struggles for many years in an effort to build some type of a great power turbine.

There have been fortunes made on pins and other fortunes on hooks and eyes, but such fortunes have been built through a universal demand that called for quantity, and the popularity of these goods and immense sales for them have been created by reason of their very small retail cost. This low cost is made possible by automatic machinery that takes the wire or metal from a reel, feeds it through the machine, and drops out the completed article. Without such machinery, neither the pin business nor the hook and eye business would be possible, and the general public would still be using the makeshifts of our ancestors.

The inventor of the hook and eye or the inventor of the pin probably could not design a machine for making them, and they must perforce go to other inventors who could build one for them. Like thousands of other things, the hook and eye was an idea. Properly made and properly put on the

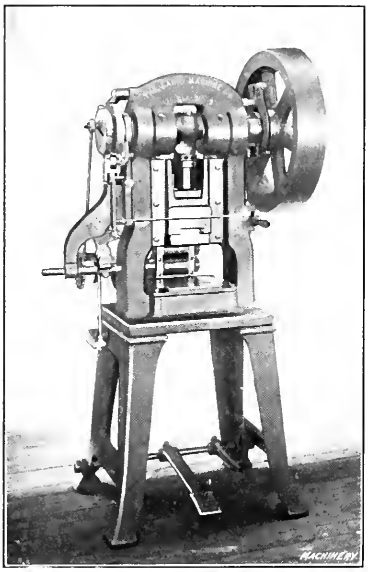

Fig. 5. A Roller Feed Automatic Press performing Half a Dozen Operations and provided with Automatic Stop

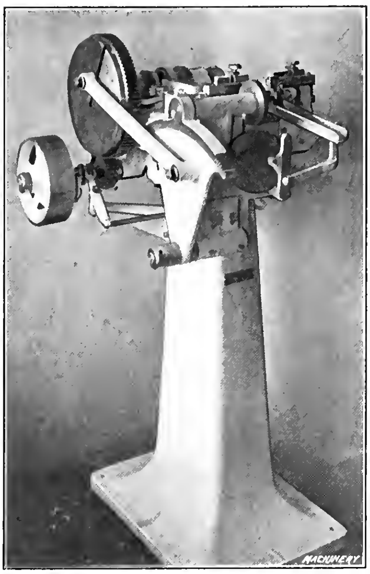

Fig. 6. A Spring Winding Machine which receives Wire from the Coil and completes Springs at the Rate of 150 per Minute

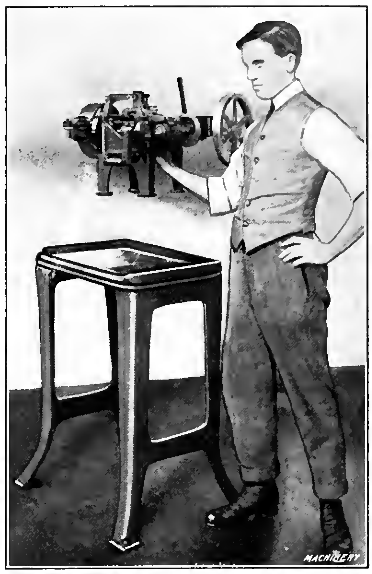

Fig. 7. Paper Clip Machine which turns out Finished Clips at the Rate of 450 per Minute

market, it was a builder of fortune, but it required the machinery back of the hook and eye to make such an idea successful.

The machine part of the proposition is really the fundamental basis for success. Fish-hooks would still be made by hand and at home by those who use them were it not for the automatic machines which turn them out so rapidly and at so low a cost that it would be a foolish waste of time and energy for anyone to attempt competition by older methods, even for their own use. The dollar watch is made possible through the design of special machinery. Even the automobile might still be an idea were it not for the machine builders who have made the rapid and uniform manufacture of the various parts possible.

Whether the article be a suspender buckle or a gas engine, the very first essential of operation will be "How can it be manufactured?" Financial success may entirely depend upon the answer to this one question. Throughout the New England states, that "Yankee district of the country so well known for its ingenious contrivances," there are shops which could be well called "inventors' factories." Probably the oldest of these, and perhaps the largest, is located in Bridgeport. To go through this factory is a liberal education on the

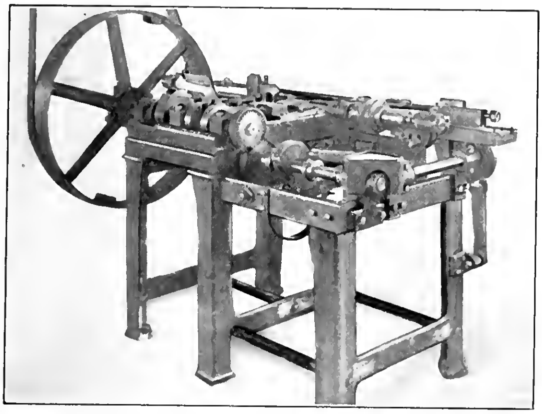

Fig. 8. Machine for making Hinges for Pianos

reduction of cost in manufacturing methods. The founder was the inventor of the original pin sticking machine, which counts the pins and sticks them in papers, so many pins to the row, and so many rows to the paper. A comparatively simple contrivance, it revolutionized the pin business, and is used in every country where pins are manufactured. It was the machine in this case that put into the hands of the manufacturers a popular, easily handled package for the retail sale, while at the same time making a reduction of cost in handling.

There is practically no industry today where the machines for making some part of the product are not the real factors of success. We hear of the inventor of a typewriter or of some other product, but we never hear of or give a thought to the inventor of special machines and special attachments which make the manufacture of the typewriter or product possible. And in the same way, there are manufacturers of special machinery whose factories are probably unknown to the general business man, yet special machines of their design are in every corner of the world, and turning out completed products or parts for pretty nearly every line of business.

A recent visit to one of these factories showed on the testing floor, having a final try-out before shipment, the following machinery: An upholstery tack machine, a form of press which pulled wire off a reel on one side, flat metal from a coil on the other side, and delivered large round headed upholstery tacks at the rate of 125 per minute; a patent thumbtack machine biting pieces out of a coil of flat brass and dropping those aids to the drawing board at 135 per minute; a butt hinge machine rolling off hinges faster than one would want to stand and count them; an electric lamp socket machine assembling the brass and porcelain sections at the rate of 60 per minute; a hook and eye machine spinning wire off a coil and dropping the familiar hump hook at 225 per minute; a paper clip machine making 300 clips per minute; a hairpin machine; a machine for making screw-on jar tops; a machine for making the wire guards for lanterns; a machine for making wire clothespins; a machine for making bed springs; a machine for making small springs; an eyelet machine for glove fasteners; a safety pin machine; a pin ticket machine for clothing; a machine for making, printing, and coating with paraffine the paper caps for milk bottles; a capping machine for beer bottles; a bucket machine; a garter clasp machine; and a great variety of wire and metal bending and forming machines.

Often a single machine will be found adequate to supply a whole industry. At the speed of 100 per minute, there is a total of 50,000 to 60,000 pieces to represent a ten-hour day. Now, 60,000 pieces per day for 300 days in the year often represents a greater quantity than can be disposed of, and there are cases where one machine pays good dividends, and is run perhaps only half or quarter of the time.

Work which is done by hand represents labor charges. It, also, if fairly large quantities are wanted, represents lack of uniformity and interchangeability. High labor charges require a high selling price, and the higher the price, the more restricted the field. Bring machinery into the question, and the labor charges for a single piece drop, the selling price drops with it, the selling field is enlarged, and the greater quantity demanded increases the business and produces a larger net profit. The machine or manufacturing part of a proposition is often lost sight of by reason of the ingenuity shown in a device, or its evident salability. Wrecked hopes are the reward of such short sightedness. The world may be waiting for a device to accomplish a certain purpose, but it will continue to wait if the price is beyond certain set limits.

There are hundreds of men earning a most excellent income by devising practical improvements for everyday products. These men do not always know all the angles regarding the particular product they may be working on, but they waste but little time on developing an idea until they know the probable market price, the quantity likely to be sold, and that it can be manufactured for the price by machinery.

* * *

REWARD FOR A RUBBER TIRE SUBSTITUTE

The Austrian War Department has offered a prize of $10,000 to be awarded to the person who with adherence to certain prescribed conditions will construct an elastic tire for motor trucks which possesses essentially greater durability, or, with equal durability, the attribute of essentially smaller cost of construction than the rubber tire, having, in addition, the properties of elasticity and adhesiveness of pure rubber. The weight must not exceed that of a pure rubber tire. Competitors must hand in a model of the fabric in natural or reduced size, together with drawing and description, before June 30, 1914, to the Automobil-Versuchsabteilung (Automobile Trial Division), VI., Gumpendorferstrasse 1, Vienna, Austria. Further details may be found in the *Militarische Rundschau*, published at I. Graben 23, Vienna, and to be had also on application, in German, to the K. K. Kriegsministerium, Vienna, Austria.

* * *

A tap is a tool for cutting internal threads. Its efficiency does not depend on a highly polished shank, nor should its sale be affected by the characteristics of superficial finish. The fact is, though, that tap makers generally bestow a great deal of care and labor on superficial finish because of the prejudices of the average run of customers. A maker of forged pipe taps—having forged flutes and squares—leaves the flutes and square black after hardening but imitates the shape of milled flutes in order that purchasers shall not be adversely influenced by the too obvious fact that they are forged. As a matter of fact a forged flute tap should be better than when cut from the solid.

NOTES AND COMMENT

It is reported that Prof. Lummer, of Breslau, Germany, has discovered a method of obtaining carbon in a liquid condition. Leading scientists believe that the possibility of producing liquid carbon will also make it possible to produce artificial diamonds by its crystallization.

The Brown-Boveri Works, in Switzerland, are constructing what is claimed to be the largest electro-steam turbine set built. The group is of about 30,000 kilowatt and is intended for the Mark electric station at Westphalia. It is expected that steam turbines in single units of as high as 50,000 or 60,000 horsepower will be constructed within the near future.

It is stated in *Engineering* that sample pieces of cast-iron pipe that have been taken up after having been in use from sixty to seventy years have been found to be practically as good as new. Many cast-iron piping systems are in use in England that were laid eighty years ago. There are some cases known where cast-iron pipes have been in service for 250 years.

The postoffice and post roads committee of the House of Representatives, on December 8, approved a bill appropriating $100,000 of the annual postoffice budget. This will be used for purchasing a number of postal cars to be operated as an experiment from which to determine the advisability of owning and operating all such cars, instead of renting them from the railroads.

The world's greatest railway tunnels are in Europe, and a brief summary of these in the *Engineer* shows that the greatest is Simplon, which is 12¼ miles long. The St. Gothard and Lotschberg tunnels are over 9 1/3 miles long, whereas the Mont Cenis is a little over seven miles long. The Arlberg, in Austria, is 6¼ miles long. The longest tunnel in this country is the Hoosac, which is 4 1/3 miles long.

The gas-engine manufacturing business is reported to be in a flourishing state in Germany. The largest of the companies has a capital of 20,000,000 marks ($5,225,000) and paid a dividend of nine per cent on this capital during the past year. The total value of the manufacturing during the year was $6,190,000. Wages continue to increase, the total increase per man per day since 1906 amounting to over forty-five per cent.

The Russian aviator and aeroplane designer, Sikorski, has built a giant biplane weighing about 7000 pounds. The new machine, it is said, is propelled by four motors of 100 horsepower each, and the biplane is claimed to have a carrying capacity of twenty people, cabins with sleeping accommodations being provided. On the trial trip, the machine rose into the air after a run along the ground of 100 yards and circled the grounds without difficulty.

Electric furnaces for the ordinary steel foundry are now being regularly built and are claimed to give good results, electric melting having many advantages from a metallurgical standpoint. The new electric furnaces are made as nearly automatic in action as possible and many improvements in their design have been introduced during the last few years, so that it is claimed to be easier at present to get good results from an electric furnace than from the ordinary type.

Lomax is a planned city in Henderson Co., Ill., which will have some novel and interesting features for manufacturers. The founders have planned for shipping facilities, power, labor and living conditions. They propose to give each manufacturing plant free power for at least ninety years on the basis of one horsepower for each male employe, charging for additional power at the rate of twenty dollars per horsepower for a year. Workmen's houses will be rented on the basis of two per cent of the actual cost and the workman will be given a chance to buy and build on small reservations without cash.

An English method of treating metal case bullets and projectiles so that the bore of the rifle will become, after continued firing, even more highly polished than a new barrel, is described as follows: Bullets or the driving bands of projectiles are first roughed by means of sand-blast. They are then treated with sodium silicate (water glass) dissolved in water. In this solution kaolin is also suspended. After the water glass has dried on the bullets, they are given a protective coating of paraffine or shellac varnish and, in addition, the bullets are given a thin coating of a lubricant such as beeswax.

The Institution of Mechanical Engineers of Great Britain has instituted a fund for the purpose of giving financial aid to prominent members who, through no fault of their own, are in poor circumstances. About $20,000 has already been contributed to this fund. The idea is to keep the fund invested and to use only the income for relief. Engineers who have held high rank in the profession and to whom the engineering field as a whole may be largely indebted may be so placed in their declining years that aid from a fund created by fellow members in the profession may be necessary and acceptable.

A new method of obtaining a black rust-proof finish on iron or steel has recently been patented by F. Richards of Coventry, England, (United States patent 1,069,903). The process can be applied to hardened steel because the work need not be heated above the boiling point of water as is necessary with some of the other black-finish processes. A solution is made of 120 gallons of water, 3 pounds of manganese-dioxide, and one-half pound of concentrated phosphoric acid. This solution is placed in a suitable receptacle and heated to the boiling point. The iron and steel articles which have previously been cleaned are placed in the solution for from thirty to ninety minutes, after which they are removed, wiped and oiled with linseed oil.

In a recent lecture given at London, England, by Mr. Richard Kerr, the title of "Father of Wireless Telegraphy" was given to James B. Lindsay, who was born in 1799 and died in 1862. This man, a not too-prosperous schoolmaster at Dundee Gaol, with a salary of £50 ($250) per year, made his own batteries and coils and sent wireless messages across the Tay and other Scottish rivers and lakes as well as across the Solent. He is said to have declared that if he only had the means to extend his experiments there was no reason why he could not send messages across the Atlantic. It was essential to the Lindsay system that there be a stretch of water between the transmitter and the receiver. Lindsay was a man of remarkable genius, but sometimes turned his energy to rather peculiar accomplishments. He died while engaged in the compilation of a dictionary on fifty languages, and was at that time regarded by his neighbors as "nutty."

Hydrogen compared to air in weight is near the irreducible minimum of the highest vacuum. There is little to hope for in reducing the bulk of dirigible balloons from the use of a much lighter gas. But an astronomer who makes the claim that the upper atmosphere of the earth is composed of coronium, a gas considerably lighter than hydrogen, suggests its use as a substitute for the latter in balloons. Inasmuch as the coronium gas is estimated to be mostly at a height of 135 miles, there is little prospect now of ever gathering it from its native "heath" in appreciable quantities. But if it could be obtained the gain would be small. At sea level and sixty degrees F. temperature, hydrogen gas weighs about 38 grains per cubic foot while air at the same pressure and temperature weighs 540 grains. The buoyancy of hydrogen is due to the difference between its weight and that of the same volume of air. The buoyancy of one cubic foot of hydrogen, then, under the given conditions is $540 - 38 = 502$ grains. If hydrogen could be replaced by a gas weighing one-fifth as much, the gain in buoyancy would be 30 grains per cubic foot, or only six per cent.

HOBBING VS. MILLING OF GEARS*

A COMPARATIVE STUDY OF THE TWO METHODS FROM THE POINT OF VIEW OF BOTH QUALITY AND QUANTITY

BY JOHN EDGAR†

The adverse criticism of the gear hobbing process has been the cause of many interesting investigations, and one of the most important of these has been the comparative study of the condition of the surfaces produced by the hob and by the rotary cutter. In making such a comparative study, it is necessary that the investigator possess the required practical knowledge, and also that he be willing to admit a point, even though his favorite processes may suffer by the comparison.

Feed Marks produced by Rotating Milling Cutters

While both the gear hobbing machine and the automatic gear cutter use rotating cutting tools, the operations cannot be placed on a common basis and considered as similar milling operations, although they may, to a certain extent, be compared as such. In comparing the quality of the surfaces produced by the two processes, consider first the milled surface produced by an ordinary rotary cutter. This surface has a series of hills and hollows at regular intervals, the spacing between these depending upon the feed per revolution of the cutter, and the depth on both the feed and the diameter of the cutter. The ridges are more prominent when coarse feeds and small diameter cutters are used. These feed marks are the result of the convex path of the cutting edge and the slight running out of the cutter, which is inevitable in all rotary cutters with a number of teeth. As is well known to those familiar with milling operations, the spacing of the marks does not depend on the number of teeth in the cutter. Theoretically, it should depend on this number, but as it is practically impossible to get a cutter which will run absolutely true with the axis of rotation, only one mark is produced for each revolution, and, hence, the spacing becomes equal to the feed per revolution. The eccentricity of the cutter with the axis of rotation is, therefore, the factor which, together with the diameter of the cutter and the feed per revolution, determines the quality of the surface, other conditions being equal.

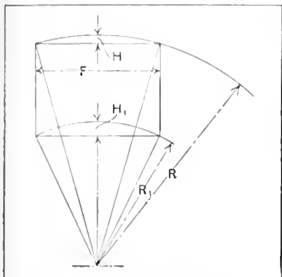

Fig. 1. Diagram illustrating the Relation between Feed, Diameter of Cutter and Depth of Feed Marks

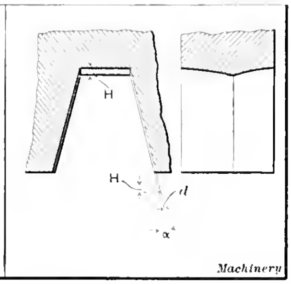

Fig. 2. Diagram for finding Depth of Feed Marks on Side of Tooth cut by Milling Cutter

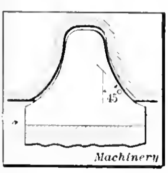

Fig. 3. Angle which limits the Feed

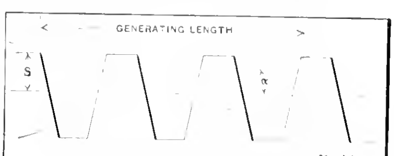

Fig. 4. Diagram for deducing Formulas for analyzing Action in Gear Hobbing Machine

The depth of the hollow produced by the high side of the revolving cutter is equal to the height or rise of a circular arc, the radius of which equals the radius of the cutter, and the chord of which equals the feed per revolution. (See Fig. 1). The length of the chord or the feed per revolution may be expressed:

$$F = 2 \times \sqrt{2\ HR - H^2}$$

in which F = feed per revolution;
H = height of arc;
R = radius of cutter.

Since H^2 is a very small quantity, it may be discarded in the expression, which is then simplified to read:

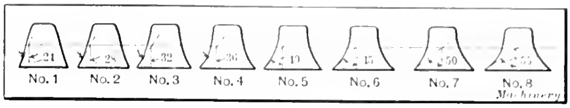

Fig. 5. Angles limiting the Feed for 14½-degree Standard Gear Cutters

$$F = 2 \times \sqrt{HD}$$

in which D = diameter of cutter.

Transposing this expression, we obtain $H = \frac{F^2}{4D}$, which is an approximately correct expression of the depth of the hollows produced by milling. As an example, take an 8-pitch rack cutter, with straight rack-shaped sides, 3 inches in diameter, milling with a feed per revolution of 0.1 inch. The depth of the feed marks at the bottom of the cut will be equal to:

$$\frac{(0.1)^2}{4 \times 3} = 0.00083 \text{ inch.}$$

The working surface of the tooth, however, is produced by the side of the cutter, as illustrated in Fig. 2, and the depth of the feed marks is normal to the surface, and is expressed as:

$$d = H \times \sin \alpha$$

in which d = depth of the feed marks on the side of the tooth, and α the angle of obliquity. In the example given, the depth d would equal 0.00021 inch, for a 14½-degree involute tooth.

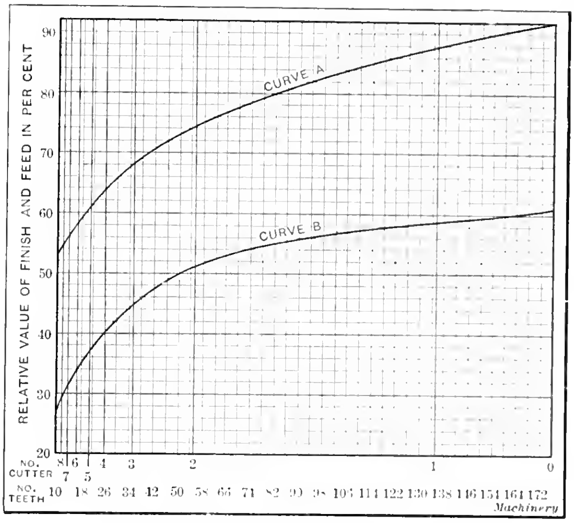

Fig. 6. Diagrams showing the Relation between Feed, Finish, and Number of Teeth when cutting Gears with Formed Gear Cutters

The depth of the feed marks is inversely proportional to the diameter of the cutter, and is, therefore, greater at the point of the tooth than at the root. In the example given, the depth would be 0.00025 inch at the extreme point of the rack tooth. It is thus apparent that the quality of the surface at any position along the tooth from the root to the point depends upon the diameter and form of the cutter and the feed per revolution.

In Fig. 3 is shown the outline of a No. 6 standard 14½-degree involute gear cutter. This outline, at the point close

* See also MACHINERY, July, 1912, engineering edition, "Hobs for Spur and Spiral Gears," and the articles there referred to.
† Address: 61 Bruce Ave., Windsor, Ontario, Canada.

to the end of the tooth of the gear, is a tangent inclined at an angle of 45 degrees, as indicated. Hence, the depth of the revolution marks is:

$$\frac{(0.1)^2}{4 \times 2.5} \times \sin 45° = 0.000707 \text{ inch, instead of } 0.00024 \text{ inch, as}$$

in the case of the straight rack tooth. It is evident that to produce an equal degree of finish with that left by the rack cutter, the feed must be considerably less for a No. 6 involute gear cutter than for the rack cutter. In Fig. 5 is shown the full range of cutter profiles from Nos. 1 to 8, with the angle of the tangent in each case which determines the quality of the surface under equal conditions of feed and diameter of cutter.

If the depth of the feed marks is used as the determining factor in comparing the condition of the surfaces produced by a series of cutters, it is evident that if the surface produced by the rack cutter is taken as a standard, the feed for cutting a pinion must be considerably less than the feed used for cutting gears with a large number of teeth. In fact, if a rack cutter is fed 0.100 inch per revolution, a No. 8 standard involute gear cutter should not be fed more than 0.055 inch per revolution to produce an equally good surface. The feed is proportional to the square root of the reciprocal of the sine of the angle of the limiting tangent.

If we assume the accuracy of the surface left by the straight-sided rack cutter as equal to 100 per cent, then the relative feeds required for cutting gears with any formed cutter can be calculated. This has been done, and the results are shown plotted in curve A, in Fig. 6. This curve is based on an equal depth of the feed marks for the full range of numbers of teeth in the gears. If, on the other hand, the surfaces left by the cutter for a given feed per revolution are compared, the depth of the feed marks will vary with the sine of the angle of the limiting tangent, and taking the straight-sided rack cutter as a basis, the relative accuracy of the surfaces is inversely proportional to the sine of the angle, and is plotted in curve B, in Fig. 6.

Comparison between Surfaces produced by Milling and Hobbing

A relation has now been established between the quality of the surface and the permissible feeds for cutters for cutting gears with any number of teeth. We will now consider the condition of the surface produced by a hob in a gear hobbing machine. The hob is made with straight-sided rack-shaped teeth and with sides of a constant angle, and is used

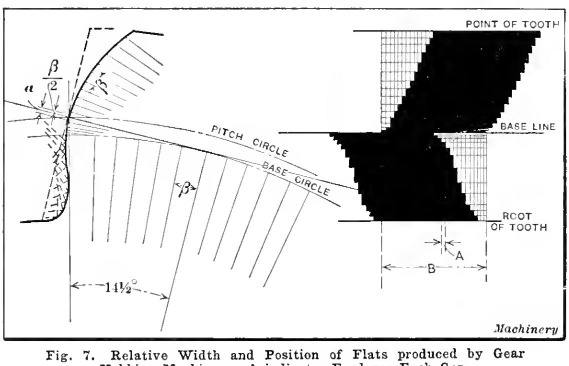

Fig. 7. Relative Width and Position of Flats produced by Gear Hobbing Machines. A indicates Feed per Each Generating Tooth; B, Feed per Revolution of Blank

to produce gears with any number of teeth. We may therefore assume that it is cutting under the conditions governing the rack cutter, as just explained, the surface produced being considered merely as a milled surface. If this assumption be correct, then the quality of the surface produced by a hob, whether cutting a gear of twelve teeth or of two hundred teeth, will be the same for a given feed, and the same relation exists between the hob and any formed cutter that exists between the rack cutter and any formed cutter; hence, curves A and B, in Fig. 6, may be assumed to show the permissible feeds and the quality of the surfaces produced by formed cutters when compared with the surfaces produced by a hob, provided the surfaces are considered merely as milled surfaces. However, a condition enters in the case of the hob which has no equivalent in the case of the formed milling cutter, and this influences the condition of the surface. This condition is the distortion of the hob teeth in hardening which causes them to mar the surface of the tooth by "side swiping," producing a rough surface. The eccentricity of the hob with the axis of rotation also has a different effect on the surface than in the case of a formed gear cutter. The effect is shown in a series of flats running parallel with the bottom of the tooth, if excessive; if the eccentricity is small, the effect will merely be to round the top of the tooth. These inaccuracies, however, can be taken care of in a number of ways.

Comparison of Output

For reasons not connected with the quality of the surface, the hob may be worked at a greater cutting speed and feed

COMPARISON OF TIME REQUIRED FOR CUTTING GEARS ON AUTOMOBILE GEAR CUTTING MACHINES AND HOBBING MACHINES

Number of Teeth	Automatic Gear Cutters		Gear Hobbing Machines

Machinery

than a rotary cutter, when cutting from the solid, the reason being due to the generating action of the hob which results in the breaking of the chips. This preserves the cutting edges and reduces the heating effect of the cut, and explains why the hob may give such good results as compared with a rotary cutter in the matter of output. It is possible to get good results in the general run of work in the hobbing machine in one-third to one-half of the time required in an automatic gear cutter. The accompanying table gives the results obtained on automobile transmission gears with automatic gear cutting machines and hobbing machines. If anything, the conditions under which the comparisons were made favored the automatic machines. The speed of the cutter in all cases was 120 revolutions per minute, except in the case of the 13-tooth pinion, when the speed was raised to 160 R. P. M. to increase the output. The hob was run at a speed of 105 R. P. M., in all cases. The hob and cutters were of practically the same diameter. The results were obtained in producing an ordinary day's work and clearly indicate the advantage of the hobbing process over the milling process, when the quality of the tooth surface alone is considered, on the basis that both processes produce a milled surface.

The Tooth Outline

Going further into the subject, we will take up the question of the tooth outline. The tooth of a gear milled with an ordinary milling cutter must be, or at least is expected to be, a reproduction of the outline of the cutter, and since each cutter must cover a wide range of teeth, the outline is not theoretically correct, except for one given number of teeth in the range. Theoretically speaking, the outline of the hobbed tooth may be considered as a series of tangents, the tooth surface being composed of a series of flats parallel with the axis of the gear. To show the significance of these flats, assume, for example, that a gear with thirty-two teeth is cut with a standard hob, 8 pitch, 3 inches in diameter, having twelve flutes. The length of the portion of the hob that generates the tooth surface is $2\ S \div \tan\ \alpha$, where α is the pressure angle, as indicated in Fig. 4. The number of teeth following in the generating path is:

$$\left(\frac{2\ S}{\tan\ \alpha} \div \text{circular pitch}\right) \times \text{number of gashes.}$$

In this case, the generating length is approximately 0.96 inch, and there are thirty teeth in the generating path. The flats of those parts of the tooth outline which each of the hob teeth form vary in width along the curves. They are of

minimum width at the base line and of maximum width at the point of the tooth. The width of the flats at the pitch circle is proportional to the number of teeth in the gear, the number of gashes in the hob, and the pressure angle. The angle β, to the left in Fig. 7, which is the angle between each flat, is proportional to the number of teeth in the gear and the number of gashes in the hob. In the example given, it is:

$$\beta = \frac{360 \times \dfrac{0.96}{3.1416 \times 4}}{30} = 0.91 \text{ degree, or 55 minutes.}$$

The Width of Flat Produced

The width a of the flat at the pitch line is equal to twice the tangent of one-half β times the length of the pressure line between the point of tangency with the base line and the pitch point, and is:

$$a = 2 \tan \tfrac{1}{2} \beta \times \tan 14\tfrac{1}{2}° \times 2 = 0.0081 \text{ inch.}$$

This is not a flat that could cause serious trouble. As in the case of the feed marks, it is not the width of the flat alone that is to be considered, but the depth must be taken into account; in fact, the quality of the surface may be spoken of as the ratio of the depth to the length of the flat. The depth of the flat is the rise or height of the arc of the involute and is approximately proportional to the versed sine of the angle $\frac{1}{2}\beta$, and with the pitch assumed in the example given, would be 0.000015 inch. It is difficult to conceive of any shock caused by this flat, as the gear teeth roll over each other. The action of the hob and gear in relation to each other further modifies the flat by giving it a crowning or convex shape. In fact, the wider the flat the more it is crowned. This explains the fact that hobs with a few gashes produce teeth of practically as good shape as hobs with a large number of gashes. It is desirable, therefore, to use hobs with as few gashes as possible, because from a practical point of view the errors of workmanship and those caused by warping in hardening increase with the number of flutes.

A peculiar feature of the hobbed tooth surface is shown to the right in Fig. 7, which illustrates the path on a tooth produced by a hob in one revolution. In fact, there are two distinct paths, the first starting at the point of the tooth and working down to the base line, the cutting edges of the hob tooth then jumping to the root of the tooth and working up to the base line, producing the zigzag path shown.

Conclusion

That the flats so commonly seen in the results obtained from the hobbing machine are not due to any faults of the process that cannot be corrected, but are due to either carelessness on the part of the operator in setting up the machine without proper support to the work or to the poor condition of the hob or machine, and that nearly all cases of flats can be overcome by the use of a proper hob, may be assumed as a statement of facts. When the hobbing machine will not give good results, the hob is in nearly all cases at fault. If a gear is produced that bears hard on the point of the teeth, has a flat at the pitch line or at any point along the face of the tooth, do not think that the process is faulty in theory, or that the machine is not properly adjusted, or that the strain of the cut is causing undue torsion in the shafts, or that there is backlash between the gears in the train connecting the work and the hob; these things are not as likely to cause the trouble as is a faulty hob.

After an experience covering all makes of hobbing machines, the writer has come to the conclusion that the real cause of the trouble in nearly every case is a faulty hob. Machine after machine has been taken apart, overhauled and readjusted, and yet no better results have been obtained until a new and better hob was produced. The faults usually met with in hobs were referred to in an article, "Hobs for Spur and Spiral Gears," in MACHINERY, July, 1912. The means for getting the hob into a good working condition were explained in the same article. It is not desired in any way to disparage the formed cutter process in favor of the hobbing process, but simply to state the facts as they appear. In every case, practice seems to substantiate the conclusions arrived at.

CALCULATIONS FOR ROLLER CHAIN DRIVES*

BY O. M. BARTLETT†

There is much that is still to be learned about the action of a roller chain upon its sprockets when running at high speed. Systematically tabulated data bearing on the durability of chains under various conditions of linear velocity, angular velocity, chain pull and numbers of teeth on the sprockets are very meager, and no conclusions have yet been reached by which it is possible to predict the behavior of a given chain under unusual conditions. With a light, steady load, short pitch, and large sprockets, chains have run with perfect satisfaction at speeds as high as 4000 feet per minute; while with heavier loads, and sprockets with but few teeth, chains have been wrecked in a short time at speeds not exceeding 1200 feet per minute.

Under ordinary conditions, however, certain rules derived from experience can be used for chain drives where the speeds range from 400 to 1200 feet per minute. Within these limits the load that can safely be carried by the chain varies inversely as the chain speed. That is, if a chain can work safely under a tension of 400 pounds at a speed of 600 feet per minute, the safe working load at 1200 feet per minute would be only 200 pounds. The load that a chain can carry should be based upon the projected wearing surface of the rivet, and not upon the ultimate strength of the chain. To find the projected rivet area of a chain, multiply the rivet diameter by the length of the bushing. To find the approximate horsepower of a chain for speeds between 400 and 1200 feet per minute, multiply the projected rivet area by 24. This is based upon an allowable pressure of 1000 pounds per square inch of projected rivet area at a speed of 800 feet per minute and of 2000 pounds at 400 feet per minute. To select a chain for a given horsepower, divide the horsepower by 24. The result is the projected rivet area (approximately) of the required chain expressed in square inches.

PITCHES OF CHAINS FOR VARIOUS HORSEPOWERS

Pitch of Chain, Inches	Type of Chain	Horsepower at 400 to 1200 Feet per Minute	Pitch of Chain, Inches	Type of Chain	Horsepower at 400 to 1200 Feet per Minute
1	Solid blocks	$\frac{1}{2}$ to $2\frac{1}{4}$	1	Roller chain	$4\frac{1}{2}$ to 8
1	Twin roller chain	$1\frac{1}{8}$ to 2	$1\frac{1}{4}$	Roller chain	7 to $12\frac{1}{2}$
			$1\frac{1}{2}$	Roller chain	$10\frac{1}{8}$ to 18
$\frac{1}{2}$	Roller chain	$1\frac{1}{8}$ to 2	$1\frac{3}{4}$	Roller chain	$13\frac{3}{4}$ to $24\frac{1}{2}$
$\frac{5}{8}$	Roller chain	$1\frac{3}{4}$ to $3\frac{1}{4}$	2	Roller chain	18 to 32
$\frac{3}{4}$	Roller chain	$2\frac{1}{2}$ to $4\frac{1}{2}$	...	...	...

Machinery

The accompanying table will be found useful in roughly determining the pitch of the chain to be used for a given horsepower. As chains of the same pitch are made of various widths and of various rivet diameters, the range in carrying capacity is rather large. The upper limit is the horsepower that can be transmitted by a chain of the greatest width and largest rivet diameter commonly supplied at the present time. Sprockets with less than 14 teeth should not be used except where the chain speed is low. The center distance, wherever possible, should be at least one and one-half times the diameter of the larger sprocket.

Having determined the pitch of the chain to be used, the pitch diameter, bottom diameter, and outside diameter of the sprockets can be found from the tables usually published by chain makers, or they may be calculated from the formulas:

$$\text{Pitch diameter} = \frac{P}{\sin \dfrac{180°}{N}} \qquad (1)$$

where N = number of teeth in sprocket and P = pitch of chain.

$$\text{Bottom diameter} = \text{pitch diameter} - \text{roller diameter} \qquad (2)$$

$$\text{Outside diameter} = \text{pitch diameter} + P\,(3N - 8) \div 5N \qquad (3)$$

* For further information on the subject of chain drives and allied subjects, see "Standard Sprockets for Detachable Link Belts," published in MACHINERY, August, 1913; "Lineometer for Determining Chain Lengths," May, 1912; "Design of Dished Sprockets," October, 1911; "Worm vs. Chain Drive for Auto Trucks," May, 1911; and "Chain Drives," February, 1909.

† Address: Diamond Chain & Mfg. Co., Indianapolis, Ind.

To estimate the outside diameter roughly, divide the number of teeth by 3 and multiply by the pitch.

To calculate the chain length, let

C = distance between centers;
D = pitch diameter of large sprocket;
d = pitch diameter of small sprocket;
N = number of teeth on large sprocket;
n = number of teeth on small sprocket;
P = pitch of chain;
θ = angle between straight part of chain and line of centers of sprockets.

$$\text{Sin } \theta = \frac{D - d}{2\,C} \qquad (4)$$

L = length of chain in inches

$$= \frac{P}{180}\,[N\,(90° + \theta) + n\,(90° - \theta)] + 2\,C\,\cos\theta. \qquad (5)$$

This gives a theoretical chain length. The actual length must, in general, be enough greater than this to make it an even multiple of the pitch. If, however, a special offset link is used, the chain length will be an odd multiple of the pitch. This sometimes means that there will be a considerable sag in the chain, unless the center distance can be adjusted to take up the slack.

To calculate the center distance for a tight chain, let:

Z = chain length in pitches $= \dfrac{L}{P}$;

C_1 = the center distance for a tight chain, in inches.

$$C_1 = \frac{P}{8}\,[2\,Z - N - n + \sqrt{(2\,Z - N - n)^2 - 0.824\,(N - n)^2}] \quad (6)$$

This is an approximate formula, but it will be found sufficiently accurate for most cases. If greater accuracy is required, continue the calculations as follows:

$$\text{Sin } \theta_1 = \frac{D - d}{2\,C_1} \qquad (7)$$

$$C_2 = \frac{P\left[2\,Z - N - n - (N - n)\,\dfrac{\theta_1}{90}\right]}{4\,\cos\theta_1} \qquad (8)$$

This formula is exact, but the value of θ is only approximate, since it was determined indirectly from Formula (6). The value of C_2 is, however, more nearly correct than that of C_1, and one may obtain any desired degree of approximation by solving (7) with the value of C found in (8), and then solving (8) with the value of θ found in (7). One or two alternations will give a result more accurate than would ever be required in practice.

To calculate the chain velocity V in feet per minute, the chain tension T in pounds, and the horsepower $H.P.$, use the following formulas, in which S will represent the number of revolutions per minute:

$$V = \frac{SNP}{12} \text{ or } V = 0.262\,DS \text{ feet per minute} \qquad (9)$$

where N = number of teeth on sprocket and D = diameter of sprocket in inches.

$$T = \frac{33{,}000 \times H.P.}{V} \text{ or } T = \frac{126{,}283 \times H.P.}{SD} \text{ pounds} \qquad (10)$$

$$H.P. = \frac{VT}{33{,}000} \qquad (11)$$

To find the minimum safe shaft diameter D_1 for a given sprocket:

$$D_1 = 3\sqrt[3]{\frac{H.P.}{S}} \qquad (12)$$

This is for a shaft of mild steel subjected to a twisting moment only. For a shaft subjected to a combined twisting and bending moment, multiply the result of Formula (12) by 1.5. As an example, let it be required to select the chain and sprockets to transmit 15 horsepower from a motor running at 600 revolutions per minute to a lineshaft running at 230 revolutions per minute, the outside diameter of the sprocket on the lineshaft not to be greater than 20 inches, and the center distance to be approximately 40 inches. The projected rivet area of the chain should be not less than H. P. ÷ 24 or 0.625 square inch. A chain is found whose rivet diameter is 7/16 inch; length of bushing, 1.440 inch; projected rivet area, 0.629 square inch; pitch, 1½ inch; diameter of roller, ⅞ inch; width of roller, 1 inch; and ultimate strength, 21,000 pounds. Since the maximum outside diameter of the larger sprocket is 20 inches, the maximum number of teeth will be 40, as found in a table of sprocket diameters. But it is necessary for the number of teeth to be so selected that the velocity ratio will be as close to $\frac{230}{600}$ as possible. Dividing 230 by 600 we have 0.3833 as the decimal equivalent of the ratio. Referring to a table of decimal equivalents of gear ratios, such as may be found in MACHINERY's Data Sheet No. 158 (published in September, 1912), the nearest fraction to 0.3833 with a denominator not greater than 40 is $\frac{5}{13}$ or $\frac{15}{39}$. We may therefore choose 15 and 39 as the numbers of teeth on the driving and driven sprockets, respectively.

Chain velocity $= V = \dfrac{SNP}{12} = \dfrac{600 \times 15 \times 1.5}{12} = 1125$ feet per minute.

Chain pull under full load $= T = \dfrac{33{,}000 \times 15}{1125} = 440$ pounds.

As a lineshaft is usually subjected to both twisting and bending stresses, the minimum allowable diameter would be

$$1.5 \times 3\sqrt[3]{\frac{H.P.}{S}} = 4.5\sqrt[3]{\frac{15}{230}} = 1.811 \text{ inch.}$$

The use of a 1⅞-inch shaft would be good practice.

The chain length is found from Formulas (4) and (5), thus:

$$\text{Sin } \theta = \frac{18.641 - 7.215}{2 \times 40} = 0.142825$$

$$\theta = 8°\ 12'\ 40'' = 8.2111° \qquad \text{Cos } \theta = 0.98975$$

$$L = \frac{1.5}{180}\,[39\,(90° + 8.2111) + 15\,(90° - 8.2111)\,] + 2 \times 40 \times 0.98975 = 121.321 \text{ inches.}$$

The next higher number than this which is an even multiple of the pitch is 123 inches. Hence $L = 123$ inches or 82 pitches. But if the center distance is 40 inches, there will be considerable sag in the slack portion of the chain. To take up this sag, the center distance must be increased to

$$C_1 = \frac{1.5}{8}\,[2 \times 82 - 39 - 15 + \sqrt{110^2 - 0.824\,(24)^2}] = 40.841 \text{ inches.}$$

If this is not thought sufficiently accurate, Formulas (7) and (8) may be used, thus:

$$\text{Sin } \theta_1 = \frac{11.426}{2 \times 40.841} = 0.13988$$

$$\theta_1 = 8°\ 2'\ 27'' = 8.0408°$$

$$\text{Cos } \theta_1 = 0.99013$$

$$C_2 = \frac{1.5}{4 \times 0.99013}\left[2 \times 82 - 39 - 15 - (39 - 15)\,\frac{8.0408}{90}\right] = 40.849 \text{ inches.}$$

This second approximation differs from the first by 0.008 inch. Substituting this value in (7) and (8), we have:

$$\text{Sin } \theta_2 = \frac{11.426}{81.698} = 0.13985$$

$$\theta_2 = 8°\ 2'\ 20'' = 8.0389 \qquad \text{Cos } \theta_2 = 0.99016$$

$$C_3 = \frac{1.5\left(110 - 24 \times \dfrac{8.0389}{90}\right)}{4 \times 0.99016} = 40.848 \text{ inches.}$$

Further approximations would affect only the decimal places beyond the third. This shows that Formula (6) is sufficiently accurate for most practical purposes.

As a final word, it may be pointed out that the life of a chain drive can be greatly lengthened by enclosing it in a case and running it in oil. Also, that both the efficiency and wear will be improved by the use of a strut rod, or its equivalent, rigidly connecting the bearings of the two sprockets, thus preventing relative motion between the sprocket centers.

PUNCHING MACHINE FRAMES*

THEORY OF SHEAR AND PUNCH FRAME DESIGN BASED ON MODERN ANALYSIS OF THE STRESSES

BY O. D. ALBERT†

While numerous articles have appeared dealing with the applicability of the theory of curved bars to such curved members as crane hooks, punch and riveter frames, and the like, the dictates of the theory as to the proper outline for such members have seldom been touched upon.

Careful mathematical and experimental investigation has shown that to approximate the maximum induced stress in a steel or wrought iron crane hook the expression used must take account of the curvature of the member. In the discussion to follow, it will be assumed that the theory of curved bars may be extended to curved members of cast iron, so long as the maximum stress induced does not exceed one-third to one-fourth the ultimate tensile strength of the material. Such limits are imposed, since up to such limiting stresses the stress-strain diagrams for cast iron in tension and in compression are almost straight and practically coincide. It can therefore be assumed without appreciable error that stress is proportional to strain and that the direct modulus of elasticity in compression is equal to that in tension. So far then as these assumptions are concerned there is no more objection to applying the theory of curved bars to curved members of cast iron than to treating straight or slightly curved members of cast iron in the ordinary way.

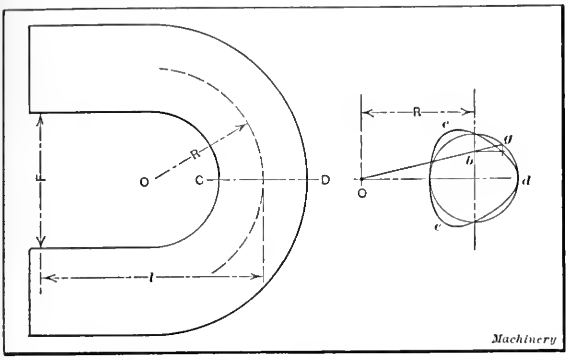

Fig. 1. Diagram indicating Notation in Formulas

The stress in pounds per square inch at any distance x from the gravity axis of the section CD, Fig. 1, is,

$$S = \frac{F}{A}\left[\frac{l}{R-x}\left(\frac{x}{R}\times\frac{a}{a-A}-1\right)+1\right] \qquad (1)‡$$

where x is positive if measured toward, and negative if measured away from, the center of curvature O.

F = the force or load in pounds acting at a distance of l inches from the gravity axis;

A = the area of the section CD in square inches;

R = the radius of curvature at section CD of the curve passing through the centers of gravity of the sections of the member;

$a = \int\left(\frac{R}{R-x}\right)\delta A$ = the area in square inches of a figure derived from the original section CD.

The expression given above takes account of the curvature of the member, but does not, as does the more complete analysis of Pearson and Andrews, take account of the lateral or transverse strains. For this reason it would, for the case illustrated in Fig. 1, indicate a somewhat lower maximum tensile stress and a somewhat higher maximum compressive stress than the more complete theory. To neglect, however, the lateral strains greatly simplifies the resulting expression, giving one that is quite easily handled and sufficiently accurate for all ordinary purposes, since in it account is taken of the curvature of the member which is the chief factor affecting the induced stress.

For irregular sections it is best to determine a graphically. Where, however, the section is made up of regular figures such as rectangles, triangles, or trapezoids, it is, as a rule, more accurate and easier to determine a algebraically. In any case a should be very carefully determined, since it is evident that any appreciable error will affect the ratio $\frac{a}{a-A}$, and therefore the results, quite seriously.

In Fig. 1, to the right, is shown how, from the original section, which in this case is circular, the derived figure *cde* is obtained graphically. From any point g on the outline of the section under consideration draw a radial line to the center of curvature O; through the point b where this radial line crosses the gravity axis draw a perpendicular; the intersection of this perpendicular through b with a line through g parallel to the gravity axis, locates a point on the outline of the derived figure *cde* the area of which is a.

Application to Punch Frame Sections

In Fig. 2 is shown a form of hollow section often used for punching machine frames, the filleting and rounding of the corners having been omitted. This section can for convenience be drawn in the form shown to the right and treated as made up of the rectangles A, B and D, and the trapezoid C.

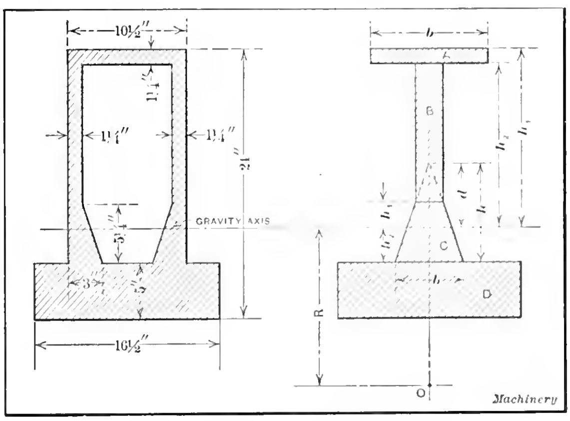

Fig. 2. Typical Section of Punch Frame

For any one of the rectangles A, B, or D:

$$a = \int\left(\frac{R}{R-x}\right)\delta A = Rb \text{ hyp. log}\left(\frac{R-h_1}{R-h_2}\right)$$

For the trapezoid C (or a triangle):

$$a = \int\left(\frac{R}{R-x}\right)\delta A =$$

$$R\frac{b}{h}\left[(d+R)\text{ hyp. log}\left(\frac{R-h_1}{R-h_2}\right) - h_2 + h_1\right]$$

To illustrate the purpose of this article as stated in the opening paragraph, a cast-iron frame for a machine to punch ⅝-inch holes in ⅝-inch plate will be taken up, the maximum resistance to punching being taken at 77,000 pounds. The frame and general dimensions shown in Fig. 3 will be found to be in fair agreement with machines of a like capacity.

In order that the radius of curvature for the horizontal or 0-degree section might in all cases be taken as the inner

* The following articles on kindred subjects have previously been published in MACHINERY: "The Design of Curved Machine Members under Eccentric Loads," December, 1909; "The Designing of Machine Frames," August, 1908; "Strength of Punch and Shear Frames," February, 1907; "Design of Punch and Riveter Frames," November, 1903.

† Assistant Professor, Department of Machine Design and Construction, Sibley College of Mechanical Engineering, Cornell University, Ithaca N. Y.

‡ The expression given is the same as that in Morley's "Strength of Materials," page 325, although it is given here in a slightly different form.

radius of the throat plus the distance from the gravity axis to the outermost fiber in tension, the cross-section of the frames for 20 degrees each side of the horizontal was kept the same. Furthermore, for the frame outlines illustrated in Figs. 3, 4 and 5, the 0-, 20-, 45-, 67½- and 90-degree sections have been kept the same in each of the three designs shown, the changes in outline being due to changes in the inner radius of the throat. The horizontal section for these frames is shown in Fig. 2.

For the purpose of the conclusions to be drawn the maximum tensile stress at the horizontal section and at the 45-degree section for each of the three frames illustrated in Figs. 3, 4, and 5 will next be computed. First the curvature of the frames will be neglected and the stresses found in the ordinary way; then the curvature of the frames will be considered and the corresponding stresses found.

For the frame shown in Fig. 3 the following values obtain:

Section	0	20°	45°	67.5°	90°
e	8	8	7.65	6.95	6.05
A	149.20	149.2	145.75	....	126.60
I	8487.00	....	7582.70	....	....
a	190.08	....	239.64	....	....
R	14.00	....	9.75	....	....

Machinery

In the table above,

e = distance in inches from gravity axis to the outermost fiber in tension;
A = area of section in square inches;
I = moment of inertia of section;
a = area in square inches of derived figure;
R = radius of curvature in inches.

Calculations Taking no Account of Curvature

Neglecting the curvature of the frames, the maximum tensile stress at the horizontal section for each of the three frames illustrated in Figs. 3, 4, and 5 is:

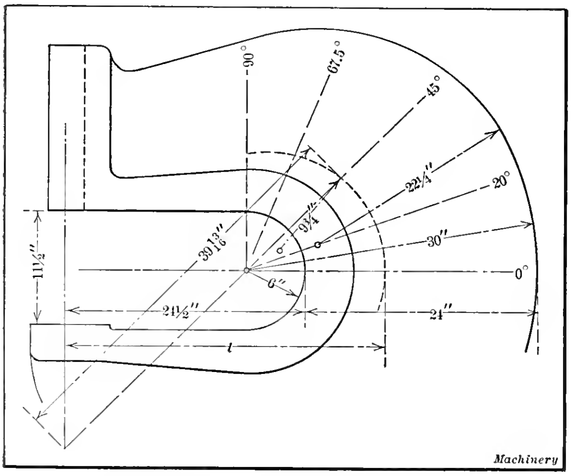

Fig. 3. Design of Punch Frame as commonly made

$$S_t = \frac{F}{A} + \frac{Fle}{I} = \frac{77{,}000}{149.2} + \frac{77{,}000 \times 32.5 \times 8}{8487} = 2876 \text{ pounds per}$$

square inch.

The maximum tensile stress at the 45-degree section due to flexure and direct stress is, for the frame shown in Fig. 3:

$$S_t = \frac{F \cos 45}{A} + \frac{(F \cos 45)\, le}{I} = \frac{54{,}450}{145.75} + \frac{54{,}450 \times 39.8125 \times 7.65}{7582.7} = 2560 \text{ pounds per square inch.}$$

The shearing stress over this section is $S_s = (F \sin 45) \div A = 374$, and the maximum resultant tensile stress is:

$$S = \tfrac{1}{2}\,[S_t + \sqrt{S_t^2 + 4\,S_s^2}\,] = \tfrac{1}{2}\,[2560 + \sqrt{2560^2 + 4 \times (374)^2}\,]$$
$$= 2615 \text{ pounds per square inch.}$$

For the frame shown in Fig. 4, the distance from the center of gravity of the 45-degree section to the intersection of the 45-degree plane with the line of action of the load is 39 inches; for the frame shown in Fig. 5 this distance is 38⅛ inches. The 45-degree sections for these frames being the same as for the frame in Fig. 3, the maximum resultant

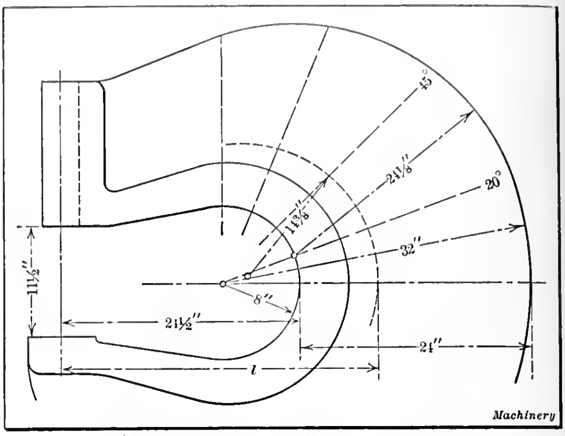

Fig. 4. An Improved Design of Punch Frame

tensile stress at the 45-degree section is for Fig. 4, 2566, and for Fig. 5, 2525 pounds per square inch.

Thus it is seen that, disregarding curvature, the frames are practically of uniform strength, but slightly weaker at the horizontal than at the 45-degree section.

Calculations Taking Account of Curvature

Considering the curvature of the frames the maximum tensile stress at the horizontal section for the frame in Fig. 3, is:

$$S_t = \frac{F}{A}\left[\frac{l}{R-e}\left(\frac{e}{R} \times \frac{a}{a-A} - 1\right) + 1\right]$$

$$= \frac{77{,}000}{149.2}\left[\frac{32.5}{14-8}\left(\frac{8}{14} \times \frac{190.08}{190.08 - 149.2} - 1\right) + 1\right] = 5150$$

pounds per square inch, or a value 1.79 times as great as that indicated by the ordinary method of computation.

For the 45-degree section frame, Fig. 3, the values obtained when considering curvature are more or less approximate, since the center of curvature does not fall in the plane of the section. So far, however, as the probable maximum stress in the section is concerned the calculation, considering curvature, is far more indicative of the true state of stress than the ordinary method not considering curvature.

The maximum tensile stress in the 45-degree section due to flexure and direct stress is for the frame in Fig. 3:

$$S_t = \frac{F \cos 45}{A}\left[\frac{l}{R-e}\left(\frac{e}{R} \times \frac{a}{a-A} - 1\right) + 1\right]$$

$$= \frac{54450}{145.75}\left[\frac{39.8125}{9.75 - 7.65}\left(\frac{7.65}{9.75} \times \frac{239.64}{239.64 - 145.75} - 1\right) + 1\right]$$

= 7450 pounds per square inch.

The augmentation due to the direct shear would raise this value, computed by the method illustrated above, to approximately 7475, or a value 2.86 times as great as that indicated by the ordinary method neglecting curvature.

The radius of curvature for the 45-degree section was determined graphically. While by this method it is perhaps impossible to say just what the exact value of the radius is, it is entirely possible to obtain a value slightly less rather than over the exact value, and thus be on the safe side.

For the frames in Figs. 4 and 5, the inner radius of the throat has been changed from 6 inches to 8 and 10 inches, respectively. The radius of curvature at each of the various sections is therefore increased with a consequent change in the value of a. For these frames the following values obtain:

	Horizontal Section		Forty-five Degree Section	
	Fig. 4	Fig. 5	Fig. 4	Fig. 5
e	8	8	7.65	7.65
A	149.2	149.2	145.75	145.75
a	179.14	172.64	178.135	173.45
R	16	18	14.375	15.625
I	32.5	32.5	39	38.125

Machinery

Results Obtained from Calculations

Having the above values, the maximum tensile stresses at the horizontal and 45-degree sections can be found. Tabulating these and the values already found we have:

Conditions		Fig. 3	Fig. 4	Fig. 5
Horizontal section	Curvature neglected	2875	2875	2875
	Curvature considered	5150	4685	4320
45-degree section	Curvature neglected	2615	2566	2525
	Curvature considered	7475	4570	4110

Machinery

So far as the horizontal section is concerned, the frame in Fig. 4 has an advantage of about 9 per cent, and the frame in Fig. 5 of about 16 per cent over the frame in Fig. 3. Now, since the breaking load for a frame cannot be computed by either method, it would seem, for the particular frame taken up, that, in so far as the horizontal section is concerned, the curvature of the frame might be neglected in our computations, if a proper limiting stress be chosen. To make such a deduction on the basis of the above problem and to extend it to any punch frame would, however, be a mistake since it is evident from Formula (1) that the maximum induced stress in such a member depends very largely on the relation of the radius of curvature to the size and general proportions of the section. The results of the computations on the 45-degree sections very well illustrate this.

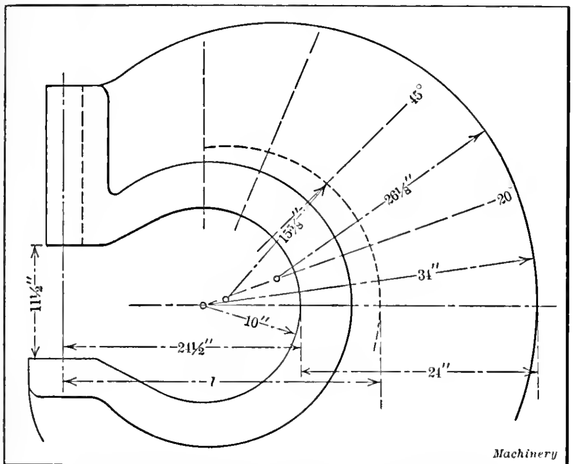

Fig. 5. A Further Improvement in Punch Frame Design

The computations, curvature considered, show the frame in Fig. 3 to be considerably weaker at the 45-degree section than at the horizontal section; the computations neglecting curvature show the reverse of this. The tabulation, curvature considered, shows the stress in the 45-degree section for the frame in Fig. 3 to be much higher than that in the horizontal section, and the stresses in the horizontal sections of the frames in Figs. 4 and 5 to be higher than in the 45-degree sections. On this basis the frame in Fig. 4 has an advantage of approximately 37.5 per cent and the frame in Fig. 5 an advantage of approximately 42 per cent over that in Fig. 3.

Conclusion

Apparently, then, that there may not be any abrupt changes of stress in the frame, there should not be any abrupt changes of curvature in the curve passing through the centers of gravity of the sections. Furthermore, the radius of curvature at the horizontal section should be as great as possible and the value of the radius of curvature at any other section as we pass forward should be as little below that at the horizontal as possible. The inner outline of the throat should, therefore, be a smooth curve with no abrupt changes of curvature. The frames in Figs. 4 and 5 suggest a way in which the above requirements may be met, due account being taken of appearance and the general limitations of the problem, and are much to be preferred to the frame in Fig. 3.

THE SAFEGUARDING OF BELTS, SHAFTS AND PULLEYS

The following concise rules have been issued by a large British steel company with a view to preventing accidents in the company's mills, arising from moving belts, shafts or pulleys. The rules are practical and concisely stated, and may be of considerable value in formulating similar rules to meet the conditions in other plants:

Belt, rope, and cable transmission should be arranged, so far as possible, to be easily guarded.

Pipe or angle railing placed 18 inches from the pulley or belt should be provided where there is but little danger of persons getting caught by the belt.

Wire-mesh or perforated-plate casing should be provided where the location of the belt is such that persons are likely to get caught between the belt and the pulley.

Where the belt is located in such a position that, should it break, flying ends would strike passers-by, it should be enclosed by a suitable guard.

The width of a belt should be allowed between two pulleys or a pulley and a hanger on shafting so as to prevent the belt from becoming wedged and possibly pulling the line-shafting down.

Belt splicing should be made so as to eliminate ragged edges or projections which might catch employes' clothing. Endless belts are recommended, especially for high-speed machines.

Belts should be inspected frequently and kept in a condition to avoid accidents. Tight belts should be avoided.

Wherever it is necessary to shift belts a mechanical device should be provided.

Where it is necessary to unship a belt, a hook or belt-perch should be provided to prevent the belt from resting on the shaft.

Shafting not over 12 inches above floor should be covered.

Shafting over 12 inches and not over 7 feet above floor should be encased or railed off.

Exposed ends of shafting should be encased or otherwise guarded.

Overhead shafting which must be oiled should be equipped with a walk for the oiler, if practicable.

Electrically-driven shafting should be provided with a safety switch, to be used when men are working on it. This switch should be placed at the top of the ladder or in some place where no one will tamper with it.

Shaft couplings should be guarded where a safety coupling is not used.

To prevent gears or pulleys from working off the ends of shafting, shaft ends should project at least the diameter of the shaft beyond the hub of the gear or pulley, so that the key can be locked in place.

Hangers for shafting should be particularly strong and well secured.

All projecting keys in shafting, when exposed so that a person might get caught thereon, should be guarded or cut off.

Wherever possible, cotter pins or spring washers should be provided to prevent nuts from working off the ends of bolts.

Set-screws should be guarded, countersunk, or placed in safety collars with flanges high enough so that the set-screw head will not project above the flange.

POWER REQUIRED FOR ROLLING METAL*

Twenty-eight years ago the writer was asked to compute the power required to roll billets to rods, and also the power required to draw the same rods to wire. It was first necessary to assume a common unit for comparison. One base only appeared rational, the power required to cause a unit reduction of a unit mass in a unit time. The units the writer first adopted were a unit reduction of 50 per cent or doubling of the length; a unit mass of one ton; and a time unit of one minute. This gave a formula

$$H. P. = CTD$$

where C = constant;

T = tons worked per minute;

D = doublings or number of times the length has been doubled.

A table of lengths and doublings was prepared corresponding with each successive per cent reduction from 1 to 99 per cent. The last column of this table was a table of logarithms having 2 for a base. For example:

50 per cent reduction = length 2.00 log 2.00 = 1;

75 per cent reduction = length 4.00 log 4.00 = 2; etc.

As is well known, the logarithms of any base are made by multiplying common logarithms by the reciprocal of the common logarithm of the desired base, or, in other words, by a constant. Hence, the formula is more available when common logarithms are used, and it becomes

$$H. P. = CT \log E$$

where

$$E = \text{elongation} = \frac{\text{length after rolling}}{\text{length before rolling}}.$$

This simply changes our unit reduction from 50 to 90 per cent; 90 per cent reduction gives an elongation of 10 to 1, and 10 is the base of our common logarithms which are universally available. In the above formula, C is a constant when other conditions are constant, but other conditions are seldom constant. Careful and extended dynamometer tests of cold-rolling relatively wide strips of commercially pure aluminum showed clearly that the power required increased somewhat faster than $\sqrt{\frac{D}{t}}$ where

D = roll diameter,

t = finished thickness.

This changes the formula to

$$H. P. = CT \log E \sqrt{\frac{D}{t}}.$$

Commercially pure aluminum was chosen because its malleability is perhaps exceeded only by gold and silver, and it does not harden appreciably with continued rolling. Averages of repeated tests plotted on logarithmic cross-section paper from the above formula appear to indicate that the power does increase almost directly as $\sqrt{\frac{D}{t}}$, between the values $\sqrt{\frac{D}{t}} = 5$ and $\sqrt{\frac{D}{t}} = 10$. After passing the latter point, the power required increases more rapidly, until for values $\sqrt{\frac{D}{t}} = 15$ the unit power required was 30 to 50 per cent more than that called for by the formula. Perhaps this was partly due to the hardening of the aluminum by the continued rolling, but is not much of it due to the increased ratio between the arc of contact and the thickness of the metal? In other words, is it not true that more pressure per unit area is required to compress a very thin sheet of metal between two flat plates than would be required to compress a much thicker sheet? The diagram previously referred to, for showing the relative work required to roll plates of varying final thickness and percentage reductions, also seemed to indicate that from 40 to 60 per cent reductions are the most economical in the use of power; that reductions less than 30 per cent are extravagant in power consumption, due perhaps to an excessive proportion of journal friction; and that rough rolls require much more power than smooth rolls.

Temperature is another factor nearly as important as roll diameter. Someone has covered this in what appears to be a perfectly logical way, by assuming that the power varies directly with the tensile strength of the bar being rolled. Adding this makes the formula quite complete:

$$H. P. = CT \log E \sqrt{\frac{D}{t}}\, S$$

in which S = tensile strength at the rolling temperature.

This formula clearly shows why a continuous sheet bar mill may require more power to deliver a bar 1/4 inch thick than it does to deliver twice the tonnage at the same speed of a bar 1/2 inch thick, and only slightly warmer. It is interesting and easy to remember that through nearly the entire range of rolling temperatures, a reduction of 400 degrees F. practically doubles the tensile strength and hence the power required to roll. The formula also shows why small rolls and high speeds will conserve temperature and power.

At least one more factor is necessary to make the formula complete, *viz.*, the efficiency of the pass. Obviously, the metal can take the speed of the roll at one point only in the arc of contact. At all other points the metal must slip either against the face of the roll or internally. As an example, it is well known that a barrel hoop may deliver fully 10 per cent faster than the surface speed of the roll. This slipping, either external or internal, requires and wastes power. The smoother the roll, the less power wasted.

Cold-rolling is done in oil and all rolls for cold work are ground as true and smooth as possible. Should not the same reason lead us to grind with much care all rolls for hot work that can be so finished? Less power is required, the rolls last longer and better work is produced. The foregoing applies to plain, flat passes.

The efficiency of all shaped passes decreases as the slipping increases. This loss of efficiency is especially noted in some of the passes used for rolling rails, but the benefits from using such passes may fully warrant the resulting excess roll wear and power. Light reductions have a low efficiency. It may not be easy to get a formula that will cover the efficiency of a pass, but it should not be overlooked in computing power requirements.

* Abstract of a paper presented before the Engineers' Society of Western Pennsylvania, Pittsburg, Pa., by Victor E. Edwards.

UNIQUE POWER PLANT FOR FORD MOTOR CO.

The Ford Motor Co. has placed contracts for a gas engine-electric power plant that will be not only one of the largest in the country, but in many respects absolutely unique. The company has appropriated about a million dollars for the project, which will put into effect plans that Henry Ford has long had in mind for utilizing the waste heat of the ordinary producer gas engine. Four 6000 H. P. Hamilton-Gray gas engines of novel design will drive four Crocker-Wheeler 3750 K.W., 250 volt, 80 R. P. M. engine type direct-current generators. A plan view of each engine will be similar to a cross-compound steam engine, with two cylinders in tandem on each side. One pair of cylinders will be operated by producer gas and the other by steam. The steam will be generated from the water used in the water jacket of the gas engine, further heated by the exhaust gases and by waste heat from the producer gas plant. This water or steam will be used as the feed water for the boiler which supplies the steam engine cylinders. A heavy flywheel will equalize the characteristics of the gas and steam driven elements of the engine. These generators are designed for much higher efficiency than is ordinarily found in commercial practice. Full load efficiencies will be not less than 94½ per cent. By these means and by the utilization of energy usually lost in waste heat, it is proposed to make the new Ford power plant the most economical in the country in respect to cost of production per kilowatt hour. The armatures will be of split construction which is necessitated by clearance requirements through tunnels and bridges in shipment from Ampere to Detroit, and the generators will be finally assembled at the Ford plant.

MAKING SECTIONAL DIE PARTS*

SOME TOOL-MAKING METHODS AND TOOLS EMPLOYED BY THE COLUMBUS DIE, TOOL & MACHINE CO.

BY DOUGLAS T. HAMILTON†

The making of sectional dies for armature disks and work of a similar kind calls for considerable ingenuity on the part of the toolmaker in devising means for producing these parts accurately and economically. It is necessary, if the best results are to be obtained, to secure a steel which will not warp or distort during the hardening process so that grinding of the parts after hardening need not be resorted to. Should the die and punch sections warp or shrink, it adds greatly to the difficulty of manufacturing the parts and greatly increases the cost of the tool. In many cases grinding of the die and punch sections is necessary, so that special devices and tools have been devised for handling this work as expeditiously as possible. In the following article, a number of the most interesting methods employed by the Columbus Die, Tool & Machine Co. of Columbus, Ohio, will be given. This company makes a specialty of producing for various firms punches, dies, tools and special equipment, and therefore is in a position to devise means for getting this work out in the shortest possible time.

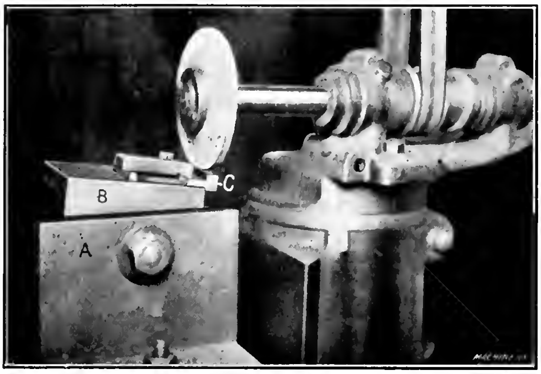

Fig. 1. Grinding the Die Sections

Grinding the Die Sections

In order that the die sections will fit properly in place after hardening and give the required outside and inside diameters, it is necessary to leave a slight amount of excess stock on the sides of the sections that fit against each other in the die holder. These sides are then ground to the required angle and thickness in a special fixture. The toolmaker figures out the required angle of the side sections and also the least or greatest thickness. The type of fixture used for grinding these die sections is shown in Fig. 1. It consists of an ordinary angle-plate *A* which is fastened to the table of a grinder of the surface type, and against which is held another angle-plate *B* that can be set around to the desired angle and carries the work to be ground. The work or die section *C* in this case is held in place by a special toe clamp, and when one side of the section is ground it is reversed and the other side is ground.

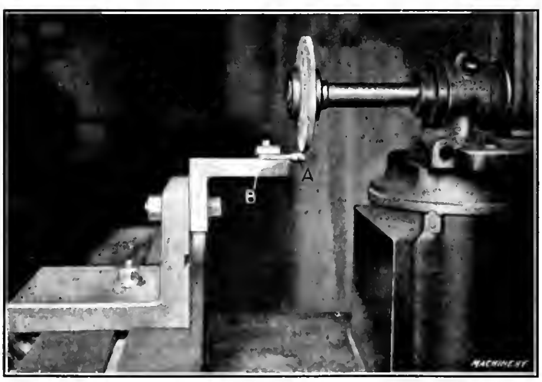

Fig. 2. Grinding the Punch Sections

The sides of the punch sections are ground in a similar manner on the same fixture which, however, is swung around into the position shown in Fig. 2. The punch section *A* is held to the small angle-plate *B* as illustrated, and when one side is ground the section is reversed on the angle-plate and the other side finished. When the fixture has once been set up, however, all the punch or die sections are ground on one side first. Then the setting of the machine is changed and the other side of all the sections ground. This enables the toolmaker to turn out the work much more quickly than if he were to reset the machine for both sides of the piece, thus finishing it complete without removing it from the fixture to put another in its place.

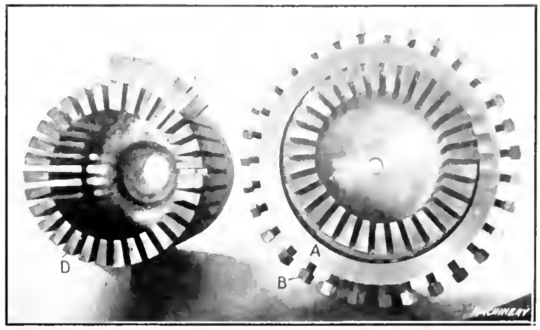

Fig. 3. Special Chucks for holding Die and Punch Sections while Grinding

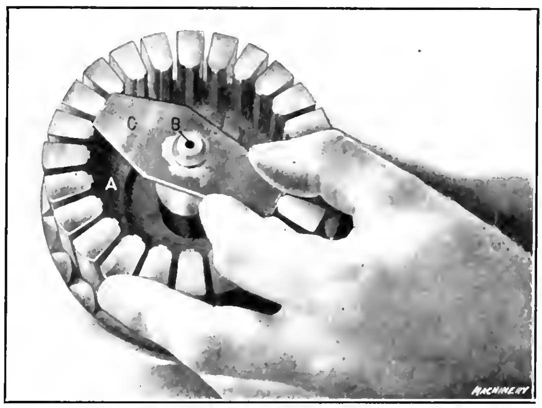

Fig. 4. Assembling a Sectional Armature Disk Punch

Special Chucks for Holding Die and Punch Sections while Grinding

In Fig. 3 are shown two special chucks which are used for holding punch and die sections while grinding the inside and outside diameters and the top and bottom faces, so that all the important machined surfaces can be finished at the same setting. The special chuck for holding the die section is shown to the right of the illustration. This, as can be clearly seen, consists of a cup-shaped body *A* around the periphery of which are located set-screws *B*. These set-screws bear against the backs of the section and bind them together, the beveled surfaces of the punch section being wedged together by the action of the set-screws, and consequently held rigidly in place for the grinding operation. The grinding is accomplished in a cylindrical grinding machine, the chuck being screwed to the nose of the spindle in the ordinary manner. The outside surfaces are ground tapered to an angle of 5 degrees to enable them to be held in place in the punch holder by a retaining ring.

* For further information on sectional punch and die work, see "Punch and Die made in Sections," March, 1913, and "Sectional Punch and Die Construction," July, 1913.

†Associate Editor of MACHINERY.

The special chuck for holding the die sections for grinding is shown to the left of the illustration. Here only four die sections C are shown in place, simply to indicate the manner in which they are held. The narrow portion of the die section is a drive fit in the slots of the die holder and these sections are tapped lightly into place until the beveled surfaces contact. The chuck D is also held in a cylindrical grinder, being screwed to the nose of the spindle as previously mentioned in connection with the chuck for the punches. This chuck enables the inside and outside diameters of the die sections to be ground and also the top face. The lower face is ground by reversing the position of these sections in the chuck, and then holding them in the manner in which they are held in the illustration.

Assembling an Armature Disk Punch

After the beveled sides of the punch sections have been ground, it is then necessary to test these sections to see whether the correct inside and outside diameters have been secured, and also if the small projections on the inner surfaces of the punch sections are properly located axially. This, of course, proves whether the correct amount of stock has been ground from the sides of the punch sections. The fixture used for this purpose is shown in Fig. 4 and consists of a block A, circular in shape, in which a stud B is located. This stud acts as a means for holding the gage C, which as can be seen, is cut out to fit over the projections on the punch sections and is also fitted over the stud, being centrally located in this manner. In this particular case, a limit of only 0.0005 inch is allowed from the center of the plug to the inside face of the punch section. Also the blank must be re-

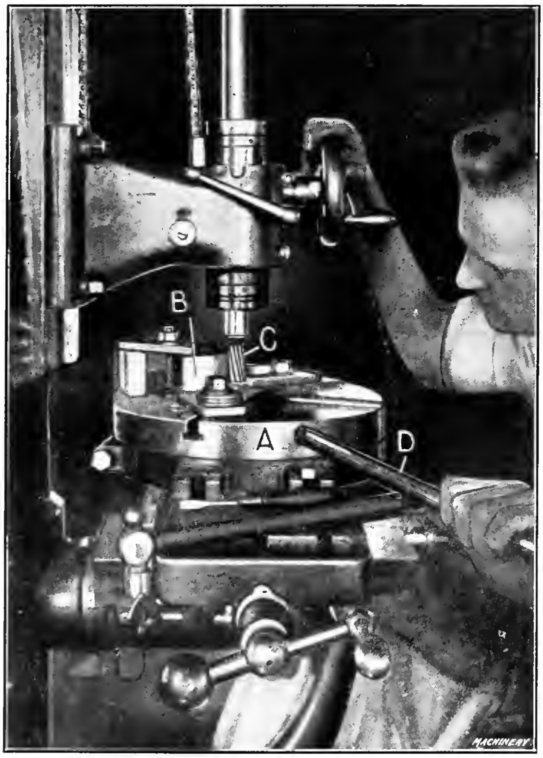

Fig. 5. Milling Segments for Pole-piece Punches

versible on the punch. When it is realized that these dimensions are governed entirely by the amount of metal removed from the sides of the sections, it will be seen that the grinding operation is one that must be very carefully handled and that requires considerable ingenuity on the part of the toolmaker if the parts are to assemble accurately.

Milling Segments for Pole-piece Sectional Punches

Fig. 5 shows how segments for pole-piece sectional punches are milled both on their circular and angular faces. A Knight milling and drilling machine is used for this purpose, being equipped with a circular milling attachment A. The section B of the pole-piece punch to be machined is clamped to the top face of the circular milling attachment by clamps as illustrated, and the machining is accomplished by an end-mill C held in the spindle of the machine. The circular attachment is operated by a bar D which can be located in holes provided around the periphery of the faceplate. For milling the beveled faces, the circular attachment is clamped to prevent it from rotating and the feed-screw for the table is operated.

Boring Sub-press Die Guide Pin Holes

After all the various members of the sectional punch and die have been completed, they are assembled in the punch and

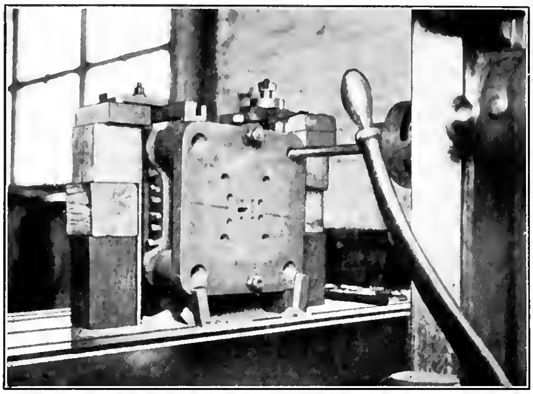

Fig. 6. Boring Sub-press Die Guide Pin Holes

die holders and then the next operation is to bore the holes for the aligning pins, when the dies are of the sub-press construction, which is the usual type of construction adopted for complicated sectional punches and dies. The manner in which these guide pin holes are machined is shown in Fig. 6. The punch and die holder are located in the proper relation to each other and are fastened together by through bolts as illustrated. Then these holders for the sectional members are located on the table of a milling machine and the holes are first drilled and then bored by a boring tool held in the spindle of the machine. The two lower holes are bored and counterbored first, the center distances, of course, being located by the micrometer dial on the feed-screw. Then the table is lowered and the top or two remaining holes are bored and counterbored in a similar manner. This method of boring the guide pin holes enables them to be produced quickly and accurately with very little difficulty.

* * *

One of the most important iron mines in the world is the Loussavaara-Kürunavaara, situated at Kiruna, Lapland, in latitude 68½ degrees north, which is about the same as the northernmost boundary of Alaska. The climate is somewhat milder than in Alaska, and these mines are worked the year round. About 1600 men are employed. The plant is operated by steam power, the coal coming from England and Spitzbergen. The electrification of the mine is in progress, and this power will be used exclusively as soon as the new power plant of the Swedish government, now under construction at Porjus Falls, is completed. The capacity of this station will be 150,000 H. P. to be transmitted at 78,000 volts over a distance of 150 miles. The ore is shipped from Kiruna to Narvik on the Norwegian coast by rail, and from there by water to Germany, a small percentage finding its way to other countries. The ore is magnetite and contains from 53 to 68½ per cent iron. Owing to the comparatively large content of phosphorus it was impossible to utilize it until the Thomas furnace was developed.—*Daily Consular Report.*

At the International and Colonial Exhibition to be held in Genoa, Italy, beginning in March, there will be an interesting section devoted to showing methods of packing for export. There will be nine different lines of goods exhibited with the proper packing for each, one of these lines being packing required for machinery.

DRILLING AND TAPPING FIXTURE

BY CHRISTIAN F. MEYER*

The drilling and tapping fixture to be described in this article was designed for machining holes in the bed of a textile machine. Fig. 1 shows a section of the bed *A*; this bed is about 30 feet long and is supported by legs *B*. After the bed has been machined, a number of other parts are assembled on it, the finished surface of the bed being used as a base in lining up the other members. When the assembling has been completed, a number of holes *a* are drilled and tapped in the bed to receive guide pins *C*. These guide pins are screwed into different holes in the bed according to the kind of fabric that is to be woven, and it is very important to have them exactly perpendicular to the top surface of the bed *A*. They must also be accurately located in relation to other members of the machine. These conditions make it impossible to remove the bed from the machine, after it has been assembled, in order to drill the holes, and as a result it was necessary to devise a fixture which would make it feasible for the holes to be drilled and tapped with the bed in position. The drilling was formerly done with an electric drill, after which the holes were tapped by hand. This method required a considerable amount of time and the results obtained were unsatisfactory. Great care and a good deal of skill had to be exercised in order to get the holes perpendicular to the upper surface of the bed.

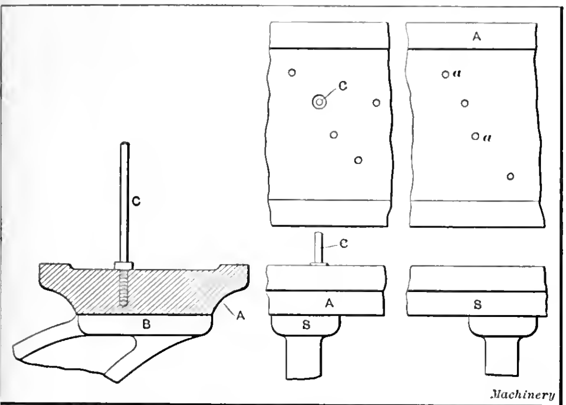

Fig. 1. Machine Bed for which the Drilling and Tapping Fixture was designed

In order to eliminate the difficulties experienced in machining these holes by hand, the drilling and tapping fixture illustrated in Figs. 2, 3 and 4 was designed. It consists of a cast-iron base *D* which is made to slide along the surface of the bed *A*. After the longitudinal position of the fixture has been adjusted the fixture is held securely by means of hexagonal headed set-screws and a clamping gib. It will be seen that this gib is held in place in the fixture by means of the cover *E*. The base *D* supports an upper slide *F* which is held in any desired position by means of a clamping gib and set-screws. Referring to the plan and sectional views shown in Figs. 3 and 4, it will be seen that the slide *F* has a lug *G* at its rear end. This lug is tapped to receive an adjusting screw which is held against longitudinal movement by means of collars at each side of the end plate *H*.

It will be seen that the slide *F* carries a round boss about which the bushing *I* can be revolved. This bushing is held in any desired position by means of a set-screw. The tool-holder *K* revolves about the bushing *I* and is supported by the flange at its lower end. It will be seen from Figs. 2 and 3 that the tool-holder is provided with three arms *L*, *M* and *N*. The centering arm *L* is provided with a long "feeler" which slides in a vertical bushing and can be fastened in the desired position by a set-screw. The drill-arm *M* carries a steel bushing which is provided with rack-teeth. The bushing and rack slide on the arm, the movement being obtained by a pinion which provides for feeding the drill. The pinion shaft has a hub at its outer end which is provided with a hand-lever *T* for operating the feed mechanism. The drill spindle *W* revolves in the bushing and is driven by a direct-connected motor *R* which is mounted on a bracket at the rear of the tool-holder. It will be seen that this motor transmits through a pair of spur gears, the shaft *k* and the bevel gears *Q*. The bracket *S* is provided at the front of the tool-holder to support the shaft *k* and the lower bevel gear *Q*. The movement of the drill spindle is limited by a stop-pin *m* carried by the bushing which slides in a slot in the arm *M*. The weight of the spindle is counterbalanced by a weight located inside the boss on the slide *F*.

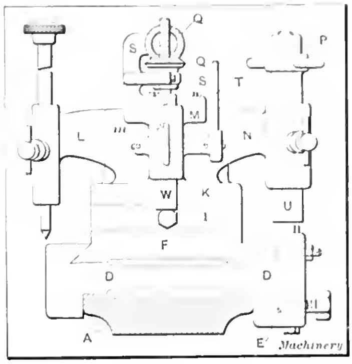

Fig. 2. Front View of the Drilling and Tapping Fixture

The tapping-arm *N* carries a steel bushing which may be held in any desired position by a set-screw. The spindle *U*, which revolves in this bushing is made with its lower end of the same diameter as the bushing. This section of the spindle is separated from the bushing by means of a leather washer, and two nuts *P* are used to draw the spindle *U* up against the base of the bushing. It will be seen that a similar leather washer is provided between the lower nut *P* and the top of the bushing. The bushing is turned by hand levers and when the nuts *P* are tightened, it will be evident that the spindle is driven by the friction of the leather washer. If the resistance of the tap becomes great enough to overcome this friction, the rotation of the spindle will be stopped, and the friction is adjusted so that slippage will occur before the resistance is great enough to break the tap.

It will be seen from the sectional view, Fig. 4, that the tool-holder *K* carries a boss on the opposite side to the arm *M*. This boss is drilled to receive the taper index pin *V* which is pressed inward by a compression spring. The taper section of the pin *V* fits into three corresponding holes in the bushing *I*, these holes being drilled radially so that their center lines and the center lines of the arms *L*, *M* and *N* all intersect at the center of the bushing. The index holes in the bushing are located 60 degrees from each other, the arms of the tool-holder being located similar distances apart. From the preceding it will be evident that the three spindles of the fixture will be located at exactly the same point over the work when held by inserting the index pin into successive holes in the bushing *I*.

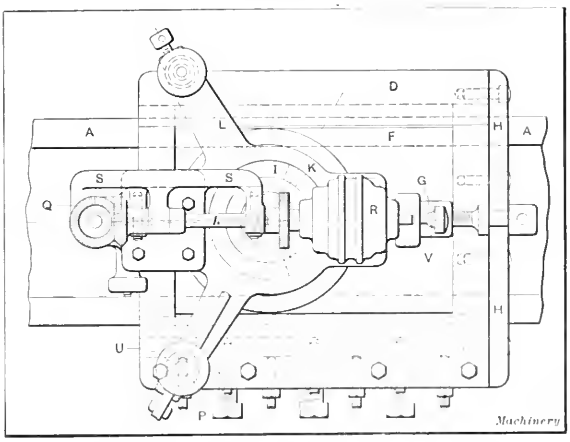

Fig. 3. Plan View of the Drilling and Tapping Fixture

The operation of this drilling and tapping fixture may be briefly described as follows: The holes to be drilled and tapped are first laid out on the top surface of the bed of the machine. The fixture is then mounted in position and slid along the bed to the first group of holes. It is fastened in this posi-

* Address: Garfield Ave., Wyomissing, Pa.

tion by tightening the set-screws against the gib. The feeler-arm *L* is next located by first inserting the index pin *V* in the proper hole; then by revolving the bushing *I* and using the adjusting screw to regulate the position of the slide *F*, the point of the center punch is brought into coincidence with the center of one of the holes. Bushing *I* is then fastened by tightening the set-screw. The index pin is then withdrawn and the tool-holder *K* is revolved through 60 degrees, when the index pin is forced into the next hole in the bushing *I* by the action of the compression spring. This brings the drill spindle into the operating position so that the hole can be drilled. As the depth of the hole is governed by the stop-pin *m*, the operator does not have to waste any time in gaging. After the hole has been drilled, the fixture is again indexed to bring the tapping spindle into the operating position, after which the hole is tapped.

The use of this fixture insures having the drill and tap held exactly perpendicular to the surface of the work so that an inexperienced workman can machine the holes more quickly and accurately than a skilled mechanic could when the old hand-method was used. Although this drilling and tapping fixture was designed for the particular class of work referred to, the same device could be used to advantage on a variety of other classes of work.

* * *

As a rule, hard water causes little or no corrosion in metal pipes, principally because of the formation of protective coatings upon the metal by ingredients in the water. The carbonic acid and atmospheric oxygen in soft waters cause corrosion. Investigations made by the Department of Water Supply, New York City, indicate that the addition of lime or soda to soft water forms coatings on the inside of the pipes so that corrosion may be practically negligible.

BROACHING ROUND HOLES

BY RALPH R. LAPOINTE*

When finishing a hole by reaming, the cutting edge of each reamer blade travels a distance approximately equal to the circumference of the hole multiplied by the number of revolutions or turns made by the reamer in passing through the work. In the case of a round broach, the distance traversed by any point on the broach in machining a hole is equal to the length of the work; hence, it can easily be seen that broaching is a much faster operation than reaming, especially when the broach has a cutting speed of at least four feet per minute; moreover, the broach will maintain its size for a longer period than a solid reamer, because the finishing end of the broach has a number of teeth of the same diameter, and as these only take very light finishing cuts they are subjected to very little wear. Even an adjustable reamer has no longer life than a well made round broach.

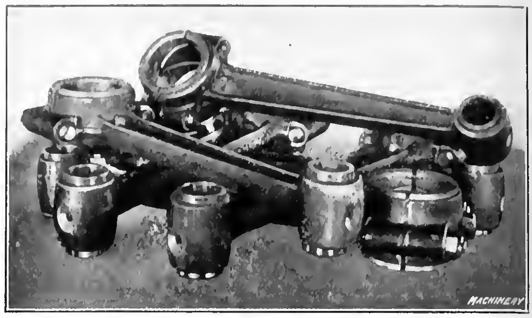

Fig. 1. Finished Connecting-rods broached as indicated in Fig. 2

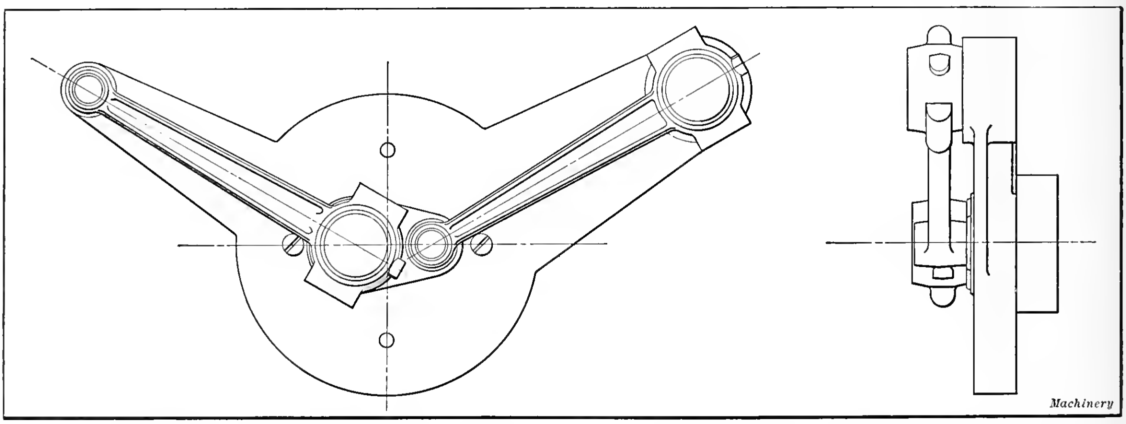

Fig. 2. Method of broaching Large and Small Connecting-rod Ends simultaneously on a Regular No. 3 Lapointe Broaching Machine

* Superintendent, Lapointe Machine Tool Co., Hudson, Mass.

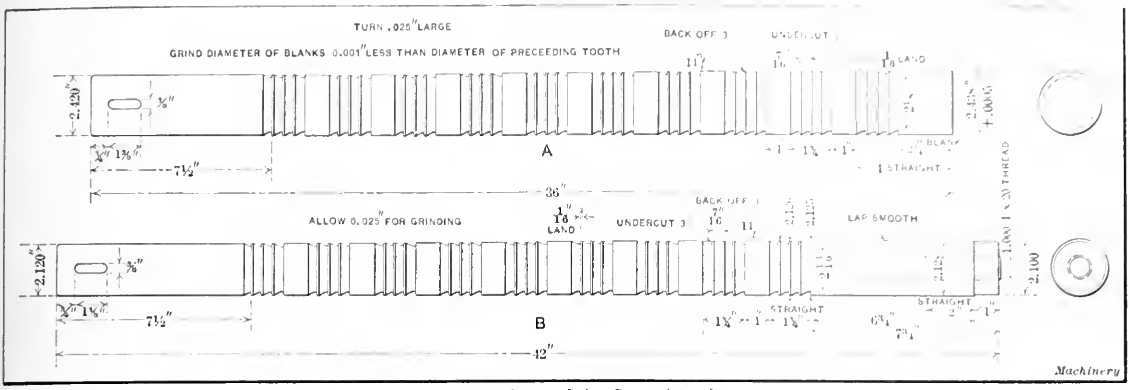

Fig. 3. Broaches used for Connecting-rods

It has been demonstrated that the broaching of hard chrome-nickel steel, such as is used in automobile work, is a much cheaper process than reaming. A typical job is shown in Fig. 2, which illustrates two connecting-rods and their broaching fixture. The small end of one rod and the large end of the other are broached simultaneously on a regular No. 3 Lapointe broaching machine. In this way, one complete rod is finished for every stroke of the machine. The fixture is not absolutely necessary but adds considerably to the production. These connecting-rods are first drilled to the size of the broach shank or to a diameter of from 0.015 to 0.018 inch under the required size. They are then finished by broaching, thus eliminating both machine and hand reaming. After the rods have been broached, the large end is split and the lining bushing for the large end is inserted. The bushing for the small end is pressed into the rod. These bearings or bushings are then broached, and the finish obtained can only be duplicated by scraping, although broaching is, of course, much cheaper, and the metal is compressed somewhat, thus giving the bearing a hard, glazed surface that resists wear. A number of finished connecting-rods are shown in Fig. 1.

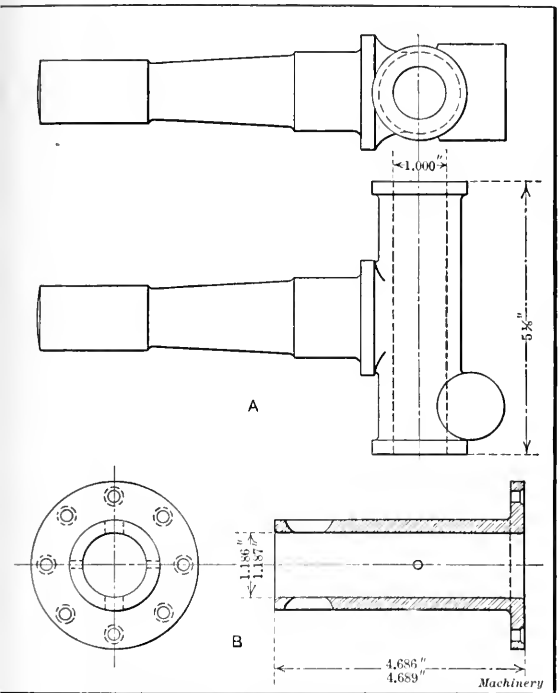

Fig. 4. Examples of Work machined by broaching

The broach illustrated at *A* in Fig. 3 is used for broaching the hole in the large end of the rod, whereas the smaller broach *B* is for finishing the bushing. The plain round sections seen on these broaches are for the purpose of keeping the broach from "running" or "crawling," as it is essential that the center-to-center distance of these rods be kept fairly accurate. By introducing plain blanks or sections between the teeth, as shown, the broach is kept properly aligned with the hole because there is always some portion of the blank section in the work while some of the teeth are cutting.

When using a broach, it is passed through the work and is fastened to the draw-head of the machine by a cotter-key which passes through the slotted end in the usual way. Only such clamping as is necessary to support the work is required, as the blank sections on the broach will hold the part in alignment. When using these broaches in cast iron, a soap cutting compound is used, as this gives the broached surface a highly polished finish. For chrome-nickel steel, a good grade of cutting oil will give satisfactory results. On some work, no drilling whatever is done prior to broaching, and very often only one broach is used, but if the work is longer than, say, two inches, a roughing broach usually precedes the finishing broach. Of course, broaching from the rough can only be done when the broaching operation comes first, as otherwise the broach would follow the rough hole and, consequently, the finished hole would be out of true with any other surfaces which might be machined afterward.

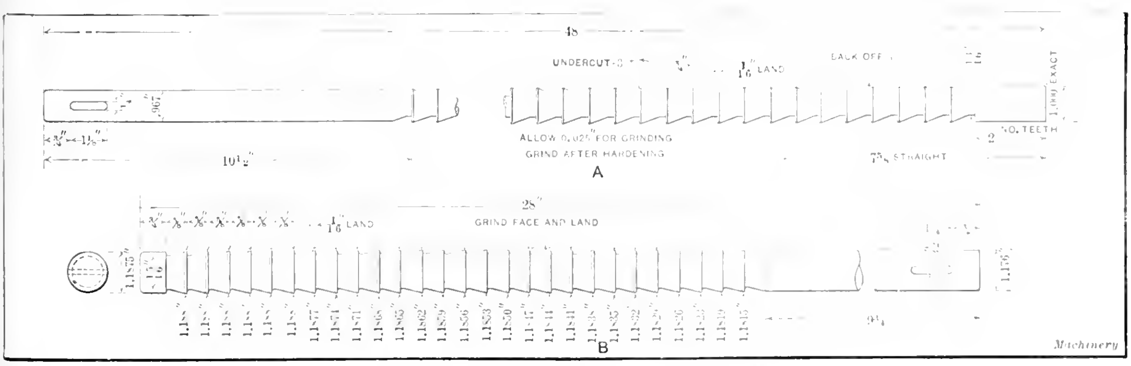

Fig. 5. Broaches used for Parts illustrated in Fig. 4

The part shown at A in Fig. 4 is another example of work on which broaching saved considerable time. This is a steering pivot for the front axle of an automobile. The hole is 5⅛ inches long and 1 inch in diameter. These pivots, at one time, were machined by first drilling the holes with two drills of different diameters which were followed by a rose reamer and a machine reamer, but even with these four operations, the hole was not finished straight and a hand reamer had to be used to secure satisfactory results.

Prior to the broaching operation, the pieces are roughly drilled 1/32 inch under size and then they are broached. The result is that the work does not need hand reaming and is produced cheaper and with a better finish than could be obtained by hand reaming. In this case, the broaching was done before any of the other machining operations. The material is chrome-nickel steel. The broach used for this work is shown at A in Fig. 5.

The example of work shown at B in Fig. 4 is another automobile part that is made of vanadium steel. The average production of these parts by broaching was sixty per hour, and one broach machined as many as 7685 pieces before it was worn too much for standard work. The dimensions of the broach used are given at B in Fig. 5.

CENTRIFUGAL FORCE ON AUTOMOBILE TIRES*

At first glance it would seem that every element going to make up the running gear of the modern automobile is balanced to such a nicety that any speed attainable under normal conditions would hardly be sufficient to necessitate serious consideration being given to any small, unbalanced weight. However, it has been demonstrated that even such a small weight as the tire valve is subjected to sufficient centrifugal force at high speeds, especially in racing cars, to warrant the placing of an equal weight on the opposite side of the wheel to overcome the energy developed by the rapid motion of the unbalanced valve.

The valves, including their caps, vary in weight for the different sized cars on which they are used from 3½ to 8½ ounces, and these weights seem insignificant when compared with the weight of a wheel and rim. But when the wheel is revolved at several hundred revolutions per minute a considerable centrifugal force is exerted, acting at any point in its travel radially away from the center of the wheel. It is intended to show here the tremendous forces that are developed at different speeds if the valves are not counterbalanced by weights on the opposite sides of the wheels.

The velocity V in feet per second of any particle of matter moving in a circular path with a constant radius, is represented by the product of the circumference and the number of revolutions per second. Now the centrifugal force of the same particle is the product of the weight and the square of the velocity, divided by the product of the radius and the force of gravity, which is 32.16 feet per second. Then substituting the value of V^2 in this second formula, we derive the equation, $C = 0.00034\ WRN^2$ pounds, where W is the weight of the body, R the radius of action, N the revolutions per minute and C the centrifugal force.

For the purpose of demonstrating by means of this formula, the necessity of balancing the wheels on high-speed cars, values will be assumed to correspond as nearly as possible to actual practice. Let the distance from the center of the wheel to the center of gravity of the valve be 15 inches; the weight of the valve and cap, 7½ ounces or 0.468 pound; and the diameter of the tire, 36 inches. Cars which will not attain a speed of 60 miles per hour are unusual, and it is an everyday occurrence for racers to maintain a speed of 75 or 80 miles per hour throughout a long contest or trial run. As a speed that is not at all unusual, let us assume 70 miles per hour for the first example. This is equivalent to 6160 feet per minute, and in traveling at this speed a wheel with a 36-inch tire will make 654 revolutions per minute. Substituting these values in the above equation we get:

$$C = 0.00034 \times 0.468 \times 1.25 \times 654 \times 654 = 85.1 \text{ pounds.}$$

In other words, a 7½-ounce valve on a 36-inch wheel traveling at 70 miles per hour will exert a lifting force of over 85 pounds when the valve reaches the top of the wheel. In case both valves of either pair of wheels are in the same relative position with regard to the axle, they will exert a combined lifting force of 170.2 pounds, and if they are opposite each other there will be a seesawing force acting on the car. Considering that there are four of these valves it is easily seen that they will exert forces in various and constantly changing directions as the wheels shift their relative positions in rounding turns in the road.

Since the centrifugal force varies as the square of the speed it requires only a slight increase in the speed to make a large increase in the force exerted. For instance, if the car travels at 75 miles per hour the force is increased to 97.5 pounds, and at 80 miles, which is frequently attained, the force on each valve will be 111.3 pounds, while at only 40 miles the force is 28 pounds. In a car going at the fastest rate of speed yet attained by man, 142 miles per hour, the force exerted by the valve is nearly 400 pounds.

Considering these almost neglected forces it is easily seen that some cognizance of them should be taken the same as is done in designing balanced wheels of stationary machinery. That racing drivers are coming to realize what these neglected forces might mean in case of an accident and loss of control of the car, is shown by the fact that a famous English driver has equipped each of his tires with two valves instead of one, the valves being placed on opposite sides of the tires in order to provide a perfect balance. It is said that the car will run at 80 miles per hour and hold the road remarkably well, where before it skidded badly at high speeds and was very difficult to control. Many American drivers also balance their valves by placing metal weights on the rim or felloes of the wheels opposite the valves.

* From an article by C. E. Palmer in the "Scientific American."

MOVING PICTURES OF AUTOMOBILE BUILDING

The Ford Motor Co. of Detroit, Mich., has just finished and equipped a complete department for taking motion pictures in its plant showing how Ford cars are made. A portion of the basement under the main office building has been fitted up as a studio and demonstrating room. The equipment is complete in every detail, and contains in addition to the regular photographic equipment a motion picture machine which is used for demonstrating to dealers and others interested. The films are made here and will be sent around to the principal cities both in this and foreign countries for exhibition in regular motion picture theaters. This is the first attempt that has been made by automobile manufacturers to exhibit their product in this manner before the general public, and it is reasonable to assume that it will create an unusual interest in the already popular Ford car.

The object of the company in establishing this department was to interest dealers and prospective purchasers. When a group of Ford dealers visit the Detroit office they are shown through the plant, taken out and photographed in a group outside the office building, and then are given a luncheon, after which the motion pictures of manufacturing Ford cars are shown. This entertainment lasts the greater part of the afternoon, and in the evening the party is treated to a banquet.

Duplicates of the films showing the processes of automobile manufacture are made from the original films and are sent to the principal cities and exhibited in regular motion picture theaters. After they have gone the rounds, they are turned over to district dealers and shown from time to time as occasion requires.

* * *

The use of natural gas as fuel in steam boilers is very wasteful, as it will take from four to five times the volume of gas per horsepower-hour to produce power through the medium of steam as it would if the same power were developed in a gas engine.

LETTERS ON PRACTICAL SUBJECTS

We pay only for articles published exclusively in MACHINERY.

ONE-PIECE ARMATURE DISK TOOLS

Having read the interesting article in the January number of MACHINERY, on "One-piece Armature Disk Tools," I can hardly understand how good results can be expected from these dies. After twenty years' experience in designing and constructing tools of this kind, I fail to see how it is possible to punch perfect blanks concentric and free from burrs with blanking or follow dies. I would prefer the compound sub-press construction, as this method keeps the upper and lower dies in perfect alignment, and saves a great deal of time in setting up the die. We make the lower or blanking die of one solid piece of "Ketos" steel (we also use "Intra" oil-hardening non-shrinking steel), machine to the required sizes and mount the die on the faceplate of the lathe to be bored (not drilled) to size. The device for mounting the die consists of a double plate with studs, and pawl to index for the required spacing. We also bore the holes for the oblong slots in the shedder and punch pad, with the same setting of the mounting device.

The prongs or individual punches for the upper die we make separately and mill them to the desired shape with forming cutters. This method enables us to replace a punch that breaks or distorts in hardening. Using a shedder that fits these punches nicely, not only sheds the punchings, but also supports and keeps the punches from springing. In shedding blanks in this manner one can leave the holes in the lower die straight without any clearance, whereas the method described in the article referred to requires some clearance to allow the punchings to drop through the die, which roughs up the holes to some extent. The holes in the die also become larger as the die is ground down; consequently the punchings will have heavier burrs. The pilot pins on follow-type dies that are depended upon to locate the stock cannot do so exactly, since they are made smaller than the piercing punches in order to prevent them from pulling the

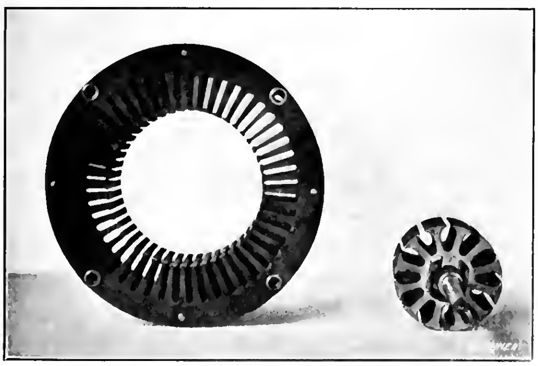

Fig. 1. A Series of Armature and Field Disks assembled—Note Perfect Alignment

blank out of the die; nor is the operator sure that the pilot pin enters the hole pierced centrally, so that it does not crowd the strip and thereby punch an imperfect blank. We are using black electrical sheet iron 0.015 to 0.019 inch thick, and make our punches 0.001 inch smaller than the dies for this thickness of stock, which gives good results. We make about fifty different sizes and styles of these, 1¼ inch to 14½ inches.

P. J. Mc.

[The chief advantage to be gained from making punches and dies from one piece of steel in preference to segments is the cheapness of construction. The method described in the foregoing criticism is the conventional one of making armature disk tools and contains nothing of unusual interest. The sectional sub-press type of armature punches and dies is not only difficult to make but is also extremely expensive. It was for this reason that the Robbins & Myers Co. decided to make its dies from one piece of steel and of the compound follow type. If this type of die is properly made and the press operator exercises the necessary care in setting up and operating, it is possible to produce blanks that are concentric and free from burrs. Fig. 1 shows this to good advantage. The series of field disks which have been clamped together look like one solid piece so exactly do the various segments conform to each other. By allowing only a small amount of clearance on the side of the die, it is possible to produce good clean disks until the dies are practically worn out.

As regards the toolmaking methods criticized in the above article, it is just as easy to machine a die in the milling machine as it is in the lathe, and, in fact, the milling machine is preferable if an accurate indexing head is obtainable. In the lathe it is necessary for the die to be trued up by means of an indicator which, of course, is only located by means of previously made prick-punch marks. Consequently, any inaccuracy in laying out will not be rectified in setting it up in

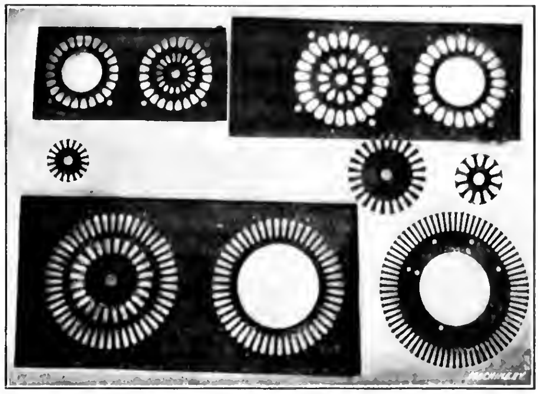

Fig. 2. Compound Punchings possible with the Solid Type of Armature Disk Tools

the machine to bore the holes. The Robbins & Myers Co. has been using the solid type of armature punches and dies for two and one-half years, and in that time has only had to repair two punches due to breakage of the prongs. In both cases repair pieces were set in with good results.

Another phase of the solid type of punch and die that is interesting is the production. This is considered to be greater than can be obtained with the combination sub-press type. With the solid type it is possible to get an armature or field disk, as shown in Fig. 2, at every stroke of the press and also to start the operation on another blank. This is impossible in the sub-press type because of the sectional type of construction used, and the prohibitive first cost. The solid type of armature disk tools is a good example of the advances made in the toolmaking art.—EDITOR.]

POSSIBILITIES OF RUSSIAN TRADE

The writer would like to add a few words to the item on page 379, engineering edition, of the January number of MACHINERY, concerning Russian export trade. It should be realized that, at the present time, Russia is recuperating from the effects of the Japanese war, and that great opportunities for American trade lie in the fact that this great country is keenly desirous of catching up with the progress of the rest of the world. To begin with, there are great expenditures for military purposes offering opportunities for trade. The government is, at the present time, building eleven large warships and twenty smaller ones. The army is very active in the development of aeroplanes and other military devices.

Russia is not so extremely backward a country as many would make us believe. There are thousands of investors and merchants familiar with developments in mechanical and other trades in other countries who are willing to take steps to develop the resources of their own country, but it is necessary that American manufacturers reach these people directly, as they do not yet seem to have the necessary push to take the initiative themselves. Advertising and direct methods for obtaining trade are necessary. Very few people seem to realize the rewards that may be waiting for the pioneers of American industries who enter Russia. The only serious competition that can be encountered is from Germany. Sweden can hardly compete with the United

States on the Russian market on account of its limited number of products*

As an example of the undeveloped state of Russia and the possibilities for further development might be mentioned the fact that there are only 120,000 miles of telegraph and 318,500 miles of telephone lines, these having been mostly constructed by Belgian and Swedish enterprises. The opportunities offered by this field alone are enormous. Russian water powers are also practically undeveloped, and there are great possibilities for turbines and electrical machinery. American agricultural machinery is used mostly on the larger estates at the present time, while the middle-class farmers hardly know of the existence of this class of implements. In addition, there are great possibilities for machinery for flour mills, beet sugar refineries, distilleries, breweries, and for the tobacco trade.

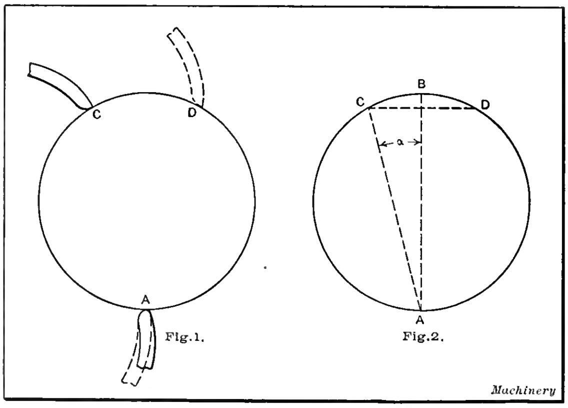
Several far-seeing concerns reached out early for the Russian market and profited thereby. As an example may be mentioned typewriters, small arms, and sewing machines. These have created a fine reputation for American products, and some firms, in fact, have had so large an amount of business that they have built factories in Russia.

It is, indeed, difficult to state all the possibilities that exist in Russia for the wide-awake American exporter. The writer can only say that if anyone has a product that has been successful in this country, he should go to Russia and try to find the same success there; also, now is the time!

L. J. W.

JUDGING MEASUREMENTS BY "DRAG" OF CALIPERS

It is evident that calipers set to 10 inches will not pass over a piece having a diameter of 10.010 inches without springing. That the distance *CD* in Fig. 1, which represents the "drag" of the calipers, depends upon the relation between the diameter of the work and the caliper setting, is equally self-evident. Probably most men who use lathes, especially when turning quite large work, sometimes rely on



Figs. 1 and 2. Diagrams illustrating how Allowances are judged by Drag of Calipers across Surface of Work

the drag of the calipers to show how much metal remains to be removed, and many veterans in the trade remember when allowances for press fits, etc., were made in this way, before the day of micrometers and vernier calipers.

I remember a man who was turning a part, the finished diameter of which was to be 20 inches. He roughed it down until the calipers dragged about 1/4 inch; then setting the tool in 0.005 inch, started the finishing chip in serene confidence that all was well. When the foreman, exasperated by the spoiling of a somewhat valuable piece, had concluded a full and free expression of his sentiments, the lathe hand quoted in his own defence what he believed to be a fact indisputable as the laws of gravitation. "Everyone knows, Mr. A., that the drag is always twenty times the oversize." As in this case the drag corresponding to 0.010 inch oversize is not 1/4 inch, but about 1 1/4 inch, his statement failed to meet with enthusiastic approval.

DRAG OF CALIPERS FOR DIFFERENT DIAMETERS

Caliper Setting, Inches	Drag for Oversize of			Caliper Setting, Inches	Drag for Oversize of		
	0.005	0.010	0.020		0.005	0.010	0.020
6	0.490	0.692	0.977	18	0.846	1.199	1.696
7	0.529	0.748	1.056	20	0.892	1.256	1.787

Machinery

It is easy to compute the distance *CD* for any given case. Referring to Fig. 2, $\frac{AC}{AB} = \cos a$, and $CD = 2\ AC \sin a$. In the instance cited, where the calipers were set to 20 inches, if the job were 20.010 inches,

$$\frac{20}{20.010} = \cos 1 \text{ degree } 48 \text{ minutes, and}$$

2×20 inches $\times \sin 1$ degree 48 minutes $= 1.256$ inch.

New London, N. H. GUY H. GARDNER

REMOVING A DENT FROM A COPPER FLOAT—A QUESTION

This contribution is submitted in the hope that some of the readers of MACHINERY may have had a similar experience and can give some information on the subject. Some years ago the writer had charge of a tool-room, and almost any old job was likely to come in. The foreman in charge (a very fine mechanic himself) brought in a copper float one morning. The float was about 5 inches in diameter and the sheet copper was brazed at about the middle. It was from the dial water gage of a steamboat and had a dent in it about 1 1/2 inch diameter and 3/4 inch deep. There were no openings in the piece and the trick was to take out this depression without drilling the hub or taking the float apart where the two halves were joined.

There was not time enough to send for a new float, as the boat was due to sail before a new one could be obtained. I was given no information as to how the work should be done and, in fact, considered that a joke was being played on me. The float was thrown on the bench and I had forgotten about it until the foreman finally called for it; then I realized that he was not joking. Well, we held a consultation but arrived at no solution and the foreman left me to figure it out. Here is the result.

The float was covered with a coating of lime about 1/32 inch thick, deposited from the feed water, and I picked up a small hammer that was used for laying out work and started to crack off the scale by way of amusement. This had not continued long before I imagined that the depression was smaller than when I started. Then I began to peen systematically around the depression, and lo and behold the dent was actually disappearing and in a short time was completely removed.

Mr. Foreman was very much surprised when the job was handed to him, and as he had said that "it was up to me" and I could worry about it, I made him guess a long time before I finally told him how the job was done. Now, I should like

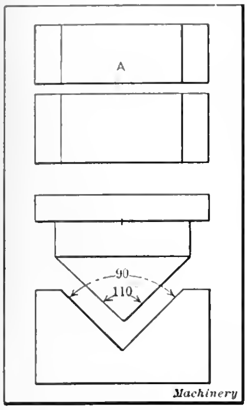
* Swedish competition is, perhaps, not to be so lightly disposed of. Sweden has made complete installations of telephone systems in a great number of the larger Russian cities in competition with the leading manufacturers both of Germany and the United States, and even nearer home it has offered United States formidable proof of its competitive qualities, in that a Swedish concern installed the complete telephone system in Mexico City in competition with manufacturers in the United States. Sweden, at the present time, and for a great many years back, has supplied Russia with most of the heavy wood-working machinery, such as saw mills, etc. used in that country, and many Swedish concerns are now establishing branch factories in Russia in order to overcome the difficulties caused by the Russian tariff. The only apparent reason why the Swedish competition might not, in the long run, be of importance would be because of the size of the country, it being too small in population to be able to supply the demands of a constantly increasing Russian market. The Swedes, however, are wide awake to the great opportunities in Russia, which many American exporters are not.

to have some of the readers of MACHINERY explain through what process the dent in this float straightened out.

Dubuque, Iowa. E. J. BUCHET

ANGLES OF ANGLE-BEAM SHEAR BLADES

J. D. Y.'s inquiry in November MACHINERY concerning angles of angle-beam shear blades calls to mind my experience in this line of work. Having described this in a contemporary some time ago, I will not go into much detail; however, I will say that by increasing the included angle of the upper or cutting blade to about 110 degrees and retaining the angle of 90 degrees at the bottom, very satisfactory results will be obtained. The reason for this is that the cutting is done gradually, beginning at the outer flanges of the angle, thus making it easier on punch, die and punch press. A further suggestion would be to do the cutting in the center *A* of two dies, as shown in the illustration, using a blade of a thickness depending on the weight and thickness of the angle to be sheared. This form of shear is excellent for this class of work and gives a very small amount of distortion in the angle.

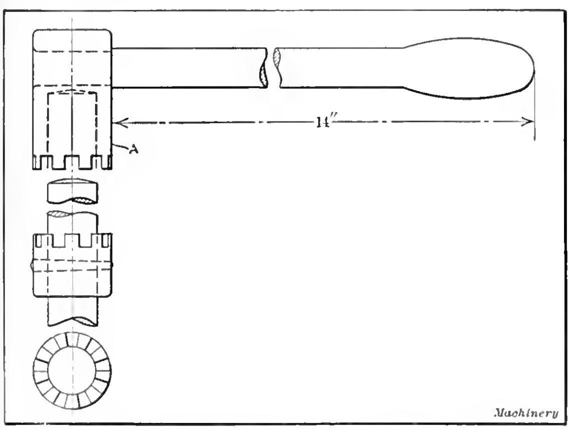


Angle for Angle Beam Shear Blades

New Haven, Conn. J. M. HENRY

HANDLE FOR CROSS-SLIDE OF TURRET LATHES

A very convenient handle for the cross-slide of a turret lathe or screw machine handling bar work is illustrated herewith. This handle is adjustable, and is therefore superior to the one sent with the machine, which is not adjustable. As the illustration shows, it is provided with clutch teeth so that by simply lifting it out of engagement the handle can be swung to any position. When two cross-slides are being used, the adjustable handle has a great advantage over the solid type. For example, if one slide is being used for cutting off finished parts while the other carries the forming tools, solid handles may interfere with each other, thus making it necessary to extend the forming tools so much as to cause chattering.



Handle for Cross-slides having Adjustment to prevent Interference between Handles on Front and Back Slides

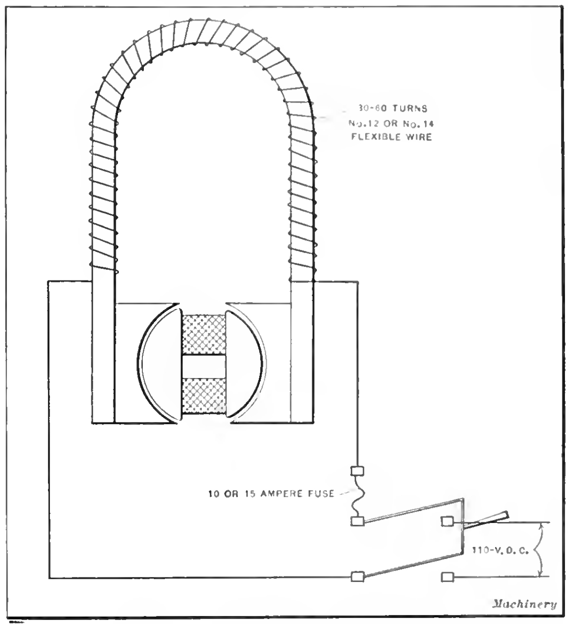
With the adjustable handles, such interference could be avoided. Another good feature is that the handle can be turned to the position that is most convenient for the operator and that enables him to exert the greatest pressure. The writer has designed and used this handle and found it a great labor saver. A handle of the solid type can be used in making the adjustable style, by simply cutting it off close to the hub ring and inserting the end in hub *A*. The particular handle illustrated has nine teeth (cut to a depth of ¼ inch) which gives all the adjustment that is required.

Pearl River, N. Y. EDWARD A. FRIEL

RECHARGING PERMANENT MAGNETS

The December number of MACHINERY has just come to my desk, and if not too late I would like to offer an answer to A. B.'s inquiry in regard to a method of remagnetizing magneto generators such as are used on automobile and motor cycle engines. These generators can be remagnetized by wrapping them with a temporary coil of from 30 to 60 turns of wire, and connecting this coil to a 110-volt direct-current circuit of considerable ampere capacity through a 10 or 15 ampere fuse and a knife switch. After the connections are made, the switch is closed, throwing the coil directly onto the line.

The fuse will be blown with some violence and the high current will force a heavy flux through the magnetic circuit and the armature. The armature, which is usually of the H-form, should be blocked in the position of least magnetic reluctance during this operation to provide for the minimum amount of magnetic flux cutting the armature winding. The proper position of the armature is shown in the diagram, which also illustrates the method of making the connections. No. 14 flexible wire and open link fuses will be found convenient and inexpensive, and a piece of sheet asbestos may be hung over the fuse to protect the workman's eyes from the flash. After the generator has been magnetized, the coil should be removed, and if flexible wire is used the same coil may be employed over and over again. The advantage of this method is that it is not necessary to take the magneto apart or remove it from the machine. This also eliminates the possibility of replacing the magnets with the polarity reversed.



Method of recharging Permanent Magnets

L. M. D.

SHRINK VS. PRESSED FITS

In answer to J. B. F.'s question in the December number of MACHINERY as to which is best, a shrink or a press fit, I would submit the results of the following experiments:

In making the rear axles of a well-known automobile, we were confronted with the question as to which was the stronger, a shrink or a press fit. This question was an-

swered by experiments as follows: The end members, brackets and housing had to be fastened securely to the steel tubing. First we tried shrinking the parts together. The tubes were turned to 2.254 inches diameter and the holes in the various members were reamed to 2.250 inches diameter and shrunk onto the tubes. Next we turned some tubes to 2.2525 inches, and the holes were reamed the same size as for shrinking, or 2.250 inches diameter. The members were then forced onto the tubes and, in both cases, were riveted with the same number of rivets. We made four axles with press fits and six with shrink fits. The axles were assembled and marked for identification and sent to the finish assembly department where they were fitted to the bodies.

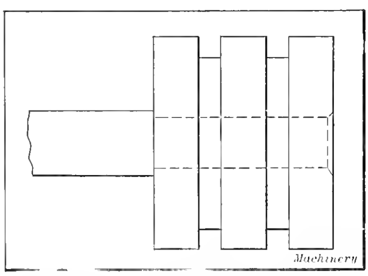
To make the story short, of the ten axles finished four were returned in less than a month and they proved to be the forced fits in each case. We never had an unfavorable report from the shrunk axles, and thereafter shrunk all parts onto the tubes and never had any complaints. The returned axles all had sheared rivets in the housing end and, in one case, the end member had sheared and was loose. This experiment was conducted with malleable iron castings. The outside diameter of the various parts was approximately 3 inches, leaving a wall about ⅜ inch thick. We afterward used Parson's white bronze, shrinking the members with the same allowance and less heat and obtained the same satisfactory results.

New Britain, Conn. W. C. Betz

Concerning J. B. F.'s problem of shrink and force fits, I would like to say that, theoretically, they would both be equal, provided the conditions were equal at the start. Theoretically, the holding power is limited by the elastic limit of the material which, in this case, would be the elastic limit of the outer member, as it is thinner than the shaft. In practice, a shrink fit will hold more firmly than a force fit because the gripping strain is equally distributed over the entire surface, while with a force fit the strain is unequal from one end to the other. This is due to the fact that the difference in diameter between the two parts must be taken care of by the compression of the shaft and the expansion of the outer member, and as the metal is not perfectly elastic, the end that goes on first will permanently set the shaft to a certain extent, so that the remainder of the fit will not grip tightly, owing to the diminished size of the shaft.

Detroit, Mich. Paul P. Vlasek

In the December number of Machinery J. B. F. asks a question in regard to the relative merits of shrink and pressed fits. In my opinion the collar which he illustrates in connection with his question should be shrunk onto the shaft. This method will be found most satisfactory where the collar or other part is relatively thin, so that there is danger of straining the metal in pressing it onto the shaft. Where a thicker piece, such as a crank disk, piston or similar part is to be secured to a shaft or rod, it is more practical to employ a pressed fit. It is a good plan to have a gage on the press so that it is possible to determine the exact pressure employed in forcing the piece into place. This insures having the fit tight enough to stand the work for which it is intended.



Small Piston to be shrunk or pressed on Rod

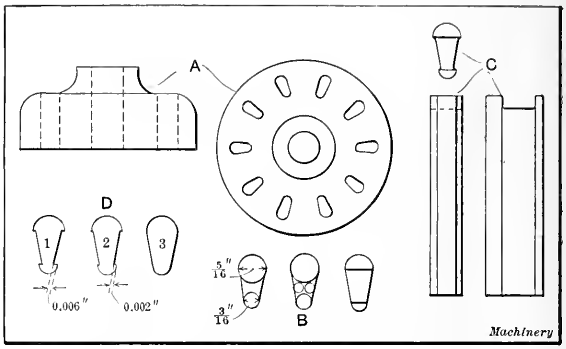
In this connection I would like to ask the most practical way of holding an 8-inch piston on its rod. Is a pressed fit or a shrink fit more likely to give satisfactory results? Will the fit become looser after the engine has run for some time and will the strain and vibration have any effect? I would also like to know how important it is to keep the rod or shaft cool while the piston or collar which is being shrunk onto it is cooling off.

W. J. M.

A BROACHING OPERATION

The method of broaching explained in the following paragraphs was worked out by the writer for machining ten holes in the core for a mold used for die-casting a small motor frame. These holes in the main core house sub-cores, as it was found impossible to produce perfect work and operate the mold in any other way. The main core is screwed to the top die, while the elongated sub-cores are fastened to a core plate. The main core is freed from the casting after the mold is separated, by the action of ejector pins, after which the sub-cores are withdrawn.

The broaching of these holes was performed by three broaches, the second and third of which varied in size by only 0.002 inch. The purpose of this was to have the third broach take a very fine cut so that the desired finish would be obtained without any other work than a small amount of filing for clearance at the back of the hole, and polishing with emery cloth. It was also important that the edges of the sub-core holes on the face of the main core should be as nearly perfect as possible; otherwise a burr would form on the casting at this point.



The Work to be broached and the Type of Broach that was used

It will be seen that these core pin holes pass through the core *A* as shown in the accompanying illustration. The core is made of machine steel and is 1½ inch thick. The core pin holes are ⅝ inch long, the maximum width being 5/16 inch and the minimum width 3/16 inch. The ends of the holes are semicircles of 5/32 and 3/32 inch radius, respectively. In laying out the work, two concentric circles were scribed on the core *A* at the required distances from the center. The next step was to draw ten equally spaced radii to locate the centers of the holes to be broached. The centers of the 5/16 and 3/16 inch semicircles were next marked with a center punch at the intersections of the two concentric circles with these radii. It may be well to mention at this point that all other machining operations had been performed on the core before starting to machine the core pin holes.

The next step was to drill ten holes of 5/16-inch diameter and ten holes of 3/16-inch diameter on the centers which were located for this purpose. These holes were then reamed. This left a wall of metal of ⅛-inch thickness between the two holes and this wall was partially removed by drilling two small holes as shown at *B*. The remainder of the wall was then broken away by pushing a cold chisel through the hole, after which the holes were ready for the broaching operations.

Three broaches were made of the form shown at *C*, the broaches being about ½ inch longer than the thickness of the core *A*. The broaches were made a few thousandths under size to provide a running fit against the remaining portion of the walls of the 5/16 and 3/16 inch holes, which served as a guide for the broaches. The cutting end of each broach was filed away to a depth of 3/16 inch at the center, leaving segments of 5/16 and 3/16 inch diameter on the broach which

served as a guide in starting it into the hole and leading it through the work.

The broaches were not stepped in the usual way, but were designed to simply cut on the end, the form of the three broaches used being shown at *D*. Broach No. 1 was cut away to a depth of 0.006 inch on each side. Broach No. 2 was cut away in a similar manner to a depth of 0.002 inch on each side. Broach No. 3 was not cut away on the sides. It will be evident that broach No. 1 leaves 0.006 inch of metal on the sides of the hole, and that broach No. 2 cuts away 0.004 inch of this metal, leaving 0.002 inch for the finishing cut taken by broach No. 3. An arbor press was used to force the broaches through the work, plenty of oil being supplied for lubricating purposes. Smooth clean holes were produced that were uniform in size and required very little finishing. The cost of the machining operation was much less than it would have been if each hole had been filed to a plug gage.

Union Hill, N. J. G. I. JOHNSON

THE SQUARE KEY VS. RECTANGULAR AND TAPERED KEYS

In an article on keys which appeared in the November number of MACHINERY, Martin H. Ball hoped to start a discussion of the subject. It is an interesting subject and it is a pleasure to me to see someone else make a start on it. Seeing the key situation in a different light does not necessarily make me right or the other fellow wrong; so let us have all the light we can. The square key, without taper, made of cold-rolled stock, fills the bill completely from my point of view. It can be bought finished to size and in convenient lengths so that it can be kept in stock. Then when a key is wanted in a hurry, as is often the case, sawing to length is all that is necessary. If the square key should be recognized as the universal standard, all squabbles as to the proportion of width and thickness would be done for. Any number of combinations can be made up for a standard of rectangular keys, but square is square all over.

Mr. Ball states that customers complain of square keys, saying that they unnecessarily weaken the shaft and hub; and broken parts returned seemed to justify their conclusion. The fact that parts were broken does not prove that the key was at fault. The shaft may have been too weak to do its work properly, and the same may be true of the hub. That is too often the case. If shafts, keys and hubs were in all cases properly designed for their loads instead of by rule-of-thumb methods, we would not hear of so many cases of hubs bursting or keys shearing. In many of my designs I have used standard safety flange couplings, but when making computations for hub and key I have often had to use two standard keys in order to keep the key stress within safe limits. And often when using a pinion that is of small diameter in proportion to the shaft I find it advisable to use two small keys in order to keep the hub stress low. In Kent's "Pocket-book" we find that common practice is to use a square key whose width and depth are each equal to one-fourth the diameter of the shaft, or as nearly as may be in even sixteenths of an inch. Ordinarily that does very well for the section of the key, but it is still necessary to make a computation to find out whether one or two keys are needed and how long they should be.

Everyone that is interested in this subject should send to the University of Illinois, Engineering Experiment Station, Urbana, Ill., for Bulletin No. 42. This bulletin contains the results of tests on numerous shafts with keyways of common sizes. On page 10 we find this significant statement, "It seems that a shaft with a single keyway of common dimensions has about the same ultimate strength as a shaft without a keyway." The statement in regard to the weakening effect of two keyways of standard dimensions must not be confused with the statement made in a preceding paragraph in regard to the advisability of sometimes using two keyways of smaller section in place of one standard keyway. To the best of my knowledge no tests have been conducted to determine the effect on the strength of a shaft of two keyways whose shearing value is equal to one keyway of standard dimensions. I have frequently used two keys in a pinion in order to keep the hub stresses down, and, of course, this means that the keys must be smaller than the standard sizes. Under such conditions I do not think the shaft is any weaker than it would be if one keyway of the regular size were cut in it. So far I have had no complaints in regard to this practice.

As an example of the use of two small keyways, consider the case of a pinion whose hub diameter is 6 inches and the shaft diameter 4 inches. The regular square key would be 1 inch thick and the remaining section of the hub left to resist tension would be only ½ inch thick. If two keys were used, each of which were ½ inch thick, the resistance of the keys against shear would be the same, and the hub would have a net thickness of ¾ inch, which represents a gain of 50 per cent. Although it is not definitely known, it appears very doubtful if the shaft has been weakened any more through cutting two ½-inch keyways than it would have been by cutting one keyway for a 1-inch key.

Experience has shown that a taper key will often produce considerable stress in the hub, tending to burst it. And also a taper key has been known to spring even quite heavy members so much as to make the machine a failure. Similar members when keyed with a square key have given a successful machine. To me, a taper key appears to be nothing more than a convenient means of tightening up a poor fit at the expense of the rest of the job. On investigation, it will be found that many of our largest makers of machinery are using the square key as their standard. The General Electric Co. might be mentioned as one of them.

Albany, N. Y. CHARLES P. WIWEKE

SEMI-AUTOMATIC TURRET FIXTURE

It was necessary to cut a fine thread on work of the form shown in Fig. 1, and as the preceding operations were performed on these pieces in a turret lathe, it was advisable to do the threading on the turret lathe also. None of the stock feed gears would produce the necessary result, and rather than make a special gear or send to the manufacturer for one, the fixture illustrated in Fig. 2 was designed. This fixture has proved not only practical, but even more economical than if the operation had been done with the feed gears and cam. Of course the device is only semi-automatic, but the threading is the last operation performed and the machine requires the attention of the operator at this point.

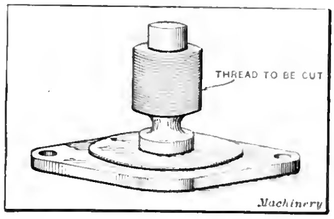


Fig. 1. Work to be threaded

It will be noted from Fig. 2 that the fixture is a sort of

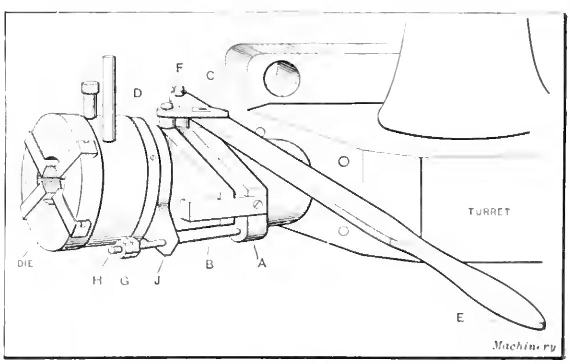

Fig. 2. Turret Fixture for threading Work shown in Fig. 1

sensitive Geometric die. The bracket *A* is fastened to the turret and the bracket *B* to the back of the die. These brackets are connected by a link *C* and stud *D* and handle *E*. The handle is fulcrumed at the point *F*, and by this arrangement the die may be fed onto the work by hand, without requiring

undue effort on the part of the operator. The turret is stationary at the end of its stroke, which does not bring the die into contact with the work, but close to it. The nuts *G* on the stud *H* may be adjusted to engage trip *J* at the desired point; this trip opens the die and allows it to be withdrawn quickly by moving back the hand lever *E*. An automatic device for resetting the die could easily be attached to the turret to make the tool ready for operation on the next piece of work.

RICHARD RUSSELL

DRILL PRESS FIXTURE

The following describes a drill press fixture which is used for holding work of irregular shape. It will be seen that the fixture consists of six bars which have shouldered studs mounted in them. The work is set on the shoulders of these

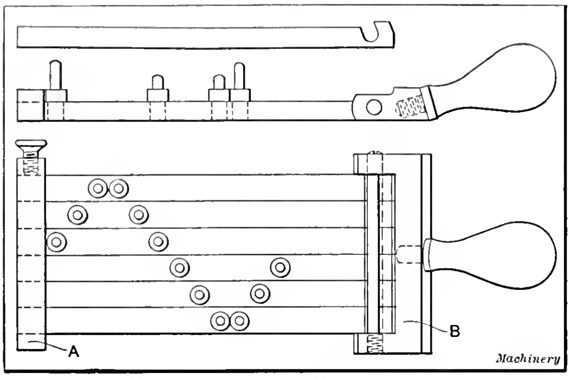

Fig. 1. Fixture for holding Drill Press Work

studs to provide clearance underneath so that the drill will not cut into the fixture. The method will be readily understood by referring to Fig. 2.

In preparing to set up a piece of work in this tool, the strap *A* and handle-piece *B* are removed. This leaves the bars free so that they may be arranged to bring the studs into the desired position, three or four studs bearing against the work as shown in Fig. 2. The handle-piece and strap

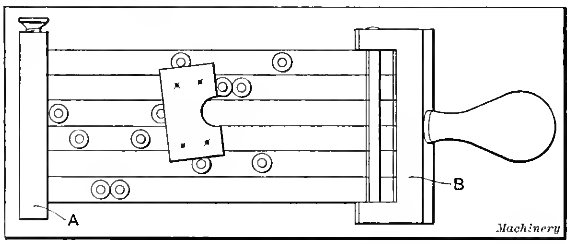

Fig. 2. Work in place in Drilling Fixture

are then replaced and the work is ready to be drilled. Before mounting in the fixture, the holes are usually centered as indicated by crosses in Fig. 2. A fixture of this kind is in the nature of a safeguard, as it does away with the danger of the operator's hands being injured through the work getting caught and being twisted around by the drill.

Kilfinane, Ireland. C. W. WHITESIDE

SLOTTING "NI-CHROME" STEEL RIBBON

In response to W. C. H.'s inquiry on slotting "ni-chrome" steel, in November MACHINERY, I do not think it is possible to produce a die that would satisfactorily slot "ni-chrome" steel ribbon. As the writer suggests, it is the toughest material to work that could be imagined. I have not had experience in this line exactly, but venture the following suggestion. In the making of the ordinary sub-treasury locks, the small flat disks that form the main part of the locking device, are slotted by means of disks of metal run at about 1500 revolutions per minute. The disks are not more than 0.100 inch thick. It was attempted at first to saw these slots, but a burr was left which made the work unsatisfactory. With just a plain metal disk, these slots are now formed, leaving practically no burr. This method was described in MACHINERY some time ago. My suggestion would be to build a machine with, perhaps, a dozen of these disks in line and a clamping arrangement to hold the ribbon down while it is being slotted, but, as I said before, this is merely a suggestion, although experiments may prove it to be of value.

New Haven, Conn. J. M. HENRY

ADJUSTABLE CLAMPS FOR T-SQUARES

In cross-sectioning drawings it is frequently necessary to keep the T-square in one position for a considerable length of time while using the triangle to cross-hatch some detail of the drawing. If the T-square slips, it means that a lot of time will be lost in erasing and then redrawing the lines over which the pen passed. To obviate this difficulty, the writer has used two forms of clamps which are illustrated herewith. The use of these clamps holds the T-square in place and leaves one hand free to use the drawing pen while the other can be used to move the triangle. In this way, quicker and better work can be obtained.

In order to use the clamp shown in Fig. 1, a slot 1 inch wide by 3/8 inch deep is cut along the left-hand edge of the drawing board. A strip of metal of the same size is then fastened to the edge of the board by means of countersunk screws, the metal being allowed to project 1/4 inch beyond the edge of the board. In this way, a slot 1/4 inch wide is left between the metal strip and the edge of the drawing board.

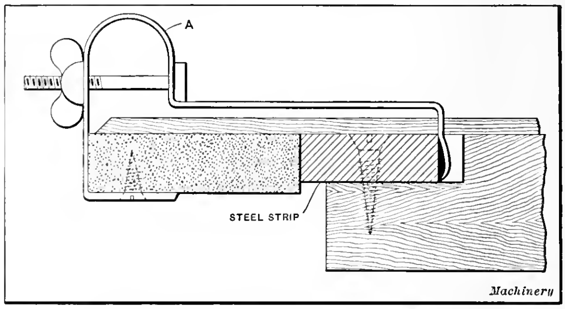

Fig. 1. T-square held by Pressure of Clamp Spring on Steel Strip

A strip of spring brass *A* is next fastened to the head of the T-square and bent to the form shown in the illustration. The right-hand end of this spring grips the strip of metal on the drawing board and by adjusting the wing nut on the bolt that is carried by the spring, the tension can be regulated to secure the necessary grip.

A simpler form of clamp is illustrated in Fig. 2. This clamp is made by attaching a block of wood to the under side of the head of the T-square, so that the combined thickness of the

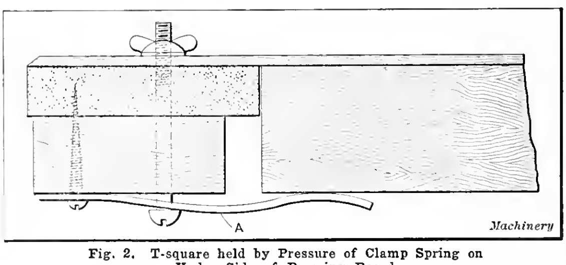

Fig. 2. T-square held by Pressure of Clamp Spring on Under Side of Drawing Board

head and block is equal to that of the drawing board. A strip of spring steel *A*, bent to the form shown in the illustration, is then fastened to the wooden block by means of a screw. The end of this spring bears against the under side of the drawing board and the desired grip is obtained by adjusting the wing nut at the top of the bolt, which passes through the head of the T-square. Although simpler than the clamp illustrated in Fig. 1, this arrangement does not work as well because the action of the spring sliding over the wood is not

as smooth as when the spring is in contact with a metal surface. Another disadvantage of this clamp is that it is impossible to hold the T-square as firmly with it.

Allegheny, Pa. MURRAY FAHNESTOCK

COMPENSATING SCREW THREADS FOR SHRINKAGE

In the December number of MACHINERY, W. B. T. presented an illustration of a chuck jaw which had shrunk 1/64 inch in pitch in hardening; the 1½-inch diameter screw to fit this jaw, which has five left-hand square threads per inch, was also illustrated. Since tool steel shrinks only 0.015 to 0.030 inch per foot of length if it is correctly handled, it is assumed that W. B. T. meant that there was a shrinkage of 1/64 inch in the entire length of the jaw—say 4 inches. The method of compensation presented in the following is applicable, however, to any amount of shrinkage and may also be used in cases where it is desired to cut screws with an odd or fractional lead.

In the case under consideration, assume that in 4 inches the lead has shrunk 1/64 or 0.0156 inch, making the length of twenty threads 3.9844 instead of 4.000 inches. Under these conditions the lead of the screw will be $\frac{3.9844}{20} = 0.19922$ inch. Consider the case of a lathe which has a lead-screw with six threads per inch. It is then necessary to find gears with a ratio of $\frac{0.19922}{\frac{1}{6}}$ to drive this screw. Multiplying this fraction by $\frac{6}{6}$ gives $\frac{1.19532}{1}$. To further simplify this fraction, divide both numerator and denominator by 4 and then multiply numerator and denominator by 10,000 which gives the following result:

$$\frac{1.19532 \div 4}{1 \div 4} = \frac{0.29883}{0.25000}$$

$$\frac{0.29883 \times 10{,}000}{0.25000 \times 10{,}000} = \frac{29{,}883}{25{,}000} = \frac{7471}{6250}$$

This fraction cannot be easily reduced further and in order to bring it to a form where it can be conveniently handled, add to the numerator and denominator two numbers whose values are such that the resulting value of the fraction will remain unchanged. For example, if to both terms of the fraction $\frac{150}{300}$ numbers are added in the ratio of 1 to 2, the value of the fraction remains the same, thus:

$$\frac{150+7}{300+14} = \frac{157+9}{314+18} = \frac{166}{332} = \frac{1}{2}$$

This process can be continued indefinitely, provided the numbers added to the numerator and denominator are in the same ratio as that of the original fraction. The fraction $\frac{7471}{6250}$ is very nearly $\frac{6}{5}$ and so $\frac{4 \times 6}{4 \times 5}$ may be added to it without changing the ratio. Performing this step gives $\frac{7495}{6270} =$

$$\frac{1499}{1254} = \frac{1500}{1255} = \frac{300}{251} = \frac{306}{256} = \frac{6 \times 51}{8 \times 32} = \frac{30 \times 51}{40 \times 32} \text{ (approximately).}$$

The result of the preceding calculation shows that we may use gears having 30, 51, 40 and 32 teeth, respectively. The lead of the screw to be cut is equal to the lead of the lead-screw on the lathe multiplied by the ratio of the product of the number of teeth in the driving gears to the product of the number of teeth in the driven gears. In the present case, the gears with 30 and 51 teeth are the drivers and those with 40 and 32 teeth are the driven gears. This gives the screw to be cut a lead of

$$\frac{1}{6} \times \frac{30 \times 51}{40 \times 32} = \frac{51}{256} = 0.1992187 \text{ inch.}$$

This result differs from the desired lead by only 0.000002 inch, which is far too small to be easily measured even if the screw to be cut was one foot in length. Gears with 30 and 40 teeth will always be available among the collection of change gears for any screw cutting lathe and a 32-tooth gear will generally be included in the collection. This leaves only one gear having 51 teeth to be cut for this particular job.

As another example, assume a case in which the hardened jaw is 3 inches long and 15 threads are exactly 2.9844 inch in length after hardening, and that it is required to drive the lead-screw (five threads per inch) with gears having a ratio of $\frac{0.19896}{0.20000}$. Simplifying, we have:

$$\frac{0.19896}{0.20000} \times \frac{50{,}000}{50{,}000} = \frac{9948}{10{,}000} = \frac{2487}{2500}.$$

The value of this fraction is so nearly unity that the same number can be subtracted from each term without seriously affecting the result. The required driving and driven gears are thus found to be:

$$\frac{2487-30}{2500-30} = \frac{2457}{2470} = \frac{27 \times 91}{38 \times 65} = 0.994737.$$

This results in an error of less than 0.001 inch per foot.

As a further example, consider a case in which it is required to cut a screw with a lead of 0.19922 inch on a lathe whose lead-screw has a lead of 0.250 inch. The ratio then becomes:

$$\frac{0.19922}{0.25000} = \frac{9961+4}{12500+5} = \frac{1993+4}{2501+5} = \frac{1997}{2506}$$

$$\frac{27 \times 74}{23 \times 109} = 0.796968 \text{ (approximately).}$$

This gives an error of only 0.00011 inch per inch. These examples are sufficient to show that with a few odd gears and a lathe—preferably with a fine-pitch lead-screw—it is possible to cut any fractional thread with very small error. The error will frequently be so slight that it is much smaller than can be determined by measurement. The reduction of the fractions to the required form will be greatly facilitated if a list of prime numbers is available for this purpose. After a little practice a set of compound gears for any required lead can be picked out very quickly. The writer uses this method to chase tap threads, cutting the lead just enough longer than the required dimension so that the pitch of the thread will be exactly right after the tap has been hardened.

Boston, Mass. L. J. RODGERS

RECHARGING PERMANENT MAGNETS

In the December number of MACHINERY, A. B. asks how to recharge a permanent magnet. The following will be found a satisfactory method:

Attach the permanent magnet that is to be recharged to a direct-current electromagnet. Allow the two magnets to stay in this way for about 45 minutes and strike the permanent magnet light blows with a hammer every few minutes. The small particles of the steel which the chemist calls "molecules" must all lie in the same direction in order for the magnet to retain its magnetism. The light blows struck with the hammer while the current is flowing sets up a vibration in the steel which enables the molecules to adjust their position so that the magnetism is retained after the magnet to be charged is disconnected from the electromagnet.

Grand Rapids, Mich. GEORGE H. HAMILTON

BRAZING CAST IRON

Mechanics who are called upon to braze cast-iron parts together will find the following a very satisfactory method. Place the pieces to be brazed in such a position that the fractured surfaces are uppermost and then heat them slowly to a temperature of about 2000 degrees F. This is the highest temperature that can be safely used on cast iron without running the risk of melting it. After this temperature has been attained, the work is allowed to cool slowly. The parts are

next clamped securely together and brought to a bright red heat. A flux, composed of the following ingredients is then applied:

Iron carbonate.................................1 part
Powdered boric acid.........................2 parts

It is important for the parts to be brought to a bright red before adding the flux, which should be applied with a brass rod. After brazing, the work is allowed to cool in the air. In heating the work an ordinary gas torch is found very satisfactory.

East Orange, N. J. GEORGE GARRISON

SPECIAL ARBOR FOR BEVEL GEAR SHAPER

It is rather difficult to hold firmly in the Bilgram gear shaper, any pinion which has not a hole through it but is made solid with the shank as in the case of pinions for the rear drive of motor cars. For this reason, we have designed and have been using with success, the arbor illustrated in Figs. 1 and 2. Bevel pinions are bored and threaded, as shown to the right, so that they can be screwed onto arbor *A* which is supplied with the machine. This arbor has a hole through it to receive shaft *B*, one end of which is conical and the other threaded for a hexagonal nut. As will be seen, the end of arbor *A* which holds the pinion, has three or four notches in which are located strips or dies *C* that were threaded with the arbor. The inside edges of these strips bear against the taper end of the shaft *B*, and by drawing the shaft outward by means of the nut, the strips *C* expand, causing the pinion to be held firmly. Fig. 1 shows the arbor used for very small pinions. In this case, the expansion strips are held in place by set-screws which retain them in the arbor but allow some play. Fig. 2 shows an arbor suitable for pinions of larger size. There are four expanding strips held in place by ring *D* which is fixed to the arbor by set-screws.

Turin, Italy. C. BOELLA

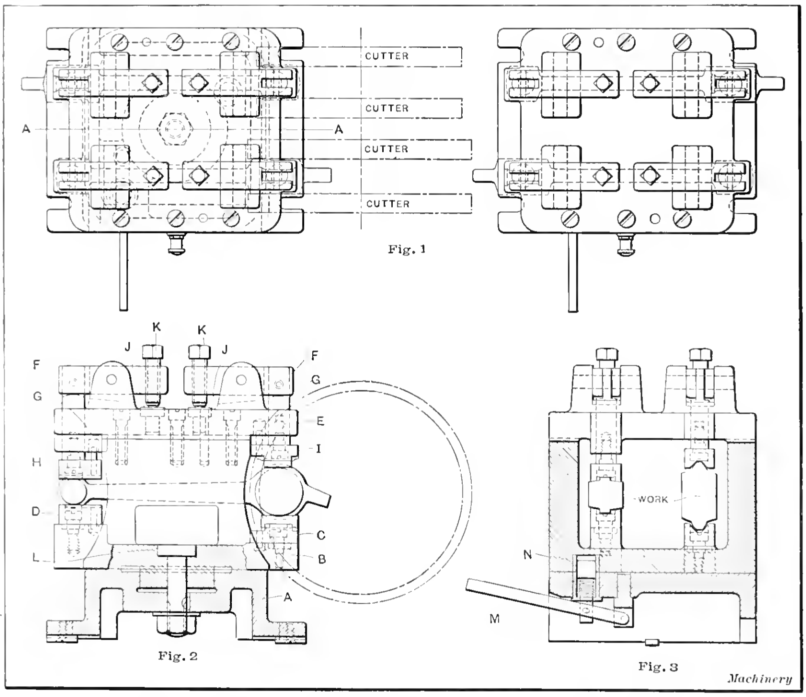
FIXTURE FOR MILLING CONNECTING-RODS

The fixture for milling connecting-rods illustrated in Figs. 1, 2 and 3, was designed to enable work to be done in one operation on one machine that formerly required two operations on two machines. Only one operator is required for handling this work in either case, the saving effected by this fixture arising from the fact that the second machine can be used for some other work. The present method also produces more accurate work and the rate of production is increased.

The connecting-rods machined in this fixture are used on automobile engines. As they are heat-treated before machining, the metal is extremely tough but with high-speed steel inserted-tooth milling cutters, we were able to turn out from 275 to 300 connecting-rods in a ten-hour day. No time was lost in indexing the fixture or in removing the finished connecting-rods and replacing them with rough forgings, as the operator had ample time to perform this part of the work on one fixture while the cutters were at work on the rods held in the other fixture.



Figs. 1 to 3. Plan and Sectional Views of Fixture for milling Connecting-rods

Referring to the sectional view shown in Fig. 2, it will be seen that the fixture consists of a base casting *A*. A casting *B* is pivoted to the base casting and the locating V-blocks *C* and *D* are bolted to it. These V-blocks are mounted on pivots and allowed to swivel through a short distance, their movement being governed by stop-pins in the V-blocks which fit into holes in the casting *B*. This movement of the V-blocks is provided to compensate for any variation in the connecting-rod forgings, and keeps the work centrally located. The cover casting *E* is bolted to the top of the swivel casting *B*, and the clamping screws, levers *F*, posts *G* and clamping V-blocks *H* and *I* are secured to this cover casting. The clamping V-blocks are provided with the same swivel movement as the locating V-blocks, which insures the required alignment. Hardened steel pins *J* are inserted in the cover to take the thrust of the clamping screws *K*.

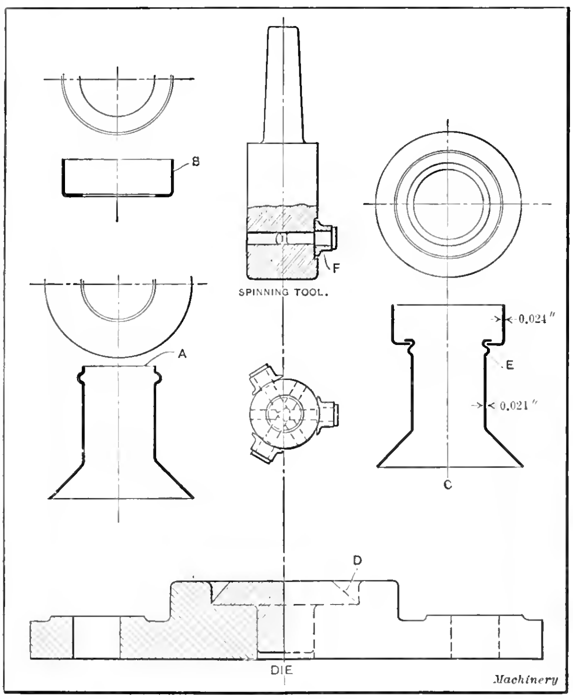
It will be seen that two connecting-rods are mounted in the fixture with their opposite ends adjacent, and the position of the straddle cutters is clearly shown in Fig. 1. The fixture is cut away sufficiently to allow the work to be fed to these cutters to machine the faces of the bearings. After one end of the connecting-rods has been machined, the lever *M* is pushed down to draw the index pin *N* free, and the casting *B* is then swiveled through 180 degrees and again located by the pin *N*. The fixture is then ready for the opposite ends of the connecting-rods to be machined. A gage, not shown in the illustration, is fastened to the base casting *A* to provide for setting the milling cutters.

Detroit, Mich. LOUIS L. ROBERTS

SPINNING TOOL FOR ASSEMBLING SHELLS

The brass shell *A* (see illustration) was to be attached to shell *B*. The regular way in which this class of work had been done was to make a split die, one-half being operated by a cam to open and close it, which allowed the work to be placed in the die. An undesirable feature of this method was that the shell was clamped, to support it, under the bead *E*, which caused the bead to be flattened.

The spinning tool *F* was devised for this work and has given good results. Besides retaining the shape of the bead, it makes a tighter joint and the production is increased over 75 per cent. The two shells, after being closed together by spinning, are shown at *C*. The spinning tool, which is used in a drill press, is run at about 500 revolutions per minute, and the vertical movement of the tool is obtained by a foot-treadle. The body of the tool is made of tool steel, hardened in oil and tempered at 495 degrees F. (brown). The rolls and pins are of tool steel, hardened in oil and tempered at 435 degrees F. (pale yellow). The rolls are an easy running fit



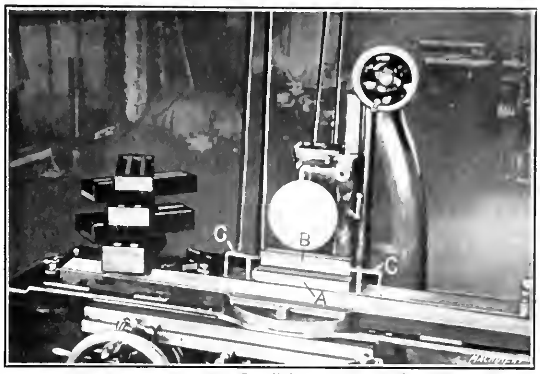
Spinning Tool and Die used for assembling Shells as shown at C

on the pins, and the pins a driving fit in the body. The die is made from cast iron and is bolted to the table of the press. The plug *D* is made of low-carbon steel and supports the inside of the shell. The shells are assembled, placed in the die and held from turning by the fingers, a slight pressure between thumb and forefinger being sufficient to hold the work while the tool does the spinning. This style of tool and die is now being used instead of the split die, except in cases where it is necessary to have the bead flattened so the inside walls will come together. W. D.

SIMPLE GRINDING FIXTURE

The accompanying illustration shows a simple fixture that was used on a No. 13 B. & S. grinder to finish accurately five sets of hardened parallels. They are shown at the left-hand end of the grinder table in hard wood boxes, which keep them in pairs and protect them from injury when not in use.

In making the grinding fixture the base *A*, which was a gray iron casting, was secured to the table by means of two 5/16-inch fillister-head screws. The base was then ground



Fixture for grinding Parallels on B. & S. Grinder

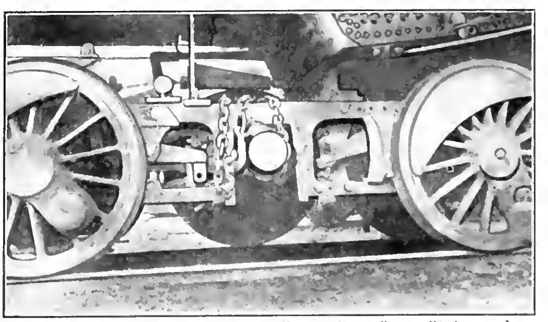
off to an accurate surface on its top face. The part *B* was next screwed to the base of the fixture and ground to an accurate finish so that its vertical face was perpendicular to the top of the base *A*. The clamps *C* were used to hold the work down and two parallel clamps were also used—one at each end—to hold the work securely against the face of the block *B*. These parallels were finished in pairs, and after being completed did not show an error of over 0.0005 inch in any direction. The sizes ranged from 3/8 by 3/4 inch to 3/4 by 1 3/4 inch, all sizes being 7 inches long.

Pottstown, Pa. CLAYTON DANE

A PECULIAR ACCIDENT

The accompanying photograph shows an accident that happened on the Birmingham division of the Southern Railway about a year ago. There are several cases on record of a pair of trucks having slipped from under a box car unnoticed, and one famous case where a whole car was lost out of a freight train without being detected until the end of the run.

The engine shown in the illustration had been stripped of all side-rods and was being hauled along with a train of cars from Atlanta to Birmingham. When the train stopped at Lincoln, Alabama, it was discovered that the left main wheel



Locomotive which lost Driving Wheel, Box, Shoe, Wedge and Pedestal Brace while being hauled in Freight Train

as well as the driving-box, shoe, wedge and bottom rest were all missing. There had been no previous indication that this wheel was loose. As is quite generally known, these wheels are pressed onto the axle with a pressure of from 100 to 150 tons, and, although they sometimes loosen after long usage, we never heard before of one working clear off the axle. The missing wheel was found twelve miles back.

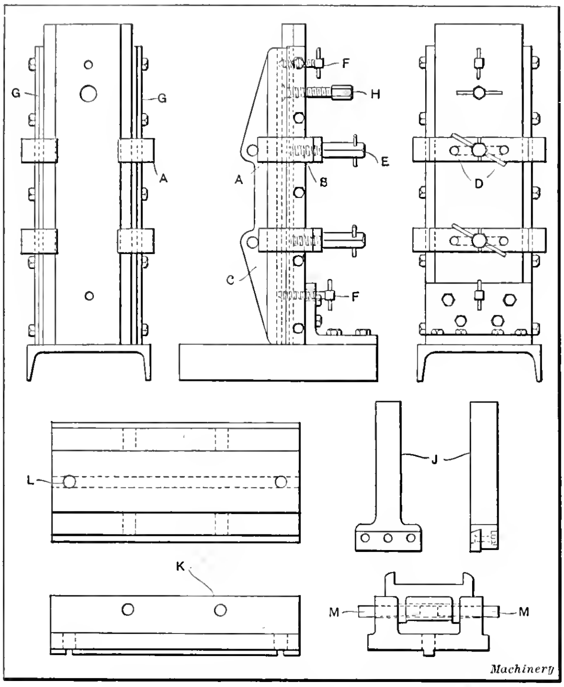
As is also well known, when an engine is being hauled by another engine, it is supposed to be attended by some person

who should have noticed this accident sooner. There was an attendant in this case but he had left his charge and was riding the leading engine. The chains shown in the illustration were put on and the engine hauled into the shop.

Birmingham, Ala. JOHN A. COOK

BABBITTING AND PLANING CROSS-HEAD GIBS

Appliances for babbitting and planing locomotive gibs, which proved very satisfactory in a Western railway shop, are shown in the accompanying illustration. The three upper views show the mandrel or fixture used for babbitting the gibs. The four U-shaped clamps *A* act as guides and hold the gib in place while being babbitted. These clamps engage shallow grooves at *B* which are cut in the back of the mandrel body. When the gib *C* is placed in position for babbitting, as shown, the clamps *A* are pushed in against stops *D* and the screws *E* are tightened. The stops *D* are provided so that the gib will be held at the proper distance from the face of the babbitting fixture. The planed surface on the back of the gib rests against the clamps so that the face of the gib is held parallel with the fixture. Screws *F* hold the gib out against the clamps.



Babbitting and Planing Fixtures for Crosshead Gibs

Before pouring the babbitt, fireclay is placed along the sides to prevent the metal from running out. This is held in place by flanges *G*. When the babbitt has hardened, clamps *A* are loosened and the gib is forced off the mandrel by the screw *H*, the side of the mandrel being slightly tapering so that the gib can be removed easily.

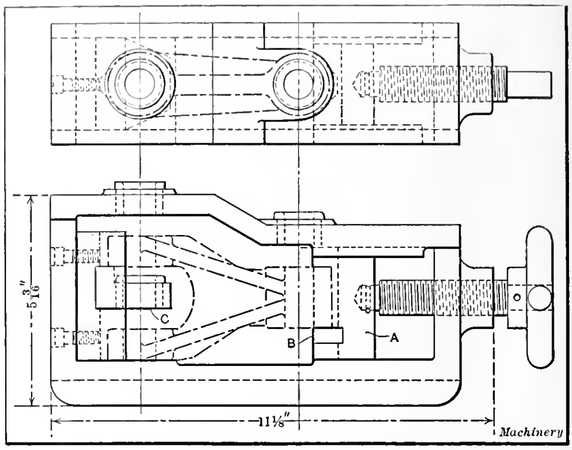
When this mandrel is used, the babbitt is distributed uniformly and the flanges have practically the same thickness, so that it is unnecessary to leave more than 1/16 inch of metal to be planed off. For this reason the mandrel is superior to types generally used, because it reduces the time required for planing.

The planing tool used for finishing the babbitted surface is shown at *J*. The cutter is fastened to the holder with three small round-headed bolts as shown. The width of the cutter is slightly less than the stand rd width of the guide so that a gib can be planed to fit a guide which has become worn. This tool has only a slight amount of clearance on the bottom, as excessive clearance causes it to gouge into the metal. The chuck or fixture used for holding the gibs while they are being planed is shown at *K*. This fixture is held to the planer table by bolts passing through holders *L* and is aligned by a tongue on the bottom. The gib is held by taper pins *M* which are driven in through the flanges at the side, as shown in the end view. The holes in the fixture are a little lower than those in the gib so that the pins will draw the gib down firmly against the top of the chuck. The planer used for this work has a cutting speed of 50 feet per minute and the gibs are planed at the rate of 5 per hour, which is three times the production obtained before these tools were made.

H. T. P.

DRILL JIG FOR FORK LINKS

The drill jig shown herewith was designed for drilling fork links. The form of these links is indicated by dot-and-dash lines in both views. The link has a round boss at one



Drill Jig for Forked Links

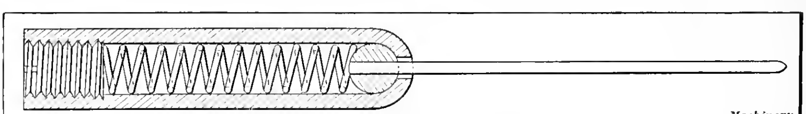
end and rounded forks at the other end. It is accurately held between two V-blocks, one being adjustable and the other stationary. The adjustable V-block *A* is clamped against the work by the star-wheel and screw shown, and it travels between finished ways, thus providing an accurate as well as rapid method of clamping.

These V-blocks have inserted steel plates *B* and *C*. The latter, which is in the stationary V-block, carries a drill bushing for drilling the lower fork, and an upper shoulder on this plate provides a support for the upper fork; thus there are two bushings in alignment for drilling the two ends. The inserted plate *B* in the adjustable block supports the opposite end of the fork link. With this arrangement, a two V-clamping jig is obtained having a three-point support. This drill jig was accurate, rapid and easily operated.

M. W. W.

INDICATOR FOR LOCATING CENTER PUNCH MARKS

An indicator for use in locating center punch marks is shown in the accompanying illustration. This form of indicator can be used on the milling machine, boring mill or drill press, and in the writer's opinion is a particularly efficient tool. The trouble with most instruments of this class



Simple Form of Indicator for locating Center Punch Marks

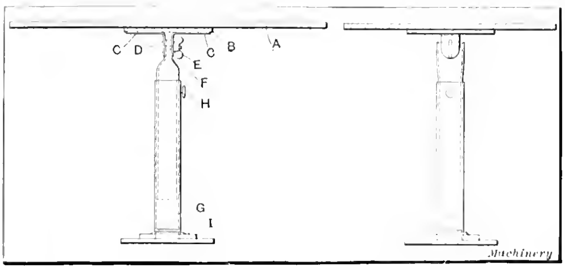
is that the body is not in perfect alignment with the hole; but with the present design, the hole can be lapped and the outside ground in accurate alignment with it.

Milwaukee, Wis. W. BUTZLAFF

AN INEXPENSIVE DRAWING BOARD

The accompanying illustration shows a cheap and satisfactory drawing board which may be made by almost any one at a small cost. The writer has used a board of this description for some time, and found that it meets all requirements that a more expensive one does. The cost of the complete outfit, including a little work that had to be done outside, was about $5.

Referring to the illustration, *A* is the drawing board. A board *B*, about 15 inches square by 1 inch thick, is secured to the under side of the drawing board by five or six wood screws, in such a way that the grain of the wood in the two boards is at right angles. The plates *C* are made of flat steel, 1/4 inch thick by 2 1/2 inches wide. Each of these plates is fastened to the board *B* by means of three wood screws.



Design for an Inexpensive Drawing Board

Holes are drilled in the lower edge of these plates for a 1/2 inch carriage bolt, the hole in one plate being filed square to receive the head of the bolt *D*. The nut *E* on this bolt is an ordinary wing-nut, which may be obtained in any hardware store.

The support *F* is made of a piece of ordinary 3-inch wrought iron pipe, two feet in length. One end of this pipe is hammered flat so that it will fit between the plates *C*, and the hole is drilled to receive the bolt *D* which holds the table to the support. The lower section of the support *G* is a piece of 3 1/2-inch iron pipe, one end of which is screwed into a standard 3 1/2-inch floor flange *I*. The height of the drawing board can be regulated by adjusting the position of the pipe *F* in pipe *G*, and then screwing up the binding screw *H*. The flange at the end of the support is screwed to a board which should be about 18 or 20 inches square.

It will be readily seen that the design of this drawing board makes it possible to have it set at any desired angle. When the board is not in use, it may be folded down into a vertical position and then pushed over against the wall, where it occupies very little space. The pipe sizes referred to were selected because the outside diameter of the smaller pipe fits nicely in the inside diameter of the larger one. Furthermore, the standard flange used on the larger pipe is heavy enough so that it will hold the table without requiring it to be screwed down to the floor.

Indianapolis, Ind. FRED E. HOSMER

HARDENING DRAFTSMEN'S RULING PENS

During my experience as a draftsman, I have found that even the highest-priced ruling pens do not always have the proper temper to hold a satisfactory point for any length of time. If a pen is too soft, it requires frequent touching up with a hone and as is well known, one or two improper strokes will spoil the result of the most careful effort to obtain a good working point. I use the following treatment for sharpening a pen. First use an ordinary stone of close medium grit. With such a stone and the proper care, a pen can be brought to a very satisfactory point. In order to be sure that the pen is of the desired hardness, I use the following method of hardening: After the pen has been sharpened, the screw is removed and the pen heated with a Bunsen burner or any other gas flame which does not smoke. The flame of an ordinary gas range can be used with satisfactory results. The heating is commenced at the point, care being taken to turn the pen continually in order to have both points evenly heated. The pen is heated slowly until a bright red is obtained about 3/16 inch back from the point.

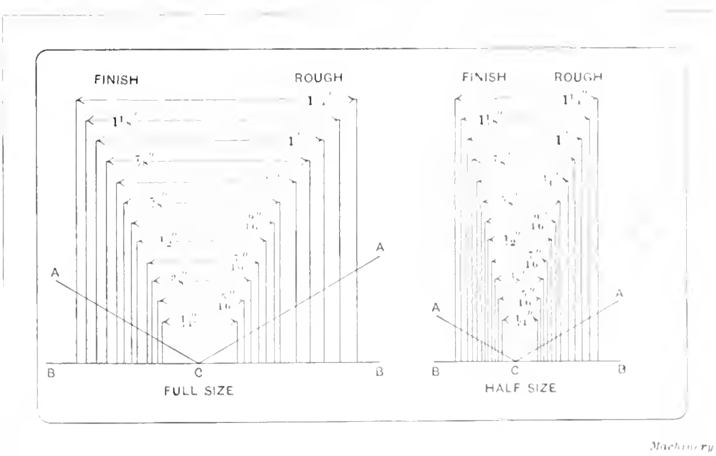
I have found that the best way of quenching the heat is by thrusting the point of the pen into a cake of beeswax to a depth of about 3/4 inch. If beeswax is not obtainable, a cake of clear castile soap is almost as good. The pen is left in this position until the wax sets around it and is then allowed to cool for about an hour, after which it can be removed and the wax cleaned off with gasoline or benzine. The point is then brought to a final finish by using a fine oilstone. Of course, the original polish will have been spoiled by this treatment but it may be easily restored by using a piece of crocus cloth.

Fort Wayne, Ind. HOMER R. TALMAGE

LAYING OUT HEXAGONAL HEADS

The accompanying illustration shows a convenient method of laying out hexagonal heads and nuts and the following gives a brief description of the way in which a diagram of this kind is laid out. On *BC* lay off from *C* distances equal to one-half the length across the flats of the heads and nuts most commonly used. The distances on one side of *C* are made to represent the finished sizes and on the other side of *C* the rough sizes. Next, draw lines to form the 30-degree angles *ACB*. Then draw vertical lines from the points laid off on *BC* and connect the top of these verticals on the "finished" side with the tops of the corresponding sizes on the "rough" side. Mark each horizontal line with the diameter of the bolt which the line represents.

It will be evident that with the compass set from the point *C* to the proper point on the line *BC*, a circle can be drawn, around which the plan of the head or nut can be laid out. To draw the side elevation without the plan, the compass is set from the point *C* to the intersection of the proper vertical line with the line *AC*, which represents one-half the distance across the corners. This distance is then laid off from the center line of the bolt. The compass is then set from the proper point on the line *BC* to the intersection with the line *AC*, which represents one-half the side of the head or nut, and this distance is laid off on each side of the center line of the bolt. After these dimensions have been secured, the head or nut can be laid out in the ordinary way.



Half and Full Size Diagrams for laying out Heads and Nuts

I use a piece of bristol board carefully laid off with fine lines. The size of the card is made 2 1/4 by 4 1/4 inches. I have found that two charts, one full size and the other half size, are most convenient for my work, but the same principle can be applied to other scales.

Barberton, Ohio. L. F. PARKER

HOW AND WHY

QUESTIONS ON PRACTICAL SUBJECTS OF GENERAL INTEREST

UNIVERSAL TYPE METAL

R. O.—I have heard of a new type metal that can be successfully used for linotype machines, monotypes and for stereotyping, and would like to know the constituents.

A.—You doubtless refer to a new alloy compounded by George R. Wagner, chief linotype machinist of the *New York World*. This alloy is said to work equally well for linotypes, monotypes and stereotypes. It consists of lead 82 per cent, antimony 13 per cent and tin 5 per cent. It is not patented.

HIGH-SPEED STEEL JIG BUSHINGS

C. R.—Is it practicable to use high-speed steel for jig bushings? What are the advantages of high-speed steel for this purpose?

A.—The advantages that would result from the use of high-speed steel for jig bushings would hardly seem sufficient to warrant its use. The high cost of high-speed steel and the difficulty of working it would seem to make its use practically prohibitive. The question is submitted to readers for discussion.

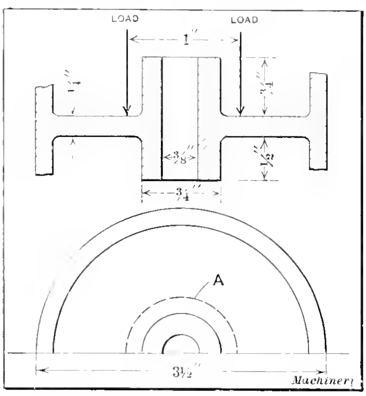
PRESSURE REQUIRED TO UPSET COLD STEEL

W. J. S.—How much pressure is required to upset a 3/8-inch round rod of machinery steel, the head formed to be 5/8 inch diameter?

A.—Experiments made by William Kent and recorded in his "Mechanical Engineers' Pocketbook" indicate that soft steel rivets require a pressure of about 100,000 pounds per square inch for cold heading. If the maximum diameter of the head on the rod is 5/8 inch, its cross-section area is nearly 1/3 square inch; hence, a maximum pressure of 30,000 to 33,000 pounds would be required to form the head.

CALCULATING STRESSES IN MALLEABLE IRON PLATE

W. N. A.—I would like to know how to proceed in calculating the stresses in the malleable iron plate illustrated herewith, when a load of 1000 pounds is applied on the circumference of a circle A 1 inch in diameter. Do the bosses 3/4 inch high and 1/2 inch high increase the strength of the plate? Would this be considered a circular plate fixed at the edge, with a concentrated load in the middle and a radius of 1/2 inch? There is a 3/8-inch rod passing through the boss in the middle of the plate and it is possible that the load may create a tendency for the metal to deflect and grip this rod. What I would like to obtain is formulas that will show the deflection and the stresses in the metal in order to be able to determine whether the design is capable of safely supporting the load of 1000 pounds.



Malleable Iron Plate in which it is required to determine the Stresses

Answered by W. L. Cathcart

A.—Only general answers can be given to these questions for several reasons. First, the diaphragm supporting the load is, technically, an unstayed "flat plate," circular and fixed at the edge, and the theoretical analysis of the resistance to bending of such plates is as yet unsatisfactory. Second, the plate in question has a central hole with bosses or stiffening rings, and this modification materially affects the results from such formulas as have been deduced. Third, while both strength and rigidity are required in this design, the plate is only 1/4 inch thick and it is to be made of malleable iron. For castings no thicker than this, the composition and heat-treatment of this material are usually such that it is far from stiff and is capable of much distortion without rupture—that is, it is strong but not rigid. However, the following discussion of the general principles affecting the design will be of service in judging its fitness for the work.

Stresses—General Methods

Formulas for the stresses in unstayed plates can be deduced in several ways. Thus—following Merriman's method—let Fig. 1 represent a circular plate of radius r and thickness t, supported at the edge and carrying a uniform load of p pounds per unit of area of the upper surface. The total load is then

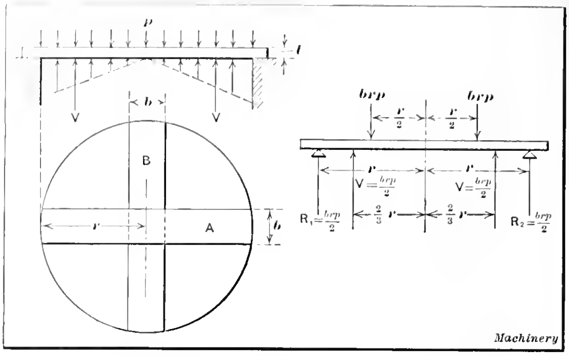


Fig. 1. Diagram showing Method of determining Stresses in Plate

$\pi r^2 p$ and the length of the support of this load is $2\pi r$. Hence, the reaction of that support, per unit of length, is $\dfrac{\pi r^2 p}{2\pi r} = \dfrac{r p}{2}$.

Now, take an elementary strip A of width b, whose center line is a diameter. The area of this strip is $2br$, the total load on it is $2brp$, and the reaction at each end is $\dfrac{brp}{2}$ or brp for both ends. Since, to support a load $2brp$, only reactions of brp are thus available, there must be, for equilibrium, upward resisting shearing forces at the sides of the strip equal to brp, the remainder of the load.

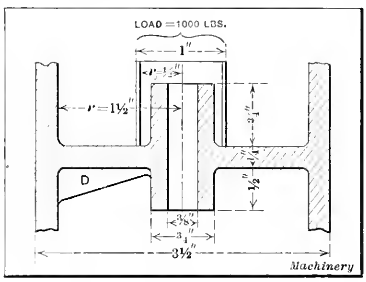

Fig. 2. Cross-section through the Plate

As the load is uniformly distributed, the intensity of these shearing forces is zero at the middle of the beam and increases at a uniform rate to the supports. Hence, their resultant V acts at a distance $\dfrac{2r}{3}$ from the middle or through the center of gravity of the triangle which they form. The upward and downward system of forces thus constituted is shown at the right-hand side of Fig. 1. The maximum bending moment, which is at the middle of the beam, is $M = \dfrac{b r^2 p}{3}$.

The corresponding stress is:

$$S_1 = \frac{M c}{I} = \frac{6 M}{b t^2} = 2 p \frac{r^2}{t^2} \qquad (1)$$

This is, however, an apparent and not a true stress, since allowance must be made for the modifying effect of similar strips crossing A at the center. Thus, for a strip B at right angles to A, we have a similar stress S_2, equal to S_1, but per-

pendicular to it. Rupture generally occurs on the lower or tensile side of the plate. For that side, the true maximum tensile stress is then $T = S_1 - eS_2$, in which e is the factor of lateral contraction. The mean value of e for iron and steel is 1/3. Substituting this value and those of S_1 and S_2, we have for a supported plate:

$$T = \frac{4\,r^2\,p}{3\,t^2} \qquad (2)$$

For a plate fixed at the edge, the determination of T is much more complex and cannot be given here. In such plates, this stress is, however, about three-fourths of that given by Equation (2) or:

$$T = \frac{r^2\,p}{t^2} \qquad (3)$$

Stresses due to Concentrated Loads

The method of analysis given above is general and can be modified to determine the stresses due to concentrated loads. For the case in question, as shown by Fig. 2, a load of 1000 pounds is concentrated concentrically on a circumference whose diameter is 1 inch. For these conditions, with a supported plate having no central hole or bosses, the formula becomes:

$$T = \left(\frac{4}{3}\,\text{hyp. log.}\,\frac{r}{r_o} + 1\right)\frac{P}{\pi\,t^2}$$

where T = safe working tensile stress;
r = radius of plate;
r_o = radius of load circle;
P = load in pounds;
t = thickness of plate in inches.

In this case, the radius r is $1\frac{1}{2}$ inch, $r_o = \frac{1}{2}$ inch, and $r \div r_o = 3$, the hyperbolic logarithm of which is 1.1. Substituting and transforming:

$$T = 0.77\,\frac{P}{t^2} \qquad (4)$$

for a supported plate. Taking three-fourths of this result, as in Equation (3), we have, for a plate fixed at the edge:

$$T = 0.58\,\frac{P}{t^2} \qquad (5)$$

For malleable iron in tension, average values are: ultimate strength, 40,000 pounds per square inch and elastic limit, 18,000 pounds. Taking 5 as a factor of safety, the safe working stress $T = \frac{18{,}000}{5} = 3600$ pounds per square inch. Substituting this value and $P = 1000$ in Equation (5) we have:

$$t = 0.4 \text{ inch} \qquad (6)$$

While this theoretical formula gives, in general, a greater thickness than is usual in practice, this discrepancy diminishes with thin castings, in which several elements combine to lessen the margin of safety.

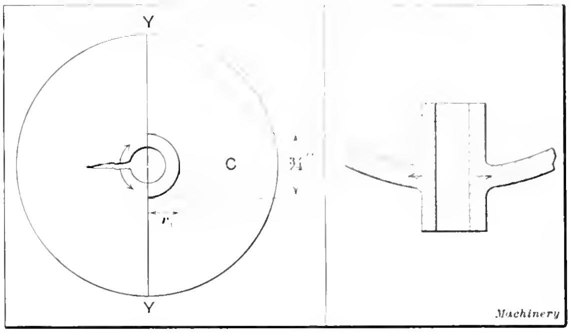
Central Hole and Bosses

A central hole, not reinforced by bosses, of course weakens the plate. This is shown conclusively by Formulas (1) and (2). Owing to the interaction of the stresses through lateral contraction, the relation between the stress in strip A, before it is crossed by strip B, and its stress after that crossing is as 2 to 4/3. That is, the crossing and consequent support lessen the stress in A, not only at the center but throughout its whole length. Since the hole is relatively small, the bosses make up, partially or wholly, for this loss of strength. In the first place, when a plate thus centrally perforated is tested to destruction, as shown at the left-hand side of Fig. 3, there is a circumferential stress at the edge of the hole, so that the plate fails by radial tearing. Therefore, any thickening of this edge will provide more metal and lessen the stress per square inch. It is evident that the wider the boss—that is, the greater the radius r_1—the better, in this respect. Again, take any elementary diametral strip, $\frac{3}{4}$ inch wide, as C in Fig. 3. At the middle on the diameter YY, there is $3/16 \times 2 \times 1\frac{1}{2} = 9/16$ square inch of metal, as compared with $\frac{3}{4} \times \frac{1}{4} = 3/16$ square inch at any other part of the strip. Finally, the location of this additional metal also increases the strength of the plate, since it increases the depth of the imaginary beam C at the bosses, and the strength of a beam of rectangular cross-section varies directly as the square of its depth.

As to the possibility of the bore contracting and gripping the rod passing through it: in order to bend, the plate must stretch—always at the lower surface, and, with ductile metal, on the upper side as well. This stretching will produce a radial tensile stress in the boss where it joins the plate, as shown in Fig. 4, and this stress will tend to increase, not decrease, the diameter of the bore. For such metal and diameters, a calculation of this stress would have no value. The difference between seizing and a close working fit would be measured in thousandths of an inch, and such minute dimensions can be computed effectively only for material like gunsteel whose composition, heat-treatment, and behavior under strain are known in detail.

Summing Up

Owing to reinforcement by the bosses, the plate is at least as strong as if it had no central hole. Then, considering it as a solid plate, Formula (6) shows that, as designed, it has



Figs. 3 and 4. Possible Results of Excessive Stresses on Plate

but 60 per cent of the required thickness. On the other hand, for heavier castings, this formula gives thicknesses which are too great; also, a low working stress has been used in the calculations; and finally, the reinforcement of the bosses may stiffen the plate sufficiently to make the designed thickness enough for strength.

The difficulty in deciding is due mainly to the thinness of the casting. In heavier plates, malleability makes the iron capable of resisting shock without material bending or breaking, but in thin castings this characteristic is usually carried to an extreme, so that the metal becomes soft and pliable. Further, slight changes in the proportion of silicon or in the treatment during melting and annealing may, with these thin castings, make a marked difference in their physical characteristics. If maximum lightness is desired, a practical way to secure it would be to make a trial casting with a moderately thick plate and the bosses as wide as possible. Then, test the plate, and, if no noticeable deflection appears, machine off a thin layer of metal, and test it again. The loss of the "skin" in this process will not affect the strength of the plate to a greater extent than the removal of any other layer of equal thickness. As a last resort, if the design will permit, the plate may be ribbed underneath, as shown at D in Fig. 2.

Questions and answers of general interest only are published. All inquiries must be accompanied with name and address to receive attention. Compliance will enable some answers to be made by mail if not deemed suitable for publication.—Editor.

* * *

The application of centrifugal force to clothes and metal chips for the extraction of water and oil, is well known, but not so well known is the use for pressing certain materials such as cork. It has been found impossible to compress scrap cork into cylindrical shapes, because of the friction of the material on the sides of the container. In a centrifugal apparatus, however, compression to any form is readily accomplished. Long cylinders of granulated cork are formed without trouble; each particle of cork is impelled outward by the centrifugal force and neither external nor internal friction of the material hinders the compressive action.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW DESIGNS AND IMPROVEMENTS IN AMERICAN METAL-WORKING MACHINERY AND TOOLS

GRIDLEY AUTOMATIC MULTIPLE-SPINDLE DRILL

In developing the Gridley automatic multiple-spindle drill, the intention of the Windsor Machine Co., Windsor, Vt., was to produce a machine applicable to the rapid drilling of parts which are difficult to handle on other types of machines. Tests which have been conducted on these machines in the builder's factory show that there is also a marked saving of floor space in addition to a reduction of time, as compared with other methods that were previously considered satisfactory.

The Gridley automatic multiple-spindle drill is, in reality, a vertical turret machine adapted for drilling, reaming, counterboring and facing a variety of classes of work. The design differs radically from other drilling machines in that the spindles are adjustable both radially and circumferentially, thus enabling all spindles to be located for operation at a common center or at different points, as may be required for various classes of work. Holes can be drilled cutting into each other or as far apart as the capacity of the machine will allow. The spindles are individually adjustable, so that any tool may be placed in position to work to

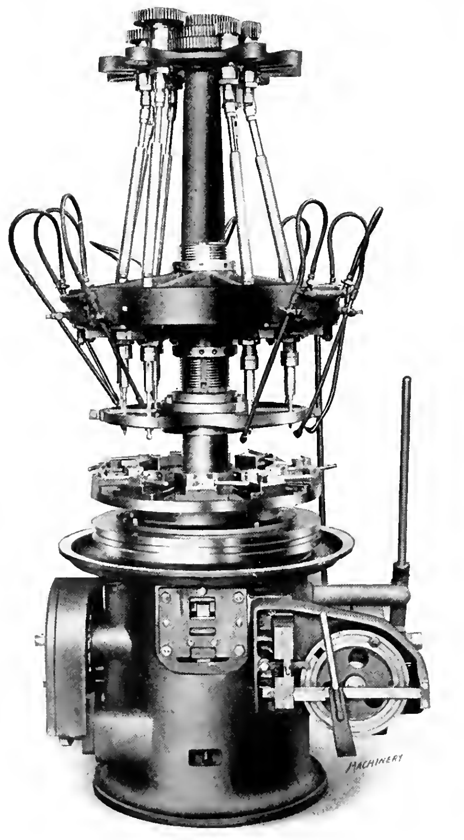


Fig. 1. Front View of Gridley Automatic Multiple-spindle Drill

any depth, regardless of the position of other tools. As all spindles are supported from the center column and distributed around an entire circle, the thrust on one side is balanced by the thrust at the opposite side. This relieves the center column of undue strain, and any tendency for heavy feeds to spring the machine is practically eliminated.

Front and side views of the machine are shown in Figs. 1 and 3, and Figs. 2 and 4 show closer views of the work-table and guide bushing holders that are employed on these machines. It will be seen that the work is held in chucks or suitable fixtures mounted on a rotating work-table which revolves around the center column. As it is necessary to have one position of the work-table idle for the purpose of

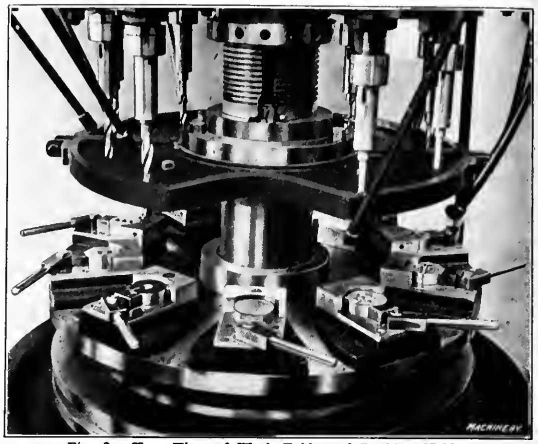

Fig. 2. Close View of Work Table and Bushing Holders shown in Fig. 1.

removing the finished piece and inserting a fresh blank, one more chuck or fixture is used than the number of spindles on the machine. This idle or loading position is clearly shown at the center in Figs. 1 and 2, where it will be seen that the blank has been placed in the fixture ready for the first indexing. In this case the machine is operating on a small threading die. The die shown to the right of the loading position is finished and will be removed when the table has advanced one point; a fresh blank will then be mounted in place ready for the cycle of operations that is to be performed on it.

The necessary number of spindles can be built into the machine to meet the requirements of the class of work to be operated upon, from five to nine spindles being the usual number. In order to divide the time of the successive operations as uniformly as possible, it is sometimes advisable to use two or more spindles working in the same hole, each of which machines a portion of the whole depth. The table indexes one point each time it is lowered from the tools, and one finished piece of work is produced each time the table moves upward. The time taken to produce the piece is that of the longest operation plus the idle time required to bring the work to the tools in the next position. Each individual spindle can be geared to the correct speed for the tool which it carries, and in cases where extra heavy service is required of one or more tools, special spindles of heavy construction can be used for these operations.

In drilling a layout of holes, to insure accurate spacing between them either of two methods of holding the drill bushings may be used. When only a few of the drills or other tools need guide bushings, holders carried by adjustable vertical and horizontal arms are employed. This arrangement is clearly shown in Fig. 4. In cases where a large number of holes are to be drilled, a plate is used which extends around the central column of the machine, the plate being located between the work-table and the spindles. There are large holes in this plate, one of which is in line with each of the spindles. Adjustable bushing holders which can be quickly set in the required position are clamped over these holes. In changing from one job to another it is only necessary to change the bushing holders, and on some classes of work it is necessary to change but one or two of the holders. This is the arrangement which is shown on the machine illustrated in Figs. 1 and 2. For drills and some other tools, hardened steel bushings are used. Other tools which have only short

flutes work more advantageously in bronze bushings which locate the tools properly and prevent all tendency to chatter when the machine is working at high speed.

Little difficulty is experienced in setting up the machine for operation on different pieces of work. The tools are inserted in their holders and a perfect sample of the piece to be machined—finished to the required size and form—is placed in the chuck or fixture. The table is next advanced by hand until the piece is located at the point under the first spindle, where the sequence of operations commences. The spindle is then swung into exactly the required position and the guide bushing fastened in place. After raising the table to its highest cutting point, the spindle is adjusted vertically in order that the hole may be machined to the proper depth. This operation is repeated for each spindle until all of the tools have been properly located.

By referring to the table of spindle speeds, the proper gears are next placed on the center shaft and spindles, and the

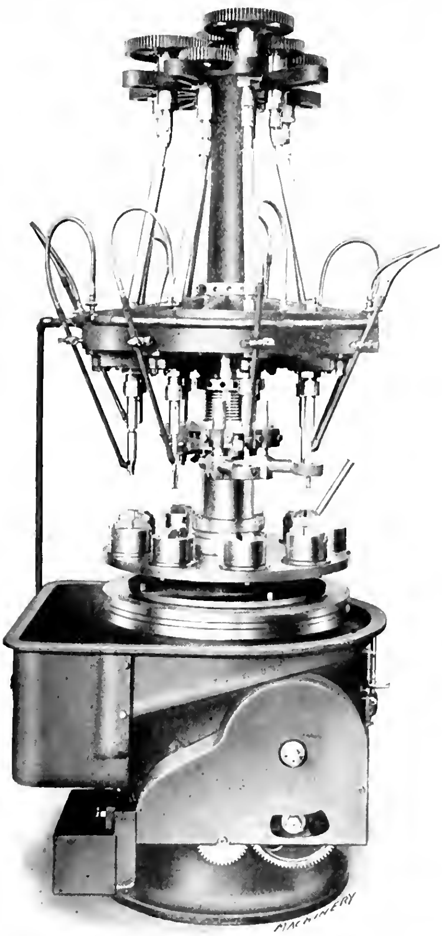

Fig. 3. Side View of Gridley Automatic Multiple-spindle Drill

gears brought into mesh. The change gears which give the different speeds for the vertical center shaft are located in the case at the lower left-hand side of the machine in Fig. 1. The change gears giving the different feeds to the table are also located in this case. After the proper speed and feed gears are in place, the table should be brought up to the position where the first tool of the set nearly touches the work. At this point, a cam-pin on the operating disk should be set to throw out the fast feed clutch; this will allow the feed gears to drive the table at the proper feed. After the table has reached its highest point and the tools have finished cutting, the second cam-pin on the operating disk should be set to throw in the fast feed clutch. The machine is then ready to start working.

The Gridley automatic multiple-spindle drill is equipped with a gear-driven oil pump, an oil tank and a separate oil supply pipe with an adjustable nozzle to deliver lubricant to each cutting tool. The arrangement of the piping, flexible tube connections and nozzles will be readily understood by

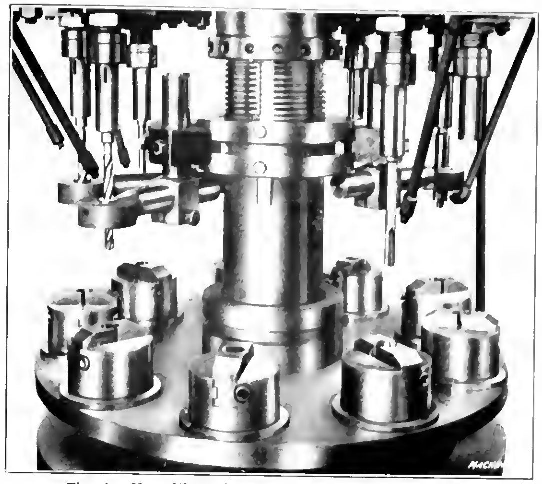

Fig. 4. Close View of Work Table and Bushing Holders shown in Fig. 3

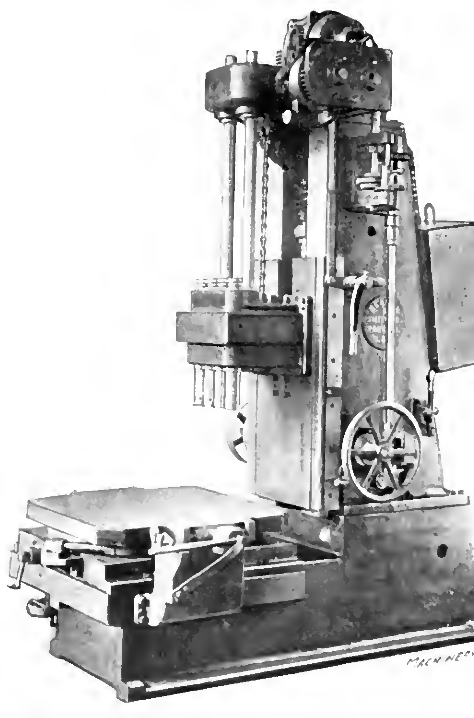
referring to the illustrations. The machine is equipped with a self draining drip tank and strainer of liberal size. There is ample room for removing chips without requiring the oil guards to be disturbed in any way.

BEAMAN & SMITH BORING MACHINE

The Beaman & Smith Co., Providence, R. I., has recently added to its line a vertical spindle cylinder boring machine which is shown in the accompanying illustration. It will be



Beaman & Smith Four-spindle Cylinder Boring Machine

seen that this machine has four spindles, but these machines are built with either three, four or six spindles. The spindles run in taper bearings lined with hard bronze, means being provided to compensate for wear The head is carried by a counterbalanced saddle which has a vertical movement of

29½ inches. The spindles have automatic feed and automatic stops are provided to trip the feed at the required point; quick power movements are also provided.

The work is set up on a revolving work table 36 inches square. There are two index points, and the finished work, which is held in suitable fixtures, can be removed from the idle position while the boring operation is being performed on a casting in the operating position. This feature provides for keeping the machine in almost continual operation. The table is supported on ball bearings so that it is easily revolved. The machine is driven by a 7½ horsepower motor and transmission of power to the spindles is through a train of spiral and spur gears.

ROWBOTTOM CAM MILLING MACHINE

The Rowbottom Machine Co., Waterbury, Conn., has recently perfected a universal cam milling machine which is adapted for cutting all types of cams. It is said to be the first cam cutting machine which has been designed with the cutter head carried on a vertical slide. Several important advantages are secured through this construction, among which the following may be mentioned: The roller which governs the movement of the cutter head is always kept in

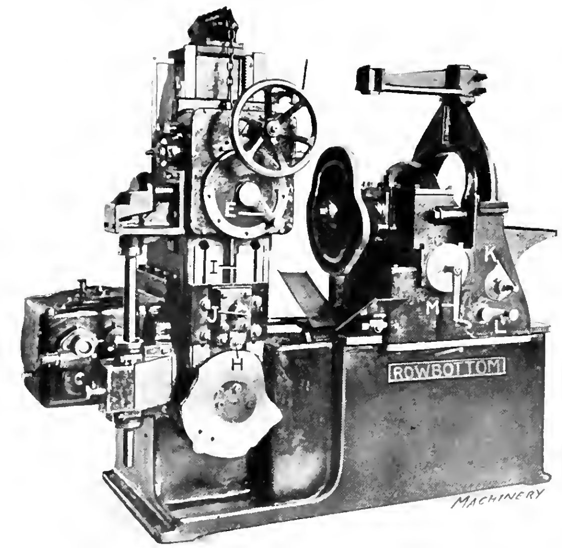


Fig. 1. Front View of Rowbottom Universal Cam Milling Machine

contact with the former cam through the action of gravity. When the cutter head works in a horizontal plane there is frequently a tendency for the cutter to creep or "flinch" away from the work, especially when difficult sections of the cam are being machined. Another advantage of the vertical cutter slide is that the chips and dust produced in cutting drop away from the work as fast as they accumulate.

Referring to Figs. 1, 2 and 3, it will be seen that the cam to be milled is held on a mandrel carried by the work head. This head may be supported with the mandrel in either a horizontal or vertical position as shown in Figs. 1 and 3. For milling plate or face cams, the mandrel is held horizontally, and for machining cylindrical cams the vertical position of the mandrel is employed. When using the mandrel in the vertical position, the outboard support is used; this support may be removed from the machine when it is not needed. The change from the horizontal to the vertical position is effected by first removing the support under the faceplate and then swinging the head down. The bolts which were formerly employed to secure the head in the horizontal position are now located in the proper position to clamp the head vertically. These bolts enter holes in the work head slide at the place where the faceplate support was formerly secured.

The machine is driven through a single pulley which is belted to a two-speed countershaft. The single driving pulley is equipped with a Johnson clutch, which is operated by the lever *A* located on top of the gear-box in Fig. 4. This lever is within easy reach of the operating position and provides for instantly starting or stopping the machine. The small lever *B* operates a sliding clutch between two bevel gears, and by throwing this lever to the forward or reverse station, the clutch is engaged to drive the machine right- or left-hand

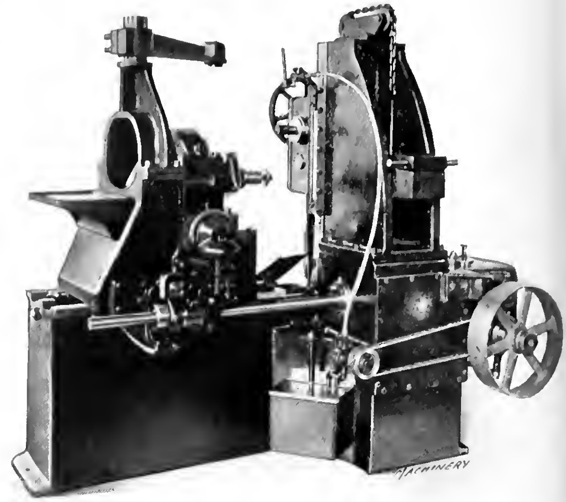

Fig. 2. Opposite Side of Machine shown in Fig. 1

as desired. There is also a neutral station for the lever *B*, in which position the clutch is out of engagement with both gears. It will also be seen that there is a lever *C* mounted at the rear of the gear-box which is provided with four stations. This lever operates a cone of gears in the gear-box to give either of four speed changes, and as the driving pulley is belted to a two-speed countershaft, there is a total of eight changes of speed available. Each of the speeds for the

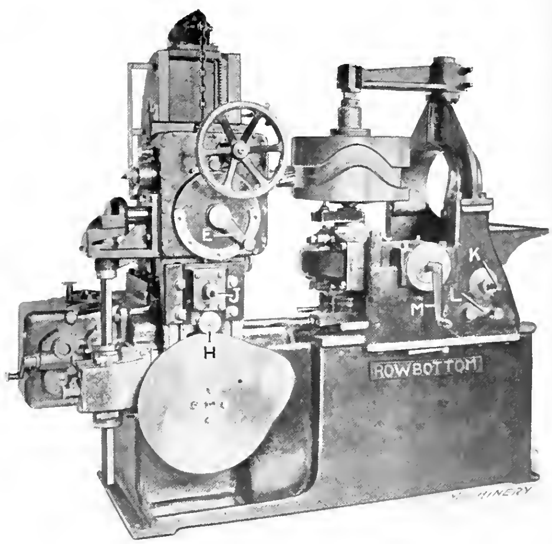

Fig. 3. Rowbottom Machine engaged in milling a Cylindrical Cam

former spindle and work spindle obtained in this way are necessarily the same in order to maintain the proper relation between the cutter and the work.

The last of the four operating levers in Fig. 4 is shown at *D*; it will be seen that this lever has three stations, the central one of which is the neutral position, while the other two stations provide forward and reverse rotation for the cutter spindle. An ingenious mechanism is used to obtain four

speed changes for the cutter spindle, and as in the case of the former and work spindles, there are eight available cutter speeds, owing to the drive being taken from a two-speed countershaft. An important feature of this cutter spindle speed changing device is that all changes are obtained through a single lever, which is shown at *E* in Figs. 1 and 3. These changes of speed are obtained through a sliding gear transmission which is shown in detail in Fig. 5. Referring to this

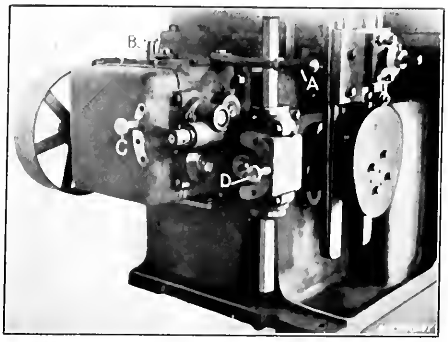

Fig. 4. Close View of Gear-box on Rowbottom Cam Miller

illustration, it will be seen that there are four pairs of gears; the four gears carried on the cutter spindle are fixed longitudinally and the same applies to the gear at either end of the driving shaft. Each of the driving gears *F* and *G* are splined to the shaft and provided with positive clutches, by means of which they may be connected to the gears at either end of the driving shaft. The longitudinal movement of these gears is controlled by fingers carried by two cam operated slides, and either of the gears *F* or *G* may be engaged directly with a gear on the cutter spindle or the clutch on either of these gears may be engaged with one of the gears at the end of the driving shaft which is always in mesh with the spindle gear. In any case, there is one of the four pairs of gears in mesh which provides for transmitting the motion to the cutter spindle at the required rotative speed.

It was mentioned that the movement of the driving gears *F* and *G* in Fig. 5 was controlled by fingers carried by a cam operated slide. The arrangement of this cam mechanism is shown in Fig. 6, the cam being operated by the lever *E* which is also shown in position on the machine in Figs. 1 and 3. The slides which move the gears *F* and *G* along the driving shaft are operated by the rollers *N* and *O*, Fig. 6, which run in a cam groove shown in this illustration. When the lever *E* is in the central station, both clutches and gears are disengaged, and consequently there is no rotation of the cutter spindle. By moving the lever *E* to the first station to the left

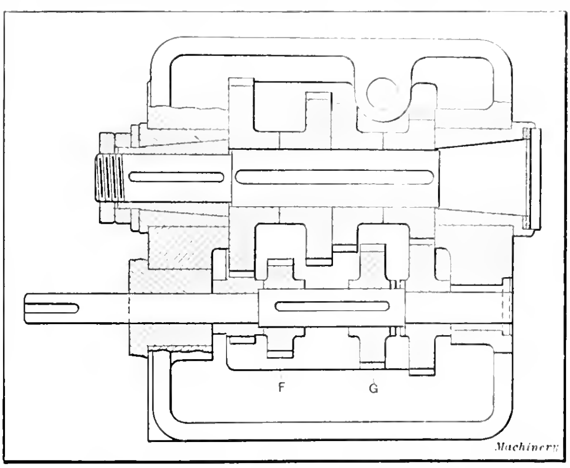

Fig. 5. Change Gears for varying the Cutter Spindle Speed

of the neutral position, point *P* on the cam groove has moved around to the roller *N* and has caused this roller to be moved toward the center of the cam. This results in a corresponding movement of the slide, which, in turn, throws the gear *F* into mesh with the gear on the cutter spindle. By moving the lever to the second station to the left of neutral, the point *R* on the cam groove has reached the roller *N*; this causes the roller *N* to be moved away from the center of the cam, and, in turn, the fingers on the slide move the gear *F* so that the clutch member on this gear engages the gear to the left of it, thus making the left-hand gear on the shaft the driving gear. By moving the lever *E* two stations to the right of the neutral position, the points *Q* and *R* in the cam groove are successively brought up to the roller *O* and cause the gear *G* to drive two of the gears on the cutter spindle as previously described for the gear *F*. In addition to the eight changes of speed obtainable through the gearing, an independent geared speeder is provided for use when small sized cams are being milled.

One of the features of this cam milling machine is that flat former plates are used for all types of cams. When the rise of the cam to be milled is relatively steep, it is advisable to use a former plate which is double the size of the work, if such a proceeding is practicable. The former plate is bolted to the end of the former spindle, and as the plate revolves it pushes the entire cutter slide up through its action upon the roller *H* shown in Figs. 1 and 3. This roller is mounted on an auxiliary slide which is connected to the main cutter slide by a screw adjustment, shown at *I* in Fig. 1. This screw adjustment is operated by a crank on the end of the squared shaft *J* to move the cutter slide on the bearings of the column, thus providing for operating the cutter at any desired distance from the center of rotation of the work-spindle. A scale is provided on the column which shows the distance that the cutter has been set from the center of the work-spindle. The adjustment for the depth to which the cutter enters the work is made on the work slide, the squared shaft *K* being provided for this purpose. This shaft has a micrometer collar so that when the work is brought up so that it just touches the cutter, this collar may be set at zero, after which the work is fed to the cutter to provide for milling to the required depth.

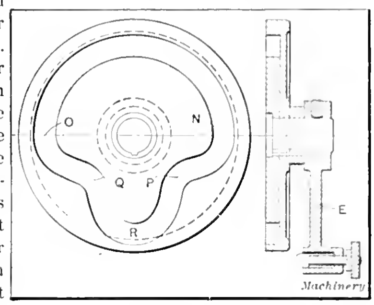

Fig. 6. Cam Mechanism for changing the Cutter Speed Gears

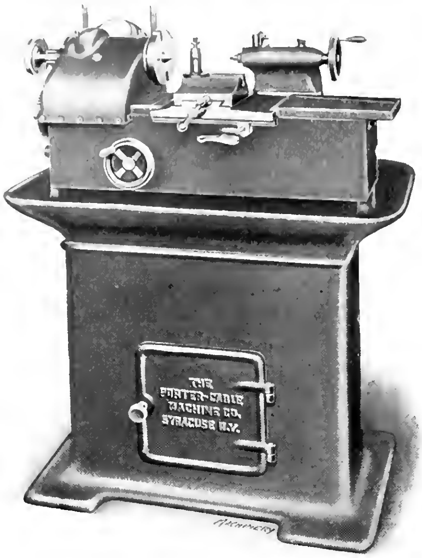
A convenient feature of this machine is the provision that is made for changing the relative position of the cutter and cam blank that is being milled. Suppose it was desired to alter the position of the cam groove slightly from that arbitrarily fixed by the location of the driving pin which passes through the work into the faceplate. The first step would be to move the lever *L*, Figs. 1 and 3, to the neutral position, which disengages the clutch that drives the work-spindle. The lever *M* is next turned through 1/12 of a revolution, after which the clutch is reengaged by the lever *L*. This clutch has 12 teeth and the result of this operation has been to re-mesh the clutch one tooth ahead of its former position. By means of the gearing in the work head, the resultant movement of the work relative to the cutter amounts to 1/4 degree. Power is transmitted to the work head by means of the horizontal shaft shown at the back of the machine in Fig. 2, and horizontal movement of the head on the ways of the machine is obtained through a horizontal screw. By reversing the direction of rotation by means of the lever *B* in Fig. 4, the work head may be traversed either toward or away from the cutter. The total length of a cylindrical cam that can be cut is represented by the traverse of the work head.

No lubricant is used on the cutter, but a strong blast of air is employed which serves to remove all chips and keep the cutter cool. This air blast is found to be an excellent substitute for lubricant even when the machine is engaged in cutting tool steel cams. However, there is a pump provided on the

machine and lubricant may be used if desired. This machine is very rapid in operation and is found satisfactory for milling practically any type of cam which is of a size within its range. The capacity is for face cams up to 28 inches in diameter, box cams up to 32 inches in diameter, and cylindrical cams up to 24 inches in diameter, with an 11-inch throw. The weight of the machine is 4500 pounds.

PORTER-CABLE LATHE

Quite a departure from standard practice has been made in the design of the lathe illustrated herewith, which is a recent product of the Porter-Cable Machine Co., Syracuse, N. Y. This machine is primarily designed for manufacturing operations on short pieces having a maximum length up to 12 inches. The machine gives excellent results when operating on work held between centers and is also well suited for a variety of small chuck and faceplate work. In developing this lathe, the idea was to produce a machine capable of handling the classes of work referred to, and at the same time save the purchaser from paying for a machine of larger size than he requires and one which occupies an unnecessary amount of floor space. This result is made possible by the application of an overhanging tailstock which travels on its own dovetail ways at the rear of the bed. This arrangement enables the carriage to be constructed on the plan of a milling machine table. The bed is 32 inches long and as it is not open at the top it is exceptionally rigid. The ways are protected at all times by the chip guards fastened at each end of the carriage, the front guard passing under the headstock.



Porter-Cable Lathe for Short Work on Centers or Small Chuck Work

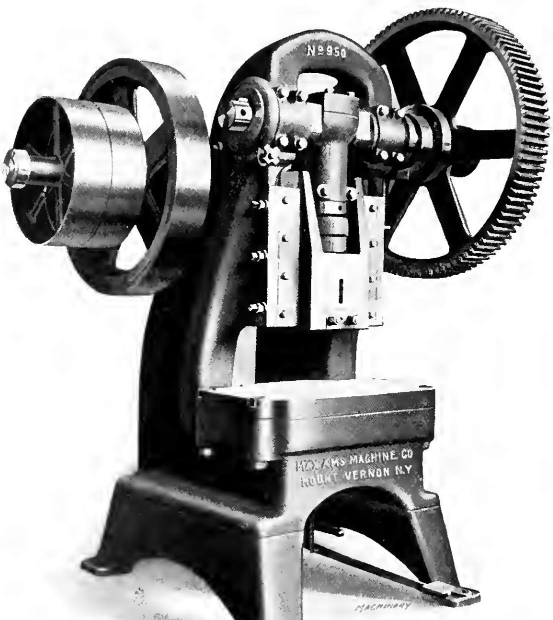
Both hand and power feed are obtained by means of a rack and pinion located nearly under the center of the carriage. This pinion is integral with a vertical shaft extending down through the bed, where it is connected through suitable gearing and a positive clutch to the regular change gears at the end of the lathe. Threads from 5 pitch down to the finest may be accurately cut. The feed in either direction can be automatically disengaged by the adjustable trip located underneath the carriage, and when thrown out the carriage may be run along by hand to the full limit of its travel without removing any stops.

The spindle is exceptionally heavy and can be furnished for use with a plain center or a set of draw-in collets for handling bar stock up to ⅝ inch diameter. The drive, which is of ample power, is obtained by a bevel gear and small pinion running at a high rate of speed, thereby permitting the use of a light belt. The gears are entirely enclosed, and as they run in oil the drive is very smooth and quiet. When it is necessary to change the spindle speed, this can be done in a moment by changing the driving pulley, the difference in the length of the belt being taken care of by the compensating countershaft. A valuable feature of this lathe is that the carriage can be run back underneath the tailstock, thus making it unnecessary to have the tail spindle extended when taking cuts near the dead center or for short work. This is also found to be a convenient feature for such operations as filing, polishing and taking measurements, as the carriage may be run entirely out of the way without disturbing the tailstock. Means are provided for adjusting the headstock sidewise in order to keep the centers in proper alignment. A reservoir for cutting lubricant is located in the upper part of the base and a cupboard in the lower part of the base is provided for keeping tools, gears, etc. For work within its range, the efficiency of this machine is equal to that of a 14- or 16-inch lathe, and it costs considerably less and also effects a saving in floor space.

AMS OPEN-BACK PRESSES

A new line of open-back presses has recently been placed on the market by the Max Ams Machine Co., Mount Vernon, N. Y. The distinguishing feature of these machines is their rugged design which is said to give them the strength of straight sided presses of corresponding size; in addition, strip stock can be fed from the side. Large sheets can be passed through the opening in the back of the press.

The frame is symmetrical in form and adequately ribbed to secure the required rigidity. The die space and the opening in the back of the press are of large size. The bearings of the slide are of ample proportions. A cap clamp, flange or dovetail for holding the punches may be provided according to the requirements of different users. The shaft is machined from a hammered steel forging and adequate provision is made for lubricating the bearings. These presses are particularly adapted for use in the manufacture of the parts of typewriters, locks, hinges and various other hardware and sheet metal specialties. This line of presses comprises eight different sizes and the patterns have been constructed in such a way that the design can be modified to suit the requirements of the different classes of work on which the machines will be used.



Ams Open-back Press

THE PROVIDENCE SHAPER

It has always been conceded that for accurate planing of machine parts having long surfaces that must be square or parallel with each other, it is necessary to use a standard planer. But on many jobs the planer is too slow and cumbersome to give very satisfactory results, owing to its inability to reverse on short strokes when operating at high speed. The slow adjustment of the cross-rail and head also reduces the efficiency of a planer when operating on such work. It has been generally recognized that for efficiency of operation on work that comes within its range, the shaper is a most desirable tool because its mechanism and all adjustments are conveniently controlled.

In designing the Providence shaper, the endeavor of the Providence Engineering Works, Providence, R. I., has been to combine the features of both the planer and shaper in a single machine; at the same time many special features have been added which increase the efficiency with which it operates. It will be evident from the illustrations that the design follows the general lines of an open-side planer, but the cross-rail is supported from the column at the left-hand end instead of at the right, which is the usual practice with open-side planers. Located in this position, the column is not in the operator's way. The open-side feature enables the machine to work on pieces that are too long to go through the housing of an ordinary planer, and also makes both ends of the work visible all of the time, so that the cutting tool can be set to a line at the beginning of the stroke instead of at the end of it. All of the operating handles for controlling the changes of feed and speed are within reach of the operator without requiring him to leave his position at the front of the machine. The head has horizontal, vertical and angular feeds secured through a sliding pinion that may be mounted on either the horizontal or vertical feed-screw, the pinion meshing with the gear on the main feed shaft. The usual type of stroke adjustment is employed.

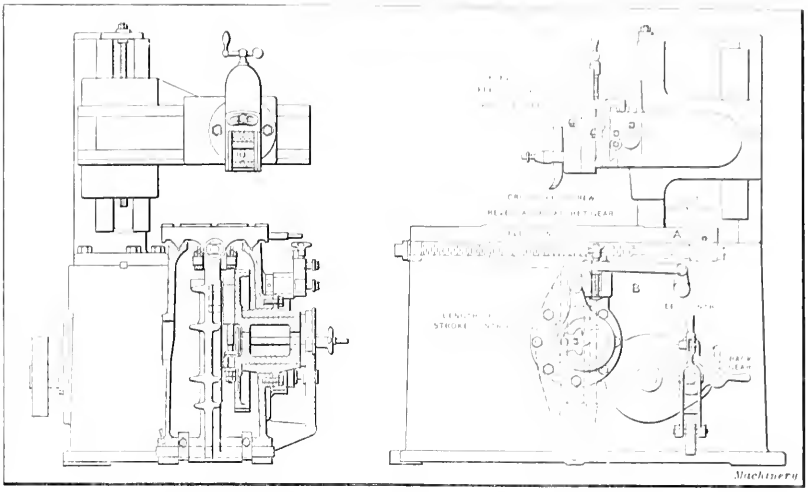


Fig. 3. Design of Machine showing Arrangement of Feed Mechanism

The frame and base of the machine are of box section, and the column is of similar construction. The cross-rail is counterbalanced by a weight located inside the column. Special attention is called to the design of the bearing of the cross-rail on the column. This bearing is longer than it is

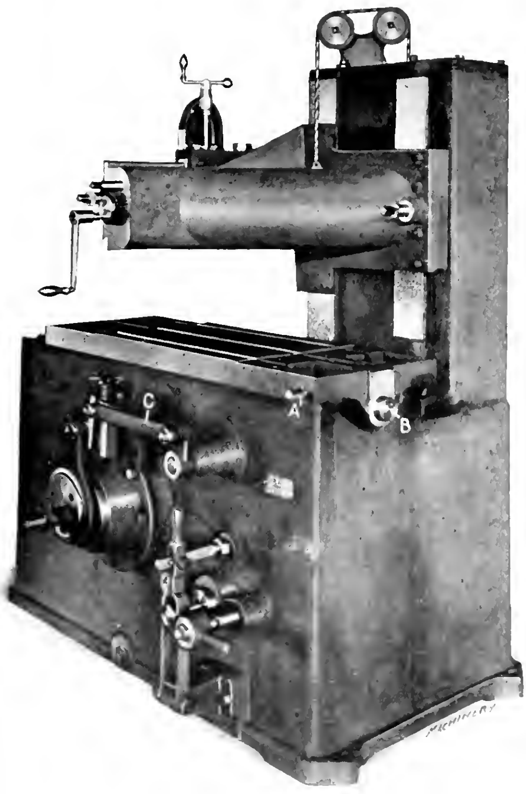

Fig. 1. Front View of Providence Shaper

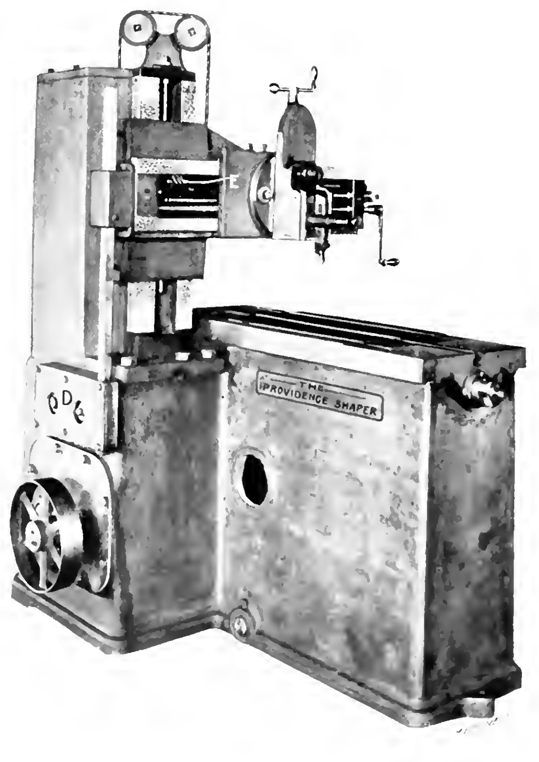

Fig. 2. Opposite Side of Machine shown in Fig. 1

wide in the ratio of $2\frac{1}{4}$ to 1. The cross-rail is secured in any desired position by drawing in the spring gib by means of a clamping bolt located at the back of the cross-rail. Tightening this bolt draws the cross-rail back against the face of the column and eliminates the chance of any play between these two members.

The positioning of the table is secured by means of a crank operated adjusting shaft *A* at the side of the table. This shaft works in conjunction with a pair of spiral gears which turn the main adjusting screw *B* beneath the table. This screw turns in a nut that moves the table to the desired position. The nut is gibbed in placed so that it acts as a support for the screw, the construction being such that there is no chance of deflection.

The motion is transmitted to the feed shaft through the rocker arm *C*, Fig. 1, the rate of feed being regulated by the star wheel. The motion is transmitted by a pair of spur gears located in the case *D* at the opposite side of the machine to the rack operating gear. By this means, the rack is operated to transmit the motion to the feed shaft running through the cross-rail. The feed operating gear is located on the opposite end of this shaft, and this gear transmits the motion to either the cross or vertical feed-screws by a sliding gear. This arrangement will be better understood by referring to the line cut, Fig. 3. The cross-rail is raised by a crank operated shaft *E*, Fig. 2, the position of which is fixed at the top of the cross-rail. This shaft provides for quickly raising or lowering the cross-rail to any desired position, the motion being transmitted to the vertical elevating screw through a pair of spiral gears.

The gear-box is of the unit type construction. By loosening the bolts on the flange of the case, the entire gear-box may be removed with the gears intact. The inner end of the gear-box is fitted over the end of the driving shaft bearing bushing, giving adequate support and insuring accurate alignment. The gears are of wide face so that ample strength is provided.

The principal dimensions of the machine are as follows: Stroke of table, 24 inches; horizontal travel of tool, 19 inches; vertical feed of tool, 6 inches; vertical adjustment of cross-rail, up to 16 inches; travel of saddle on cross-rail, 19 inches; distance from table to cross-rail when up, 16 inches; number of changes of table speed, 6; strokes of table per minute, 10 to 100; ratio of power gearing (maximum) 60 to 1; ratio of power gearing (minimum) 6 to 1; net weight of machine, 4400 pounds. Mr. James Coulter, vice-president of the Providence Engineering Works, Providence, R. I., is the designer of this machine.

STANDARD STEEL SHAFT HANGERS

The accompanying illustration shows the 1914 model of the "Pioneer" steel shaft hanger manufactured by the Standard

The "Pioneer" Steel Shaft Hanger

Pressed Steel Co., Philadelphia, Pa. The construction of this hanger includes features which represent the result of an experience of ten years in the manufacture of steel hangers and, in addition, several new features have been added. The use of steel in hanger construction insures a high degree of strength, which not only adds to the durability of the hanger but is also a factor in eliminating industrial accidents. Another noteworthy feature is the ease with which this type of hanger may be erected owing to the fact that the frames weigh much less than the corresponding size of hangers made of cast iron.

LENNOX SERPENTINE SHEAR

The accompanying illustration shows the Lennox serpentine shear that is a recent product of the Lennox Machine Co., for which Joseph T. Ryerson & Son, 16th and Rockwell

Lennox Shear having a Capacity for cutting Material up to No. 10 Gage

Sts., Chicago, Ill., have the sales agency. This machine is particularly designed for both straight and irregular cutting operations on sheets and plates. The frame is a steel casting of spiral construction designed to provide the necessary clearance when cutting material of unlimited length or width. Both straight cuts and "in and out" curves with a minimum radius only slightly larger than the diameter of the shear blades can be handled. All of the gearing is carried by the spiral steel frame which is mounted on a substantial base. All gears have cut teeth, and cast-iron gear guards are provided to avoid the possibility of accidents.

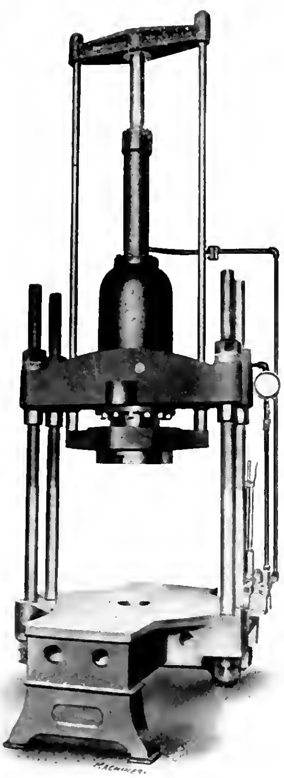
The blades are made of high-grade tool steel and set in such a way that there is very little distortion of the work in cutting. The upper cutter is positively driven while the lower cutter is mounted on an adjustable sleeve so that its position may be varied in cutting material of different thicknesses. There is also a cam movement provided which enables the lower cutter to be dropped sufficiently to permit the removal of sheets without reversing the machine. The cutters have a flush fastening on their shafts with no nut projecting out to interfere with the work. The knurled edges of the cutters feed the sheet automatically into the machine. A tool steel pin is provided to take the end thrust on the lower cutter shaft.

Where a number of sheets are to be cut to the same pattern, a templet may be bolted to the work; such a templet is then followed by guiding it against the top cutter. It will be seen that the machine is driven by means of a two-speed

pulley which gives a slow speed for intricate cutting and a high speed for simpler work. The main driving shaft is extended and squared on the end so that a crank may be used for turning the machine by hand if power is not available. The shear shown in the illustration has a capacity for cutting material up to No. 10 gage. Other sizes of these machines are made with capacities for cutting material up to 16 gage, up to 1/4 inch and up to 3/8 inch. All machines are arranged for either belt or hand power, or for direct-connected motor drive.

HYDRAULIC STRAIGHTENING PRESS

The accompanying illustration shows a 250-ton hydraulic straightening press recently built by the Hydraulic Press Mfg. Co., 84 Lincoln Ave., Mt. Gilead, Ohio. This machine is primarily intended for straightening structural steel shafts and bars, but it can also be employed for a wide range of work in the machine shop, being particularly suitable for bending, forcing, broaching and similar operations. The stock space can be varied from a minimum of 20 inches to a maximum of 48 inches. It will be seen from the illustration that the strain rods are threaded on their upper end and provided with nuts on both the upper and lower sides of the cylinder bearings.



Hydraulic Straightening Press

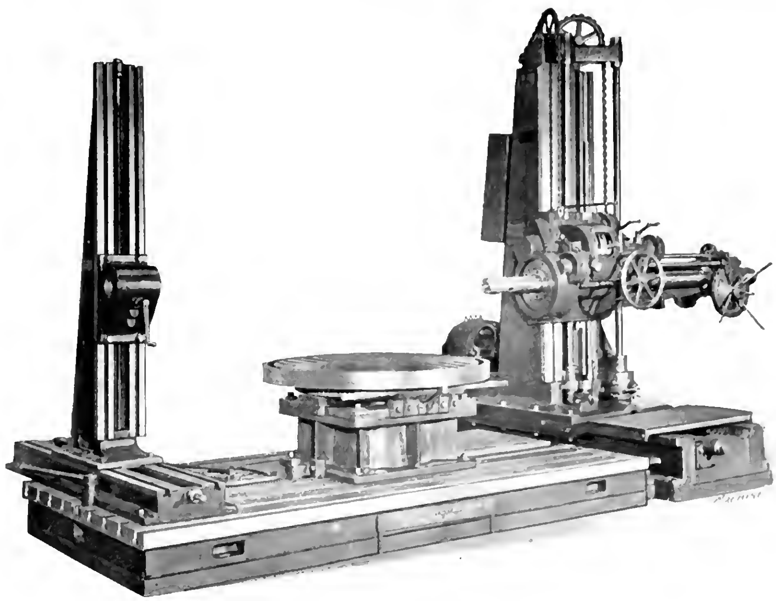
When it is found desirable to increase the stock spaces of the press a block of some suitable material is placed between the ram and the pressure bed. The upper nuts on the strain rods are then set to the desired point and the pressure applied. This action raises the cylinder until its bearings come in contact with the nuts. When the work is of such a character that it requires a smaller space, the block is still kept between the ram and pressure bed. In this case, the lower nuts are adjusted to the desired point while the pressure is still on. The pressure is then released, thus allowing the cylinder to drop to the desired point. The upper nuts are then screwed down against the cylinder bearings. In order to provide for raising and lowering the cylinder, the pipe connections have swing joints. T-slots are provided in both the ram head and bed of the press for use in attaching bending blocks, forms or dies. The body of the press provides for holding the work for bending between centers having a maximum distance of 72 inches.

It will be seen that the bed has a hole in the center which permits the press to be used for broaching, for forcing wheels on or off shafts and for similar operations. The diameter of the ram head is 20 inches and it has a run of 20 inches. The length of the press bed over all is 72 inches, while the width of working space is 26 inches. Steel is used throughout its construction. The pressure capacity of this press is 250 tons.

The four-way poppet operating valve applies the pressure to either the main pressure ram or the return ram in the pull-back cylinder, and at the same time permits the water or oil used in operating the press to return to the pump reservoir from the cylinder on which the pressure is released. This valve is operated by a single lever which has three positions. In the first position, the pressure on the main pressure ram is applied and the pressure released on the return ram. In the second position, the pressure is applied on the return ram and released on the main ram. In the third or neutral position, the pressure is held with the rams at any point in their travel in a stationary position. A five-way, high and low pressure, double-acting valve can be furnished if desired.

DETRICK & HARVEY BORING MACHINE

The illustration shows a standard No. 2 boring machine built by the Detrick & Harvey Machine Co., Baltimore, Md., which is equipped with a thread chasing attachment and a rotary table with a removable sub-base. The standard form of outboard bearing is also provided. The removable sub-base is shown in position beneath the rotary table, but when so desired this sub-base may be removed and the rotary table placed directly upon the floor plate of the machine.



Detrick & Harvey Boring Machine with Thread-chasing Attachment and Rotary Table

The thread chasing attachment is driven from the feed and is located on the rear of the saddle horn. The design is such that the chasing attachment cannot be thrown into action at the same time that the spindle is feeding. The arrangement of the change gears is similar to that used on a lathe and can be furnished to cut any required thread.

The rotary table is 60 inches in diameter, the rotary motion being hand operated. As previously stated, the sub-base can be removed from beneath the table to enable the table to be brought down closer to the floor plate. The height from the top of the table to the floor plate is 27 inches with the sub-base in position and 15 1/2 inches when the table is set directly on the floor plate. The table can be moved along the floor

plate by means of a rack and pinion operated by a lever. The rotary table is graduated to ½ degree to facilitate accurate setting.

BROWN CONTINUOUS RECORDING INSTRUMENT

The Brown Instrument Co. and the Keystone Electrical Instrument Co., Philadelphia, Pa., are placing a continuous recording instrument on the market for use as an electrical pyrometer. The instrument can also be employed as a recording volt-meter or ammeter. In its design, particular care has been taken to produce an instrument of as simple construction as possible, and at the same time to make it of the most compact form. The case of the instrument is only 15 inches high by 8 inches wide, and it projects out from the wall or switchboard a distance of 7 inches. The space occupied has been considerably reduced by placing the clock mechanism behind the record chart instead of to one side of it; the record chart is the only part shown on the face of the instrument.

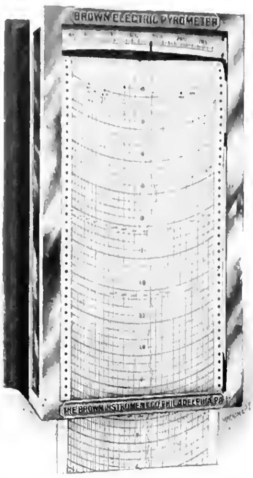


Fig. 1. The Brown Continuous Recording Instrument

A two month roll of record paper is used, which can be supplied with an inked ribbon to make a dotted ink record, or the record can be made on coated paper which entirely does away with the use of ink. It is only necessary to wind the clock once a week and to change the roll of record paper once in two months. The instrument in Fig. 1 shows a ten-hour record on the chart and a scale is placed above the record so that the indications are easily read at all times. The paper also has the scale printed on it for direct reading. Fig. 2 shows an instrument with the door open so that the interior construction may be more clearly seen. It is only necessary to open the case once every two months when the roll of record paper is changed.

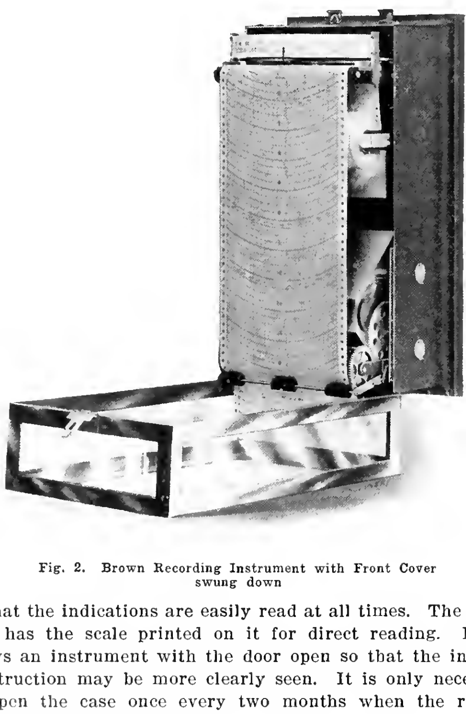

Fig. 2. Brown Recording Instrument with Front Cover swung down

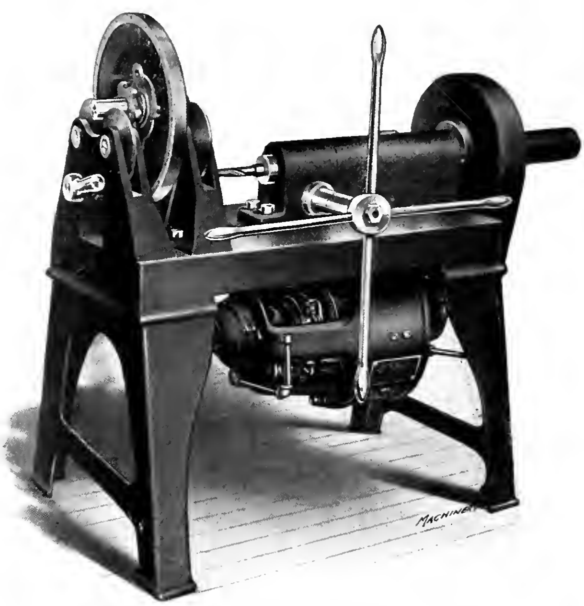
This recording instrument will prove particularly useful as an electrical pyrometer used in conjunction with thermocouples, for resistance thermometers for measuring temperatures, or for recording the voltage or current in an electrical circuit. As the d'Arsonval type of direct-current instrument used is of the frictionless type to prevent lag in the readings, it will be seen that a particularly sensitive and accurate instrument is secured.

ROCKFORD COMBINATION DRILLING AND BALANCING MACHINE

Where the practice of balancing flywheels, armatures, and other rotating parts by removing the stock by drilling is employed, a great amount of time is lost in transferring the work from the drill to the balancing ways in order to determine whether the required balance has been secured. The accompanying illustration shows a combination balancing and drilling machine which has been developed by the Rockford Tool Co., Harrison Ave. and 11th St., Rockford, Ill. This machine eliminates the necessity of moving the work back and forth between the drill press and balancing ways, after each hole has been drilled, and as cases are not uncommon where eight or ten holes have to be drilled before the required balance is secured, the saving effected will be readily appreciated.

The arrangement of the machine will be easily understood from the illustration, where it will be seen that the part to



Rockford Combination Drilling and Balancing Machine

be balanced is carried on an arbor supported on rotating disks. These disks are hardened and ground and the pivots run on ball bearings which insures a very sensitive movement. The work can be clamped in place and a hole drilled, after which it is released and the balance tested. Subsequent drilling operations are performed by merely retightening the work, this operation being repeated until the required balance is secured.

SIMONDS IMPROVED HACKSAW BLADE

A new "hard edge" flexible hacksaw blade has been put on the market by the Simonds Mfg. Co., Fitchburg, Mass. The chief feature of this blade of importance to users is that it will do the cutting work of the regular hard blade, and in addition is so flexible that it can be bent a great many times without breaking, thus eliminating a large percentage of the breakages that every user of hacksaw blades expects. The Simonds "hard edge" flexible blade is made in the standard lengths and numbers of teeth per inch.

POTTER & JOHNSTON AUTOMATIC PISTON AND PISTON-RING MACHINES

The Potter & Johnston Machine Co. of Pawtucket, R. I., has recently developed a special automatic piston and piston-ring turning machine, known as the No. 2 P. This machine is intended for use by automobile manufacturers in turning eccentric and concentric piston-rings, as well as in turning the pistons themselves. Any diameter of piston from three to eight inches and up to twelve and a half inches long may be turned, and piston-rings of any width and from three to eight inches diameter are turned and cut off automatically from the piston-ring sleeve. The machine is entirely automatic in operation, the attendant simply placing the piston on the draw-back arbor and starting the machine. The turning and grooving are then automatically done. Similarly, on piston-rings, the piston-ring sleeve casting is held in the chuck and the entire casting turned up, boring out the center and turning the outside eccentric, at the same time marking each ring at the thin spot for separating, as well as cutting off the entire number of pistons automatically. A general view of the machine is shown in Fig. 1, while in Fig. 2 the machine may be seen as viewed from the rear. In both these views the machine is shown set up for piston-ring turning. Figs. 3 and 4 are plan views of the machine with the tooling equipment necessary for piston-ring turning and piston turning, respectively.

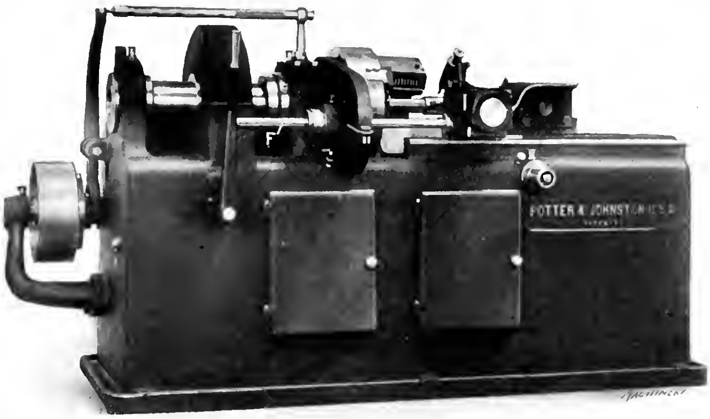


Fig. 1. Potter & Johnston Automatic Piston and Piston-ring Machine

From Fig. 1 it will be seen that, in general, the machine resembles the Potter & Johnston automatic chucking machine, except that it is simpler, the different feeds, speeds and attachments being eliminated from this machine, and everything is done to make it extremely powerful and simple on the operations for which it is intended. Power is carried to the driving shaft by a thirteen-inch single pulley drive. The driving shaft is supported by an outboard bracket and also fitted with a friction clutch so that the machine may be started and stopped independently of the drive.

As may be seen in Fig. 2, the gear-box from which the machine is controlled is at the rear and by its means the forward feeding of the tools is effected; a quick return movement to the tools in the ratio of 65 to 1 is provided for, and also the gears may be put into a neutral position so that no feeding of the cutting tools will take place. The general design of the gear-box is the same as that employed on all Potter & Johnston machines, but is much simpler because there is not the range of feeds and speeds to be provided for. The forward feeding of the tools is accomplished by planetary gearing in which there are two gears side by side varying by one tooth, and meshing with them is a planetary pinion that travels around these two gears, gaining a tooth at each revolution, thus causing one of the gears and hence the feed to advance by this amount. When in the neutral position, no feeding taking place, the ratchet and latch that gives the feed are disconnected, and the position is called the "latched-up" position. For the return motion, a clutch is thrown in, connecting the back-shaft directly with the reverse gear and causing the tool to return at a speed sixty-five times greater than the advance.

From the intermediate shaft, gearing transmits power to the main spindle directly through a large driving gear. This gear is encased as may be seen in the photograph. The driving spindle is 5¾ inches diameter and has long bearings, giving it ample power and long life. The spindle speed is constant and fixed according to the diameter to be turned, any variations in speed being obtainable through change gears. The oiling system is located over the gear-box (see Fig. 2) and from the central reservoir, tubes run to the important bearings. Each tube is fitted with an independent regulator to govern the supply of oil to the individual bearings.

The back-shaft, which may be seen at *A* in Fig. 2, transmits motion to a cross-shaft through bevel gearing, and then by a worm and worm-wheel to the turret drum-shaft. A friction clutch is located beyond bearing *B* so that in case of excessive strain on the cutting tools, the friction clutch will slip and save the mechanism from injury.

The turret drum-shaft and turret drum are, of course, within the machine and directly under the turning slide *C*. The cam-plates on this turret drum are of hardened steel and thus have a long life. The turning slide corresponds to the ordinary turret slide, but does not rotate as in the chucking type of machine, its working face always being presented to the work. The turning slide carries the cutting arbor *D*, and actuates its forward movement. The rocker arm *E* upon which the cutting-off tools are mounted is actuated by a face-cam on the turret drum-shaft.

At the front of the machine is the eccentric driving shaft *F*. This is driven by a pair of spur gears from the main driving spindle, and transmits motion to the eccentric turning slide that provides the motion for the eccentric turning. Referring now to the plan view, Fig. 3, the operation of the tools may best be observed. Here the eccentric driving shaft is shown at *F*, working in an eccentric bushing *G* that gives the in and out motion through a vertically operating slide *H* to the cutting tool slide *I*. On the end of this cutting tool slide is the eccentric turning tool *J*. Mounted at the left of the eccentric tool slide is the automatic marker that locates the thin point on each ring and marks it so that it can be correctly cut. This marker bracket is shown at *K*, and the marking plunger *L* is operated through a connection with lever *M* which is, in turn, operated from cam *N*. This cam follows the eccentricity of the piston-ring being turned and has an abrupt drop at the thin point, allowing the marker plunger *L* to come in quickly and make an impression upon the piston-ring at the low point. A spring in this marking tool is, of course,

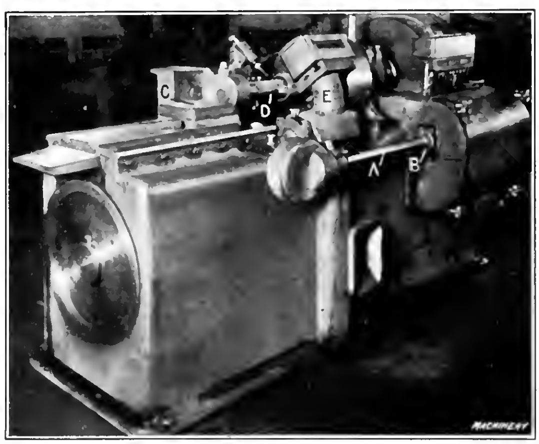

Fig. 2. Opposite Side of Machine shown in Fig. 1

necessary to cause the tool to cut into the ring. In addition to being held and supported by the turret slide, the eccentric turning tool and its bracket and the automatic marker are well supported by a bearing plate *O* which has a continuous bearing upon the steel plate that is bolted to the top of the front way of the machine.

The operation of the machine when working on piston-rings is as follows: The piston-ring sleeve casting is held in machine and the thirteen rings are turned, marked and cut off in 4½ minutes.

The cutting-off tools carried by the rocker arm are first adjusted and set in position in a removable block that is, in turn, held on the rocker arm. This block, with the tools intact, can easily be removed at any time for resharpening and the block returned without affecting the adjustment of the machine in any way.

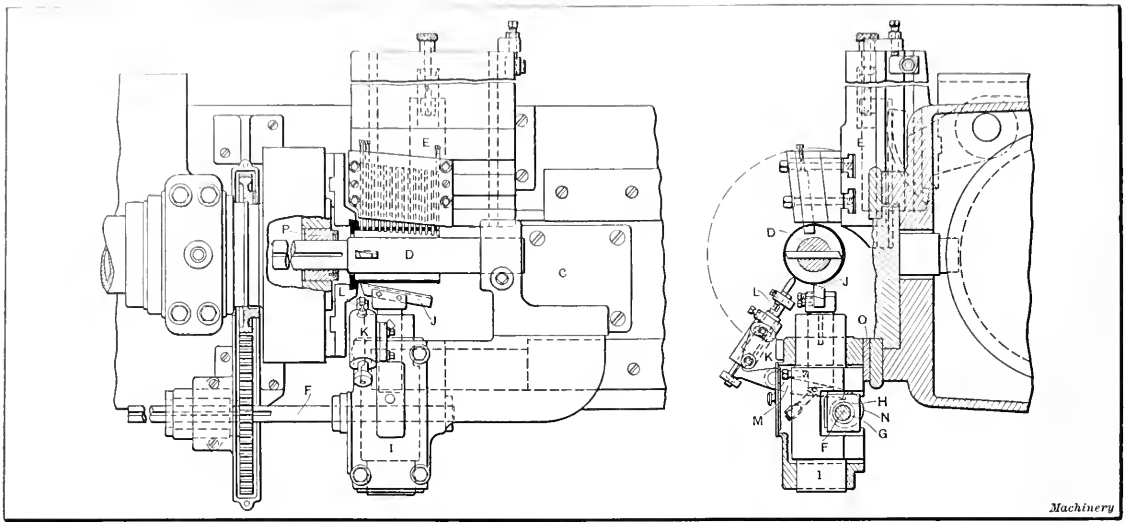

Fig. 3. Plan View of Machine tooled for turning Piston-rings

the universal chuck upon the main spindle of the machine. The boring bar is held on the turret slide and its inner end is piloted in the bushing *P* which may be seen in the line illustration, Fig. 3. This bushing is fitted with a felt washer which keeps dust and chips out of the bushing. The concentric boring tool is, of course, located in the boring bar as shown. The eccentric turning tool is firmly bolted in the eccentric turning slide and receives its motion in the manner just described. As soon as the eccentric turning tool has

When working on pistons, the tool set-up is about as shown in Fig. 4. Here the piston is shown at *A*, being held in place upon the spindle nose *B* by means of a cross pin *C*, passing through the wrist-pin hole, which is drawn back by a draw-back bar *D*. The draw-back bar is quickly operated by means of lever *E*. The pistons are bored and turned on the open ends before coming to this machine. When used for piston-turning, no eccentric turning slide is necessary, so the bracket supporting the eccentric turning and marking fix-

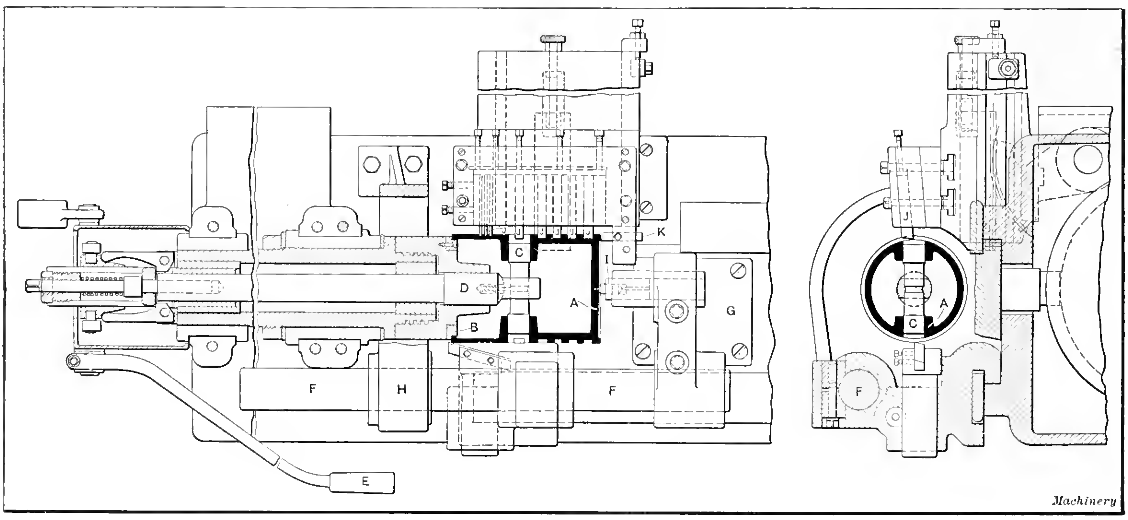

Fig. 4. Plan View of Machine tooled for turning Pistons

commenced its cut, the rocker arm with its multiple set of cutting-off tools comes in from the rear. This is clearly shown in Fig. 3, and as the cutting tools are set each slightly ahead of the other, the rings are separated about as soon as the outside portions have been turned and marked. An idea of the speed at which piston-rings are made may be gathered from the fact that a casting which will make thirteen piston-rings, 5/16 inch wide and 4 1/4 inch diameter, is put into the

tures is removed. The turning bar *F* is operated from the turning slide *G* and its outer end is piloted in a bracket *H* bolted to the frame of the machine. By thus piloting the turning tool, great stiffness is secured. A centering tool is located at the front of the turning slide. The grooving tools *J* and the end turning tool *K* are operated from the rocker arm, these being substituted for the cutting-off tools used in piston-ring turning. As in the case of piston-ring turning, the

different operations on the pistons are performed simultaneously, being centered, faced, turned and grooved at the same time.

In accordance with recognized practice, pistons are finished on this machine in two operations, roughing and finishing, sufficient time being allowed to elapse between these operations to insure accuracy. The turning time for pistons, 3¾ diameter by 3¾ inch long, is 6 minutes. This includes roughing and finishing.

STANDARD ROLLING MILLS

The accompanying illustrations show two rolling mills which constitute an addition to the line of machines manufactured by the Standard Machinery Co., Elmwood Ave., Auburn, R. I. The machine shown in Fig. 1 is a light mill with rolls 5 inches diameter by 8 inches face width. This machine is equipped with a constant-speed motor used in connection with a special Cutler-Hammer controller which allows the mill to be started and stopped by a foot treadle.

Beneath the bed of the machine there is an oil switch which is connected to an automatic switch shown in the illustration; this arrangement allows the operator to press down and lock the treadle on the special treadle stand which has a shoulder on it. When the rolling operation is finished, the treadle is pushed to one side, allowing it to snap back through the action of a spring and thus shut off the current from the motor. Exclusive of the motor train, the machine is driven through a triple train of gearing which includes the intermediate and driving trains on the machine proper with cut steel herringbone gears in the housings. The motor pinion is of rawhide and meshes with a cut steel gear on the driving shaft. The teeth of all of the gears are cut.

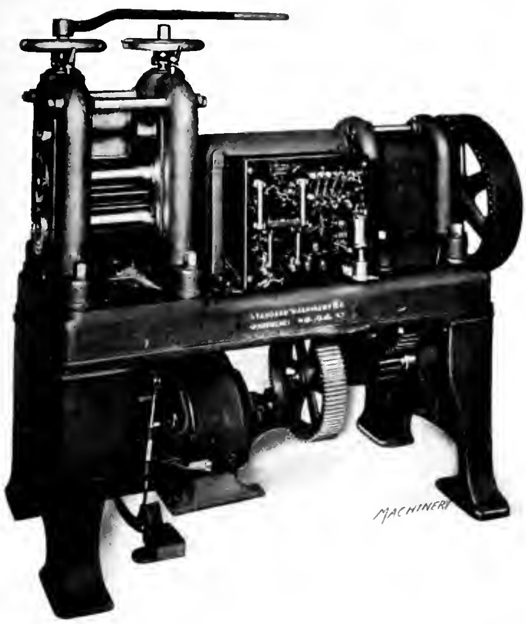

Fig. 1. Standard Rolling Mill with Constant Speed Motor Drive

The machine is equipped with hardened and ground rolls of special Krupp steel. These rolls have hardened and ground journals which run in the Standard roller bearings. The face of the rolls are mirror lapped. The housings are fitted with handwheels with micrometer dials. The principal dimensions of the machine are as follows: Sizes of rolls, 5 inches diameter by 8 inches face width; back gear ratio, 16 to 1; floor space occupied, 7 by 2½ feet; weight of machine, 3600 pounds.

Fig. 2 shows a machine which is a modification of the rolling mill illustrated in Fig. 1, the former machine being arranged for belt drive. The special features of this machine consist of making the bed all one piece and doing away with the legs and bearing bracket below the separate bed. This construction makes a self-contained machine of the same dimensions as the one previously described. All of the bearings are bronze bushed. The clutch is of the cone type and permits the mill to be started and stopped without requiring the operator to use his hands, the clutch being thrown in and out by means of a spring mechanism on the driving shaft.

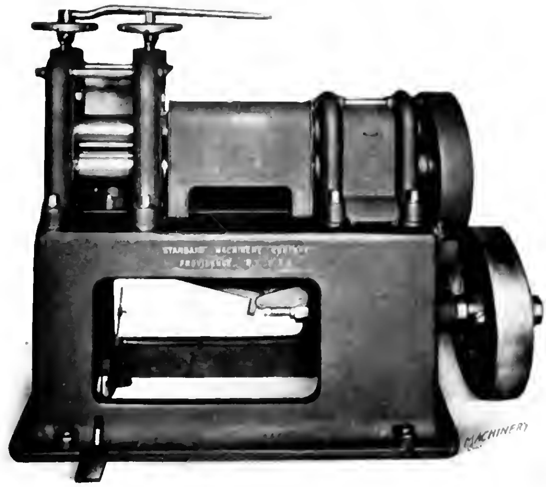

Fig. 2. Same Type of Mill arranged for Belt Drive

KNIGHT DUPLEX MILLING MACHINE

The light duplex milling machine illustrated herewith is a recent production of the W. B. Knight Machinery Co., 2019-25 Lucas Ave., St. Louis, Mo. This machine has been designed for manufacturing work where it finds application on many light jobs that can be milled on two sides simultaneously. The duplex machine cuts the operating time exactly in half, and as a second setting of the work is saved, the chucking time is also reduced 50 per cent. Among the classes of work which this machine will handle, the following may be mentioned: milling the frames of typewriters, adding machines, cash registers and similar parts where lugs occur in pairs and are to be finished on opposite sides of the casting; and milling flats, squares and hexagons on shafts, tools, etc. The work may either be handled by putting a number of

Knight Duplex Milling Machine for Light Work

pieces vertically in a jig and passing them between two end mills to finish opposite sides simultaneously, or by bringing the heads closer together and driving two cutters in opposite directions with one cutter above the other.

As the machine is particularly designed for the class of work which has been referred to, the longitudinal feed of the table is the only one required. The table is provided with a quick return at 7½ times the feed. The feeds and speeds are obtained through gears which are fully enclosed, and the feed and adjustment screws are fitted with graduated collars. The spindles run in adjustable bronze bearings. Both the uprights carrying the spindles are controlled by one handwheel which moves them toward or away from each other simultaneously. This handwheel has a graduated set collar to indicate the distance that each head has moved. The heads can be raised or lowered on the uprights, independently of each other and graduated scales on the vertical ways and graduated set collars on the vertical screws facilitate an exact adjustment which is matained by means of lock nuts. Both the uprights and saddle carrying the table are also clamped to the bed of the machine by means of lock nuts.

Gears contained in the bed of the machine provide six changes of spindle speeds, the same gear box controlling both of the spindles. The drive is through gears which transmit power from the single clutch pulley at the end of the bed. At the opposite end of the machine from the driving pulley there is another gear box which controls the longitudinal feed of the table. There are six all-geared feeds instantly obtainable, the feed range being from 0.008 to 0.060 inch per revolution. Both sets of change gears run in oil and all levers controlling changes of speeds and feeds are conveniently located at the front of the machine. Adjustable gibs are used to compensate for wear between the spindle heads and the uprights. The principal dimensions of the machine are as follows: maximum distance between spindles, 22 inches; height of spindles from bed, 2 inches to 9 inches; range of spindle speeds, 50 to 400 R. P. M.; working surface of table, 8½ by 32 inches; longitudinal table feed, 24 inches; floor space occupied, 73 by 73 inches; net weight of machine, 1550 pounds.

This machine is to be exhibited at the Boston Auto Show, Mechanics' Bldg., March 9 to 14.

WHITCOMB-BLAISDELL GEARED HEAD LATHE

The Whitcomb-Blaisdell Machine Tool Co., Worcester, Mass., has recently added to its line of lathes a geared head machine which is illustrated herewith. The changes of spindle speeds on this machine are obtained through sliding clutches which are so arranged that it is impossible to engage two speeds at the same time. The idea in bringing out these machines was to meet the demand for a powerful geared head lathe which is adaptable for either single pulley drive from the lineshaft or direct-connected motor drive through a constant-speed motor. The design combines the features of simplicity and durability.

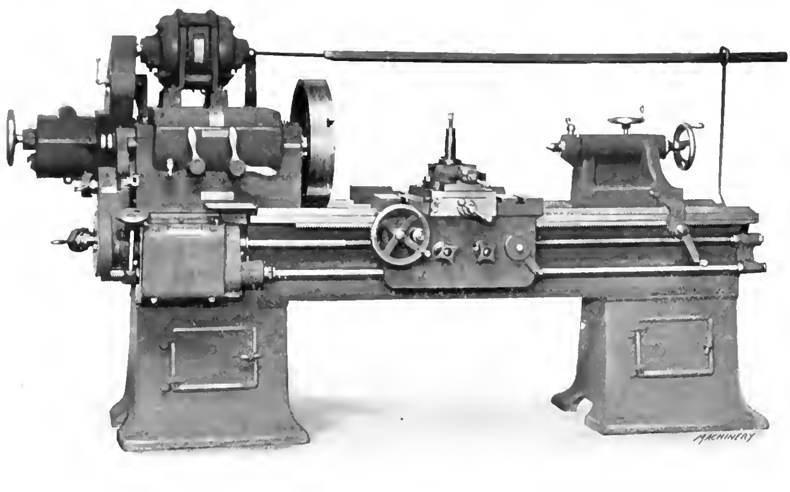

Fig. 1. Whitcomb-Blaisdell Geared Head Lathe with Single Pulley Drive

A noteworthy feature of these machines is that the spindle may be stopped, started or reversed from the operating position without requiring the use of a countershaft or reversing motor equipment. This feature is obtained through the application of two clutches and gearing located in the reversing friction gear box at the head end of the lathe. Although a single speed motor is entirely satisfactory it is, of course, possible to use a 2 to 1 or 3 to 1 variable speed motor, but the variable speed motor is by no means necessary. In addition to the reversing geared headstock, these machines include all of the regular features applied on Whitcomb-Blaisdell lathes. The line includes machines ranging from 14 to 30 inches.

ALLEN SOCKET FILLISTER SCREW

In the November, 1910, number of MACHINERY, the safety set-screw made by the Allen Mfg. Co., Inc., 135 Sheldon St., Hartford, Conn., was illustrated and described. This company has recently brought out a fillister-head screw which is turned

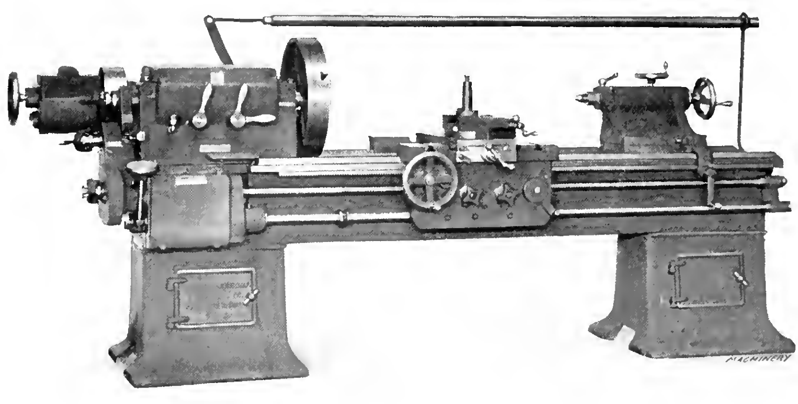

Fig. 2. Whitcomb-Blaisdell Lathe with Electric Motor Drive

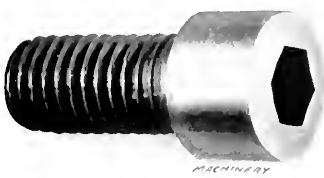
by a key fitting in a socket in the head; one of these screws is illustrated herewith, and little description will be necessary to point out its features. This form of screw will stand up under hard service where the slotted head screws soon become so badly worn that it is very difficult to turn them. Anyone who has had any experience in turning ordinary fillister-head screws with a screwdriver knows that the slot often becomes battered in a way which makes the screw very difficult to turn.

The application of the socket head idea on fillister screws enables the screw to be turned up fully as tight as an ordinary

hexagon headed capscrew. As no clearance is necessary around the head, these screws can be conveniently used in many places where there would not be sufficient clearance for a hexagon headed screw. The heads of the Allen fillister screws are trimmed so that the head and body are in perfect alignment. Screws of this kind improve the appearance of a machine and constitute a good "talking point." At the present time the Allen Mfg. Co. is making screws of this kind in sizes ranging from 3/16 to 3/4 inch, and in any length. Other sizes will be added to the line from time to time.

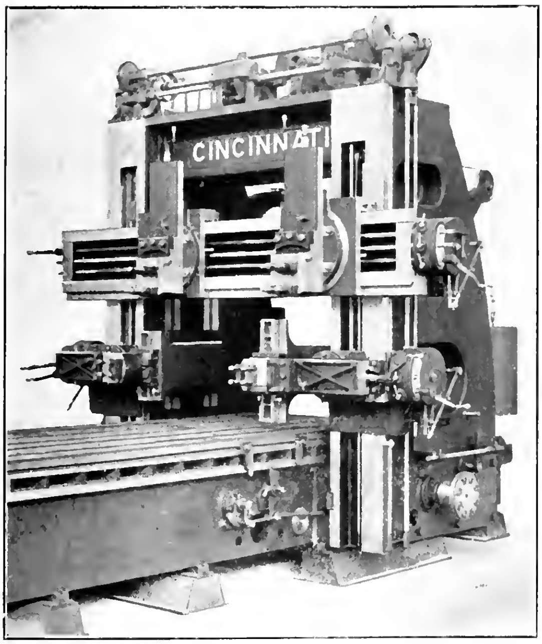


Allen Socket Fillister-head Screw

CINCINNATI LOCOMOTIVE CYLINDER PLANER

In the January, 1914, number of MACHINERY a large size planer built by the Cincinnati Planer Co., Cincinnati, Ohio, was illustrated and described. The accompanying illustration shows a machine of similar design which has been built for planing locomotive cylinders. This machine has a capacity of 72 by 72 inches and has rapid power traverse to all heads in any direction. All movements are independent of each other and can be operated whether the table is in motion or not.

The special feature of this machine lies in the provision of the auxiliary side head supports. The heads are provided



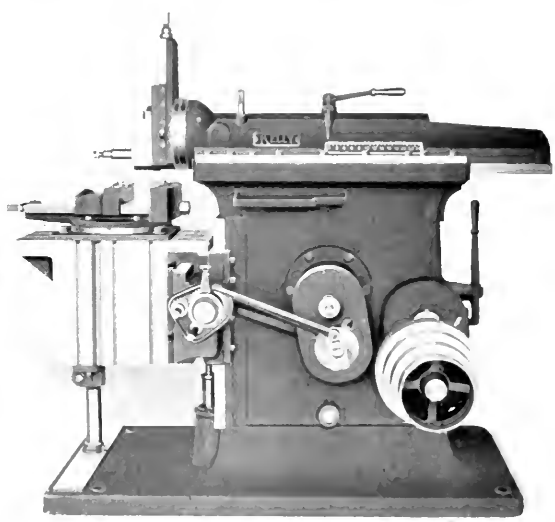
Cincinnati 72 by 72-inch Locomotive Cylinder Planer

with extra brackets which are rigidly bolted to the inside of the housing; these brackets support the slides while the machine is engaged in planing the frame fits and similar operations. They are adjustable for height and can be used in any position between the top of the table and the bottom of the cross-rail. A sliding shoe fits the front face of the brackets and has a dovetail on it which the cross-slide fits. This construction eliminates all twisting strains on the face of the housing caused by the long overhung slide and the upward pressure of the tool. These special brackets can be easily removed from the machine, thereby converting it into a standard planer. This planer is built in various sizes and lengths.

R. A. KELLY SHAPER

The accompanying illustration shows a shaper which constitutes a recent addition to the line of machines manufactured by the R. A. Kelly Co., Xenia, Ohio. The feed on this machine is through a ratchet and plunger mechanism, the ratchet being covered over the greater part of its circumference. The stroke of the pawl is always the same amount, so the feed depends upon the number of ratchet teeth that are exposed. The ratchet cover is prevented from turning, through the action of a spiral spring that holds it just tight enough so that it can be turned by hand.

The shaft which carries the ratchet cover is fastened to a



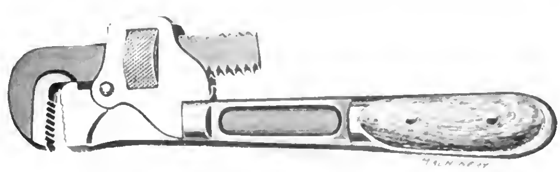
R. A. Kelly Shaper

radius rod, the other end of which is fastened to the radial gear guard carrying the lower feed gear. When the cross-rail is raised or lowered, the shaft carrying the ratchet cover rotates just enough to keep the same number of teeth in the ratchet exposed. In this way the cross-rail may be lowered from the highest to the lowest position or *vice versa* and no adjustment is needed.

The advantages of this feed mechanism are that it may be started, stopped, changed from a maximum to a minimum or reversed when the machine is in motion, without requiring any moving part to receive attention from the operator.

SMITH PIPE WRENCH

The accompanying illustration shows the Smith "perfect handle" pipe wrench which is a recent product of H. D. Smith & Co., Plantsville, Conn. The feature of this wrench is the handle which is both strong and convenient for the



Smith "Perfect Handle" Pipe Wrench

operator to hold. The swell at the end of the handle prevents the hand from slipping off and the wooden inserts make it comfortable to use in extremely hot or cold weather.

BRIDGEFORD AXLE LATHE

The accompanying illustrations show a center drive gap axle lathe with two carriages, which the Bridgeford Machine Tool Works, Rochester, N. Y., has recently designed for use

in railroad shops. This machine is intended for turning journals of car axles without removing the wheels, and as it is equipped with two carriages, both ends of the axle may be finished simultaneously. This means a considerable saving of time taken to machine a pair of journals. In other respects, the construction of the present machine is similar to that of the regular line of axle lathes built by this company.

The most satisfactory method is to place the machine in a pit so that the axles with the wheels attached to them can be placed on the centers with very little trouble. The driving gear, which is two pitch with a face width of 5 inches, is completely encased and runs in heavy bronze bearings scraped to an accurate fit. It is furnished with drivers for driving the axle, these drivers operating on the same principle as the self-centering style drivers furnished with the standard Bridgeford axle lathes. The driving gear is in two pieces, tongued and grooved together and secured by four heavy hinged bolts and nuts. These bolts are easily operated by means of a socket wrench and less than one-half turn of each nut is sufficient to release the gear so that it may be opened to allow the entrance of the wheels and axle. The upper half of the driving head operates on a heavy hinge stud in the front of the machine. To lift the head, the pull pin is pushed into place and the nuts are released. An eye-bolt is placed on the upper half of the head and a rope with counter-weights is used to lift and lower the head.

The machine is driven by a constant-speed pulley and there are three geared changes of cutting speed. The gears are of steel with cut teeth and run in oil, the changes of speed being accomplished by shifting levers conveniently located on the case. From the speed box, the power is transmitted to the driving head by a shaft located inside the frame of the machine. All driving shafts are of high-carbon steel and run in scraped bronze bearings.

There are four instantaneous changes of feed ranging from 1/16 to 3/16 inch per revolution of the axle. The gears in the feed box are of steel and run in oil; they are operated by a lever placed at the center of the lathe. The tailstocks have bearings 24 inches in length on the bed; they are secured in position by four heavy bolts and binders and the spindles may be adjusted by means of screws and handwheels. The carriages are driven by a splined feed shaft and the direction of the feed is changed at the apron. Each carriage is independent of the other. The carriages have a bearing 30 inches in length on the vees and they also have a bearing at the back of the bed which takes the forward thrust, thus overcoming the tendency to raise the carriages from the vees when the burnisher is used.

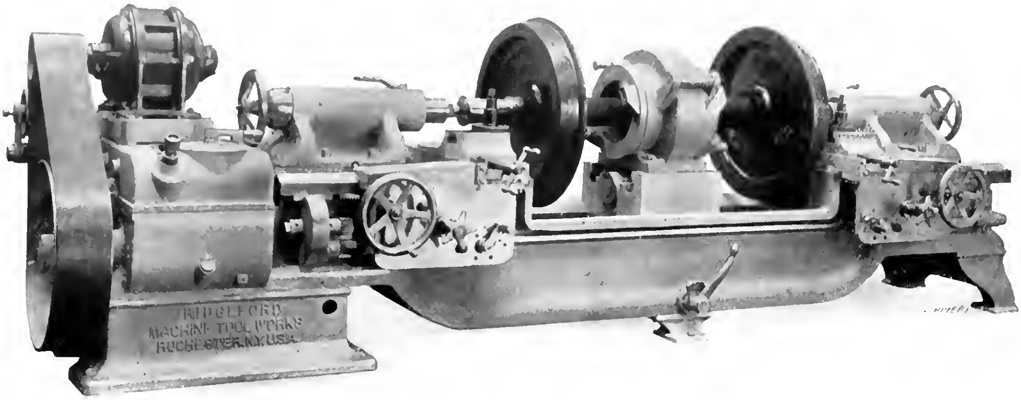


Fig. 1. Bridgeford Axle Lathe equipped with two Carriages

The bed is of rigid construction, strongly reinforced with cross ties to provide the required rigidity. The principal dimensions of the machine are as follows: Minimum distance between centers, 54 inches; maximum distance between centers, 105 inches; swing over ways, 27 inches, over the carriages, 13½ inches and in the gap, 45 inches. Fig. 2 shows a machine equipped with two extra inside carriages for refinishing locomotive and tender axles with inside bearings. Such a machine is exceptionally useful for all kinds of axle repair work. The weight of a lathe equipped with two carriages is 16,000 pounds and a lathe with four carriages has a net weight of 18,000 pounds.

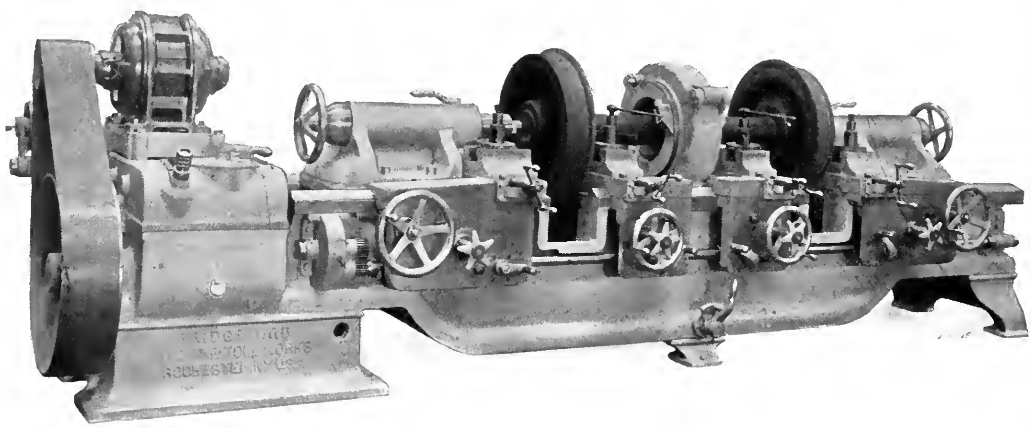

Fig. 2. Bridgeford Lathe with Regular Carriages and Two Extra Inside Carriages

PEDRICK PORTABLE MILLING MACHINE

The notable features of a portable milling machine which has recently been placed on the market by the Pedrick Tool & Machine Co., 3639 Lawrence St., Philadelphia, Pa., are the simplicity of its design, the adaptability of the machine for operation on a variety of classes of work, and the provis-

ion for driving by motor, belt or hand as desired. In a portable tool of this character, simplicity of design means less weight, greater convenience of operation and lower cost. For these reasons, automatic feed has been omitted on the No. 1 machine, hand adjustment for the longitudinal and cross traverse being provided, which serves every purpose. The No. 2 machine, which is considerably larger and intended for a wider scope of work, has automatic feed.

In designing this machine, particular care has been taken to have the construction of ample strength. The spindle bearing is proportioned to give rigid support and to have the desired durability; the bed is ribbed in the center and has removable posts at both ends. These posts may be taken out if necessary when setting up the machine, as there are cases when they would interfere with a wrench used for tightening the holding nuts inside the base. There are a number of elongated slots in the base to provide for attaching the machine to the work. An important feature of the design is that the machine will mill a surface level with the surface on which it is attached or several inches below it. The machine does not "smother" the job and it will face a small valve seat just as easily as one of the maximum size that it is capable of machining. The machine will work with equally satisfactory results in either a horizontal or vertical position.

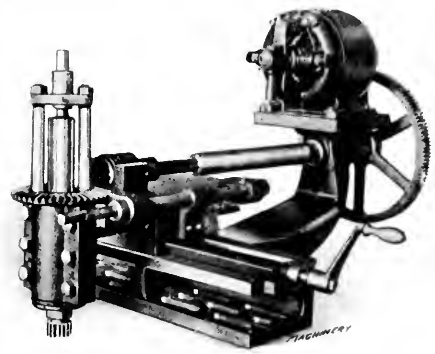

Fig. 1. Pedrick Portable Milling Machine

The spindle and quill revolve together and there are no shoulders or collars to wear and allow the cutter to flinch away from the work. Another feature is that when the cutter is no larger than the diameter of the spindle, it may be lifted out of the bearing with the spindle to enable the cutter to be sharpened or a new one to be used. This is accomplished by merely loosening two nuts and is found to be a particularly convenient feature of the machine, because if a cutter is working in a small deep chest where there is not sufficient room to reach in and unscrew it, it is not necessary to remove the entire machine. The spindle has a standard taper so that an ordinary cutter may be used.

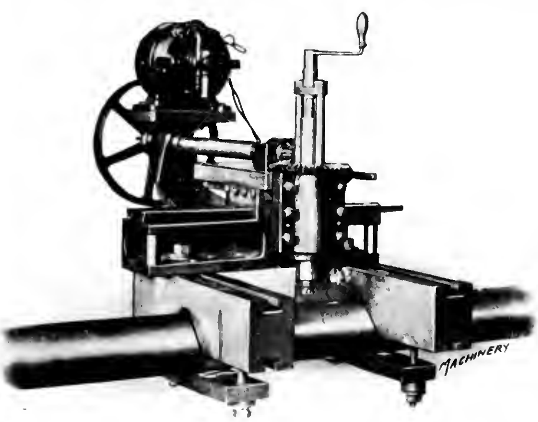

Fig. 2. Pedrick Machine milling a Keyway in a Shaft

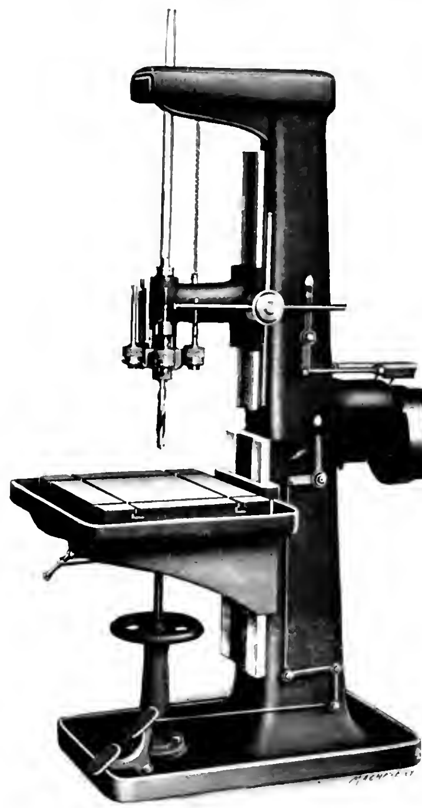
The telescopic driving shaft works smoothly and quietly throughout its full range, and is of ample strength to meet the requirements of any service for which the machine is intended. The No. 1 machine will face a surface up to 12 by 8 inches in size, and the spindle has a vertical adjustment of 6 inches. The direct motor drive is arranged as shown in the illustrations, and a machine equipped in this way is a self-contained unit that may be used in close quarters and easily set up. Besides using the machine for milling seats in pumps and engines, or pads on large frames and housings, it is found to constitute a very convenient means of machining keyways in shafts. While not particularly designed for the purpose, this machine may also be used for drilling.

ROBBINS MULTIPLE-SPINDLE DRILL

The Taylor quick-change multiple drill press illustrated herewith is a recent product of the Robbins Machine Co., Worcester, Mass. This drill was designed to meet the demand for a machine of the sensitive drill type with sufficient power to handle work beyond the capacity of a sensitive drill press, and at the same time operate quicker than a standard upright drill. It will drive a 1¼-inch drill as easily as the ordinary sensitive drill press will handle a ¾-inch drill. The feed is by hand, and when large drills are to be used at high speed, compound gearing in the sliding head can be quickly engaged to increase the pressure of the drill and decrease the pressure required on the hand lever. This enables a large drill to be forced to its full capacity by the application of a limited amount of hand pressure. The reverse motion of the spindle is of unusual strength and provides ample power to handle reasonably large taps.



Taylor Quick-change Multiple-spindle Drill

The machine is driven by spiral gears running in oil, and all gears that are subjected to excessive strain are made of heat-treated nickel steel. The quick-change gear-box is arranged for four spindle speeds and one reverse speed for tapping. The spindle speeds are quickly changed without requiring the machine to be stopped. The sliding head affords quick action in raising or lowering the spindles for tools of different lengths.

The quick-change drill chuck is designed to hold five tools such as drills, reamers, counterbores, taps, etc., which are required for performing successive operations on a piece of work. This chuck provides for rapidly moving any tool to the working or idle position without stopping the machine. When the tool to be used is swung to the operating position it is securely locked and held in perfect alignment with the driving spindle. The power is applied through a combination clutch and friction device, and the greater the strain on the tool the more powerful the drive becomes. When the machine is in operation all tools in the chuck are idle with the exception of the working tool. The clutches for holding the tools in the chuck are made to fit either No. 1, 2 or 3 Morse taper shanks.

The machine is ball bearing throughout and is practically noiseless in operation. The principal dimensions are as follows: distance from center of spindle to face of column, 10 inches; maximum distance from table to spindle, 30 inches; traverse of table, 12 inches; traverse of spindle, 16 inches; size of work-table, 18 by 24 inches; diameter of spindle, $1\frac{1}{4}$ inch; and net weight of machine, 1200 pounds.

MURCHEY PIPE THREADING DIE

The accompanying illustrations show a pipe threading die which has recently been placed on the market by the Murchey Machine & Tool Co., Porter and Third Sts., Detroit, Mich. The important feature of the design of this die consists of the four circular chasers which are similar in shape to circular forming tools. These chasers are provided with a series of annular V-grooves properly spaced for the pitch of the thread that it is desired to cut.

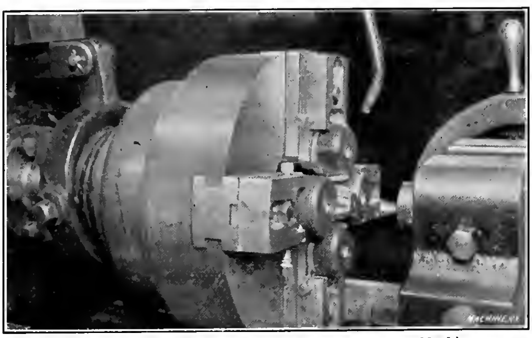


Fig. 1. Murchey Pipe Threading Die set up on a Machine

The circular chasers are carried by slides which fit in T-slots in the die head, the construction being clearly shown in Fig. 1. Interposed between the top faces of these slides and the chasers, there are adjusting plates, each of which has nine holes which are equally spaced. Three pins held in the chasers fit into these holes and adjustment of the position of the chasers is effected by loosening the square screws, lifting the chasers up and turning them around so that the three pins enter another set of holes. The cutting edge of the chasers is then set in the correct relation to the center of the work by adjusting the set-screws in the slides.

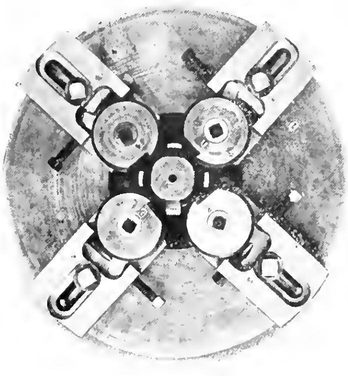

Fig. 2. End View of Murchey Pipe Threading Die

In order to cut the thread on a taper, the top faces of the slides against which the chasers are held are beveled. This serves to throw the chasers to the required angle. Different diameters of pipe are threaded by the substitution of circular blocks of varying lengths in semicircular grooves provided in the top face of the die head and the lower surfaces of the slides. The chasers can be resharpened until practically the entire circumference is ground away so that their life is much longer than that of the ordinary type of die chasers. A reamer is shown in Fig. 2 which is held in the die head to remove the burrs from the end and hole in the pipe.

STOCKBRIDGE KNIFE GRINDER

The time spent in removing and replacing the knives of planers and jointers used in wood-working shops constitutes a large part of the time involved when it is necessary to take them off for grinding. This is a difficult and unsatisfactory method, and is often done hurriedly and improperly, with the result that the machine when started up operates inefficiently and produces a poor grade of work. This is especially true of the thin hard knives used on cylindrical head planers which are almost impossible to grind and reset in perfect alignment for the entire length of the head.

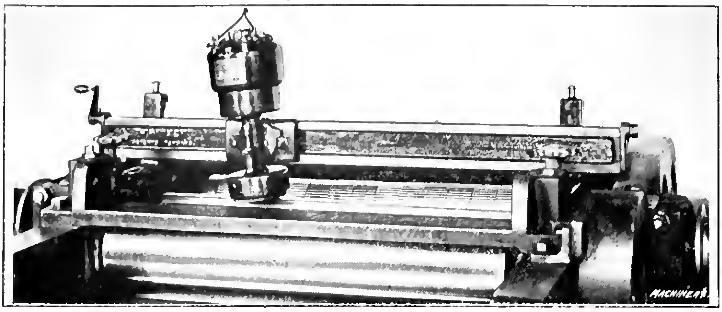

Fig. 1. Use of Stockbridge Grinder in sharpening Planer Knives

In the "Quicsharp" grinder, which is a recent product of the Stockbridge Machine Co., Worcester, Mass., these difficulties are avoided by providing a grinder which enables the knives to be sharpened while in place on the machine. The grinder is motor-driven, the motor being mounted on the head and supplied with a current from an ordinary lamp socket. The saddle has a split nut attached to it which engages the feed-screw located at the top of the bridge. The saddle can be fed across the entire length of the bridge in either direction and at any desired speed. The bridge is supported at the ends or at intermediate points by two angular brackets, which are bolted to the bed of the wood-working machine, and hold the grinder perfectly rigid. The wheel is cup-faced and can be raised or lowered by a thumb-screw to grind the required amount from the knives. The wheel is fed automatically to a positive stop. The grinder head is pivoted at

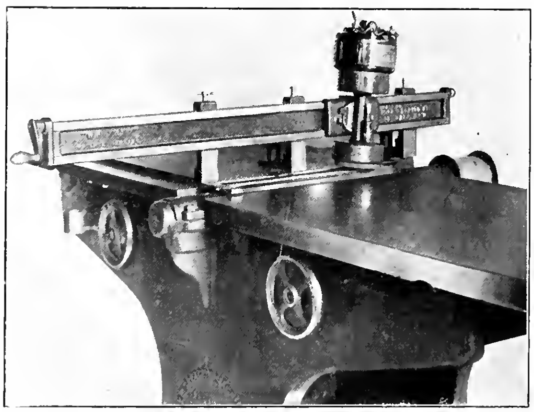

Fig. 2. Stockbridge Grinder sharpening Jointer Knives

the center and can be tilted to either side of the perpendicular; it is held in place against a stop, giving the same angle on each side of the perpendicular. With the head tilted, the knives are ground concave. A positive stop holds each knife in exactly the same relative position to the wheel; therefore, each knife must be ground true. Figs. 1 and 2 show this grinder in use on a planer and on a jointer, and reference to these illustrations will show the way in which it is used, making further description unnecessary.

DERIHON PORTABLE HARDNESS TESTING MACHINE

The illustrations presented in this connection show a portable machine for conducting the Brinell hardness test, which consists of making an impression with a hardened steel ball 10 millimeters in diameter, by the application of a pressure of 3000 kilograms. Fig. 1 shows the machine ready for the test with the lever resting on the shaft. The piece to be tested is placed on the table of the machine, which is then raised until the piece is in contact with the ball. This done, the lever is pulled slowly over so as to give a progressive pressure which is registered by a small manometer until 3000 kilograms is applied. When this figure is reached the lever is slowly returned to its former position and the test is completed. Under normal conditions it is usually sufficient to move the lever through an angle of 45 degrees to obtain the required pressure of 3000 kilograms.

With each machine a small piece of steel is furnished in which a standard impression has been made, the size of the diameter being stamped on it. This standard piece is of

Fig. 1. Machine ready for making Test

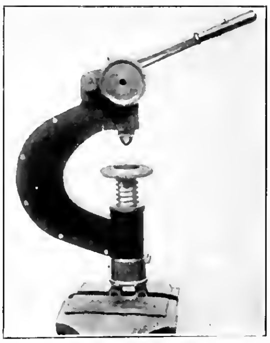

Fig. 2. Arrangement of Gears at Rear of Machine

special air-hardening chrome-nickel steel. The accuracy of the machine can be easily controlled by making an impression beside the standard impression. The construction of the machine is based on the principle of elasticity of the frame, which for this purpose has been constructed in the shape of a horse-shoe. The power produced by the pressure of the ball on the test piece has a tendency to open the frame to a certain degree in proportion to this power. The shape of the frame has, therefore, been specially considered in order to have it as elastic as possible. The pressure exerted of 3000 kilograms does not change the resistance or elasticity of the frame, as it is made of steel having an elastic limit of 242,000 pounds per square inch and a pressure of 3000, 4000 or even 5000 kilograms does not work it above 10 kilograms per square millimeter or 1442 pounds per square inch. Under these conditions, repeated tests even in large numbers do not alter the calibration of the machine.

The deflection of the frame being relatively weak (1 to 1.5 millimeter), a register, the construction of which resembles a metallic manometer, is installed in the hollowed out part of the frame. By means of a needle and a graduated dial, the deflection and therefore the pressure exerted in making the test can be quickly and easily read. To adjust the machine, all that is necessary is to open the head enclosing the mechanism above the frame. Should the machine ever get out of adjustment, a comparison should be made on the standard test piece, and when an impression of the same diameter has been made, the needle is brought over the figure "3000" by means of the small adjusting screw. This adjustment, however, would only be necessary through some accidental cause independent of the operation of the machine under normal usage. Fig. 2 shows the arrangement of the gears at the rear of the machine. This machine is placed on the market by H. A. Elliott, 507 Majestic Bldg., Detroit, Mich.

SCULLY-JONES ADJUSTABLE SPACING COLLAR

Fig. 1 shows the "Wear-ever" adjustable spacing collar for use on milling machine arbors, which is a recent product of Scully-Jones & Co., 319 Railway Exchange Bldg., Chicago, Ill., and Fig. 2 illustrates the method of using these collars. The "Wear-ever" collar was designed primarily for use in connection with manufacturing operations on milling machines, where two or more cutters on an arbor must be spaced at a specified distance from each other. Those familiar with the application of straddle or gang cutters in milling machine operations know that it is sometimes necessary to grind the sides of the teeth. This necessarily changes the distance between the faces of the cutters, and in order to maintain the required dimensions of the work, compensation must be made for the amount which has been removed from the cutters by grinding. This is sometimes done by carrying solid spacing collars of assorted lengths in stock. But if the exact size cannot be found among the collars on hand, it is necessary to grind down a collar that is too long or to shim up one that is too short. While this is being done the milling machine is standing idle.

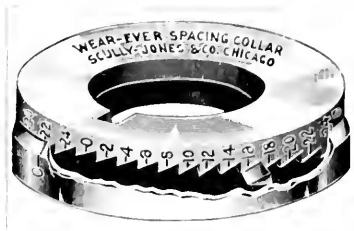

Fig. 1. Scully-Jones Adjustable Spacing Collar

The "Wear-ever" collar is designed so that the thickness may be varied up to 0.024 inch, this adjustment being divided into twelve steps of 0.002 inch each. It will be seen from Fig. 1 that the collar is provided with three sets of graduations ranging from zero to 24 by even numbers, each graduation being opposite a notch in the collar. These notches are arranged on cam surfaces, and corresponding notches in each of the three series of graduations are engaged by a tooth. In making the adjustment, the collar is moved around so that the teeth engage with the proper spaces to give the required expansion of the collar on the arbor. The adjustment is quickly made, and after the collar has been set it is exactly as rigid as a solid collar. The advantages of the "Wear-ever" collar may be briefly summarized as follows:

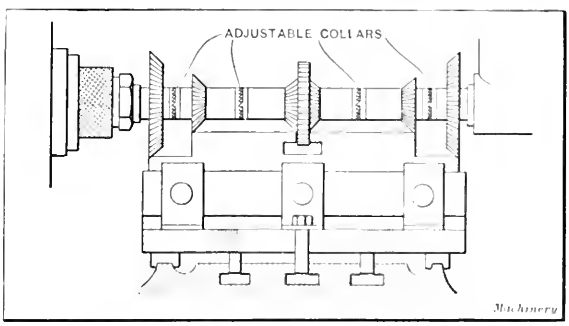

Fig. 2. Use of Scully-Jones Adjustable Spacing Collars

they are made in sizes down to less than ½ inch in width and are capable of standing up under hard service; it is impossible for chips to interfere with the operation of the collar, and the first cost is low so that a shop can afford to purchase them for any work upon which they could be used to advantage.

LOWE "LAST-WORD" INDICATOR

Henry A. Lowe, 1371 E. Eighty-eighth St., Cleveland, Ohio, is now manufacturing the "Last word" test indicator which is illustrated in Figs. 1 and 2. Fig. 1 shows the indicator carried on the ball joint toolpost shank, and this illustration also shows an auxiliary clamp which is provided with the instrument. This clamp enables an instrument to be removed from the toolpost shank and set up on the needle of a surface gage as illustrated in Fig. 2. There is ball joint connection between the toolpost shank and the indicator, which provides adjustment to meet the requirements of a great variety of work.

Fig. 1. Lowe Test Indicator carried on Ball-joint Toolpost Shank

The contact lever has a hardened taper-head stud for a bearing, which provides adjustment for wear. There is a small tapered hole through the contact ball, and contact points of special shape can be fitted into this hole to meet the requirements of special classes of work. In many cases the ordinary contact ball is quite satisfactory without providing any auxiliary point.

The mechanism of this indicator has been worked out to give the magnifying power of 100, and at the same time the instrument is of remarkably small size, which will be appreciated when it is known that the weight is only $1\frac{1}{4}$ ounce. The dial is graduated to read in 0.001 inch. This instrument can be quickly changed from the toolpost shank to the needle of a surface gage to adapt it for surface plate work, or back to the toolpost shank for lathe, shaper, planer, grinding or milling-machine work. It is adaptable for use on a great variety of tool-room and machine-shop operations.

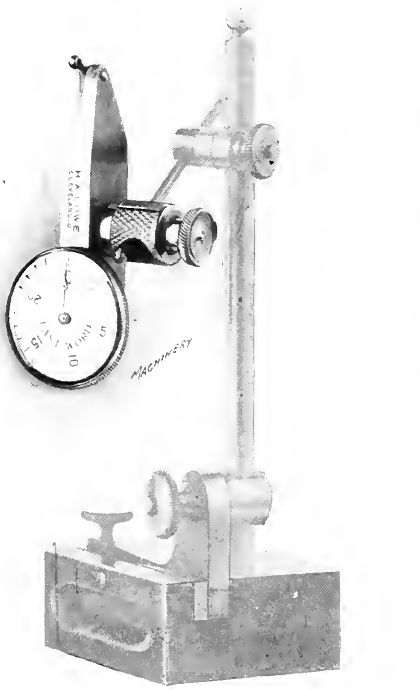

Fig. 2. Lowe Indicator mounted on the Needle of a Surface Gage

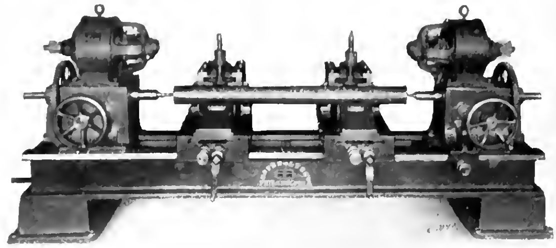
ESPEN-LUCAS AXLE CENTERING MACHINE

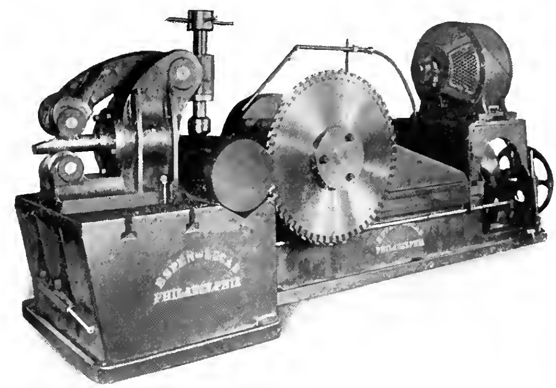
The Espen-Lucas Machine Works, Front & Girard Aves., Philadelphia, Pa., has recently placed a double-end axle centering machine upon the market. This machine is intended for centering both ends of axles up to 7 inches in diameter by 8 feet long. The machine is arranged with two spindles which are driven independently by 2-horsepower motors. On head is stationary and the other adjustable for centering axles from 5 to 8 feet in length. The two cradles are provided with rollers for centering the axles and heavy clamps for holding the work rigidly in place. The weight of the machine is about 11,000 pounds.



Espen-Lucas Double End Axle Centering Machine

ESPEN-LUCAS COLD SAW

The accompanying illustration shows a heavy type of cold saw which is one of the recent products of the Espen-Lucas Machine Works, Front & Girard Aves., Philadelphia, Pa. This machine is equipped with a saw blade 60 inches in diameter and has a capacity for sawing round or square bars up to 20 inches thick. The feed and speed variations are so arranged that the machine can be used for sawing at an advance of 6 inches per minute. The drive is through a main shaft, a phosphor-bronze worm-wheel and a crucible steel worm running in oil. The spindle extends for the entire width of the carriage and the saw blade is bolted directly against the driving gear, an arrangement which practically eliminates torsional strain between the driving gear and the saw blade.



Espen-Lucas Cold Saw Machine

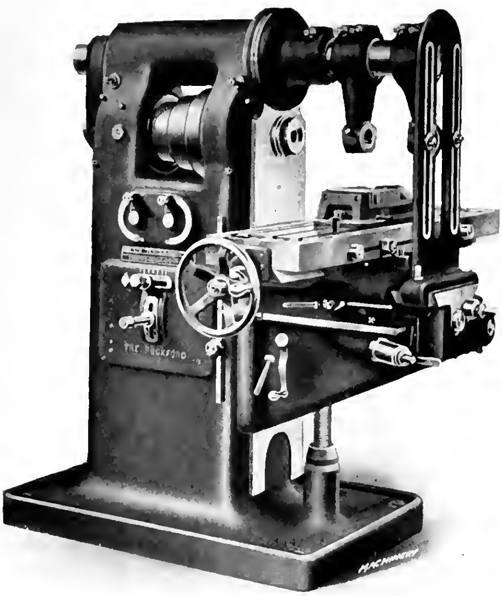
The feed is obtained from a geared friction plate controlled by an automatic lock-nut lever, by which any change in the advance of the saw can be made while the machine is in operation. The saw carriage also has a quick return movement controlled by the same lever. An automatic stop for controlling the traverse of the carriage is also provided. Any type of saw blade including the inserted tooth or solid high-speed steel blades may be used.

Compressed air or screw clamps are provided for use on this machine, depending upon the requirements of individual cases. For handling stock rapidly where multiple cuts are to be made, this saw is equipped with a stock feed attachment which will handle bars of any length up to 20 feet. The usual form of drip pan furnished on machines used for sawing smaller sizes of stock has been eliminated in the

present instance and a reservoir substituted in the foundation. The machine is belt-driven from a 35-horsepower motor and weighs 50,000 pounds approximately.

ROCKFORD HEAVY PLAIN MILLER

The Rockford Milling Machine Co., Rockford, Ill., is now manufacturing the No. 2 heavy double back geared cone type plain miller which is illustrated herewith. This machine is of exceptionally heavy construction, the approximate weight being 3750 pounds. The back gears are enclosed in the column and operated by two levers which afford a very convenient



Rockford No. 2 Double Back Geared Plain Miller

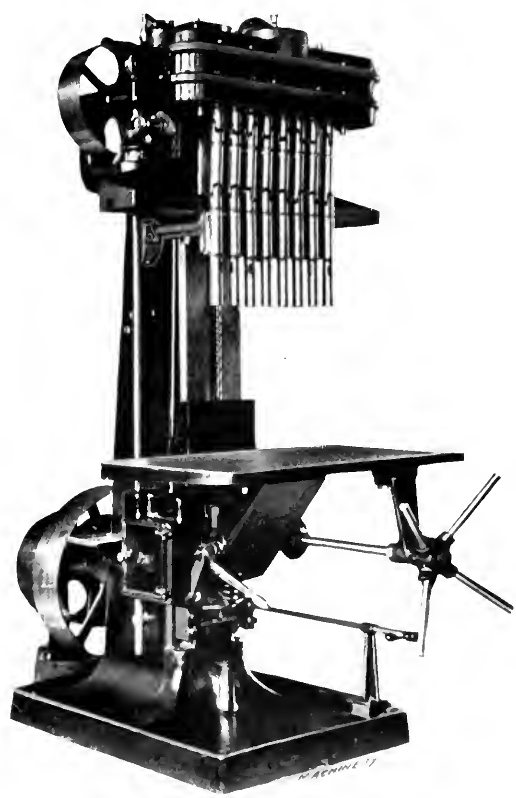
and practical control. The machine is equipped with a flanged support for the overhanging arm, which has been designed by this company; this support stiffens the construction and increases the cutting capacity of the machine. The diameter of the overhanging arm is 4 inches.

The table is provided with a quick return movement operated by a handwheel and clutch, and the handwheel can be thrown in instantly at any desired point. A wrench can be used on the squared shaft at the opposite end of the table. The table measures 50 by 11½ inches over all, and is provided with three ⅝-inch T-slots; there are also oil grooves on the sides and oil pockets at the ends of the table. All feeds are automatic. The spindle is bored No. 11 B. & S. taper, and is made of crucible steel; it runs in phosphor-bronze bushings which have tapered journals fitted with oil retainers. Wear is compensated for at the rear of the spindle by means of a nut. There are eighteen speed changes ranging from 17 to 392 revolutions per minute, and fourteen changes of feed ranging from 0.005 to 0.175 inch per revolution. Feed reverse levers controlling all feeds are located on each side of the knee. The regular equipment of the machine consists of a plain vise, a flanged support for the overhanging arm, two arbor supports and the necessary wrenches. The design has been carefully worked out to secure the maximum rigidity.

FOX MULTIPLE-SPINDLE RAIL DRILL

The No. 3 Fox multiple-spindle rail drill illustrated in this connection has been developed to meet the demand of engine builders for a high-speed multiple-spindle machine for drilling and boring push-rod holes, valve stem guide holes and cages. Particular attention has been paid to the design of the vertical adjustment for each spindle with the view of keeping the cutting edge of all tools in the same plane. This is a feature which users of the machine will appreciate. The base, column and gears for changing the speeds and table feeds are of the same construction which has been used in the past on Fox multiple-spindle drilling machines. The gears are cut from solid 35-point carbon steel blanks, which are pack-hardened and heat treated. The bearings for the gears are subsequently ground, giving the most perfect construction possible. The principal bearings in the machine are bronze bushed, and the main driving pulleys run on Hyatt roller bearings.

Rails of various lengths are furnished with this machine to meet the requirements of individual cases. The rails are made with either a tongue which fits grooves in the adjusting arms to keep all spindles in positive alignment, or the tongue may be omitted from the rail, giving universal adjustment to each spindle. The rail is an exceptionally heavy casting ribbed to provide the necessary rigidity. The gear case containing the driving pinions for the spindles provides a double bearing for each gear in the case. The gears are of 6 and 8 pitch, with broad faces. The regular gear case is bored for a maximum of twelve spindles and when less than this are furnished with the tool, the extra holes are plugged up; it is thus possible to add additional spindles should they be required at any time. The drill spindles, spindle bearings and adjusting arms are of patented con-



Fox Multiple-spindle Rail Drill

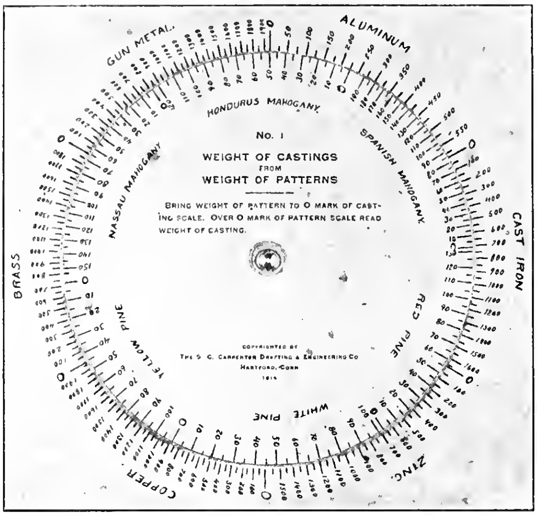
struction, which gives a wide range of vertical adjustment. This adjustment is obtained without changing the set position of the arm. The spindle bearings have a T-slot milled for their entire length and fit into the slotted end of the adjusting arms. T-bolts working in the slots in the bearings secure them to the adjusting arms and provide for adjusting the spindles vertically.

The universal joints used in these machines are made with every friction surface hardened. An oil pocket is provided in the center of the block, giving perfect lubrication. The table regularly furnished on this machine has a surface 24 by 38 inches in size and is equipped with a hand pilot wheel

for raising or lowering. A single lever is provided for manipulating the power feed; pulling up on this lever engages the feed and pushing down on it disengages the feed. An automatic trip lever is provided for automatically throwing out the feed. There are six changes of feed ranging from 0.5 to 5.0 inches per minute; four changes of drill speed are available, depending on the size of drills used. The floor space occupied by this machine is 6 feet by 2 feet 6 inches; the height is 7 feet 8 inches; and the net weight of the machine is 3288 pounds. This machine is a recent product of the Fox Machine Co., 16 Front St., N. W., Grand Rapids, Mich.

CARPENTER CALCULATING CHARTS

The accompanying illustration shows one of a series of eight calculating charts which have recently been brought out by the S. C. Carpenter Drafting & Engineering Co., 49 Oakland Terrace, Hartford, Conn. It will be seen that this chart is intended for finding the weight of castings of different metals from the weight of the patterns from which they are made, the chart being laid out for a number of different kinds of wood commonly used in pattern making. Other charts of this series which are likely to be of interest



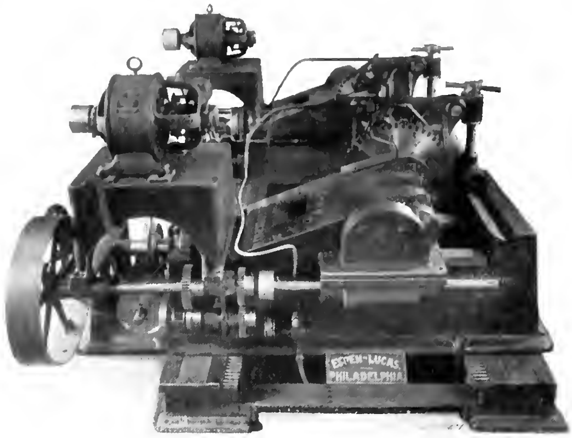
Carpenter Chart for calculating Weight of Castings from Weight of Patterns

to readers of MACHINERY are as follows: Chart No. 2, which gives areas and circumferences of circles with diameters varying by 1/16 inch, and the squares, cubes, square roots and cube roots for each 1/16 inch up to 1 foot; chart No. 3, which gives drill, drill rod, wire and machine screw sizes; and chart No. 4, which gives the sides, angles and area of right angle triangles up to 10 inches base.

ESPEN-LUCAS DUPLEX COLD SAW

The duplex cold saw illustrated herewith is a recent product of the Espen-Lucas Machine Works, Front & Girard Aves., Philadelphia, Pa. This machine is intended for cutting off both ends of axles at the same time, and for this purpose it is equipped with two 32-inch inserted tooth saw blades. The machine has a capacity for sawing off both ends of from twelve to fifteen 9-inch axles per hour. The speed and feed variations provide for sawing at an advance of 6 inches per minute. The cutting capacity is only limited by the nature of the steel that is being cut and the endurance of the high-speed steel cutters in the saw blades.

The machine is driven through a train of compound gearing, a steel worm and a bronze worm-wheel. The gearing and other parts of the machine are liberally proportioned to provide ample strength. The main bed and table are held together by heavy webs and the saw carriages have bearings of ample size on the base of the machine. The saw blades are bolted directly to the driving gears which are forged integral with the ends of the spindles. This arrangement practically eliminates the torque between the driving gear and the saw and enables the spindle bearings to extend for the entire width of the saw carriages. This drive is a strong feature of the machine. All of the gears, spindles and shafts, etc., are cut and turned from high carbon hammered steel forgings. All bearings are bushed with bronze and the thrust



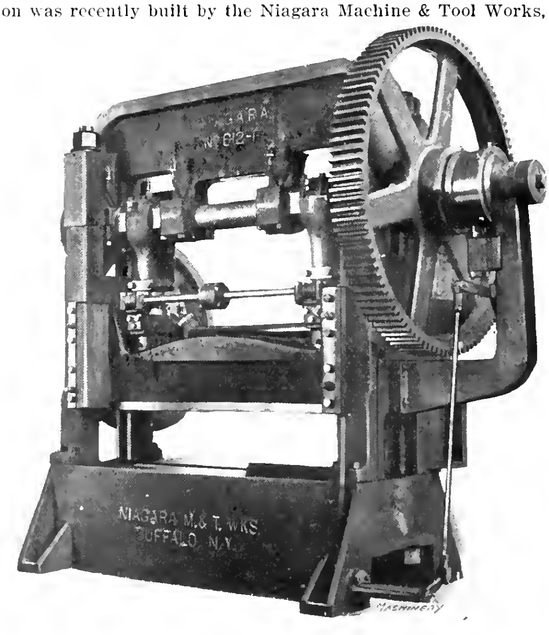
Espen-Lucas Duplex Cold Saw

of the driving worm and other revolving parts is taken up by roller thrust bearings.

The feed is variable and automatic, being controlled by an automatic stop which regulates the depth of cut up to the full capacity of the machine. The saw carriage is equipped with automatic power return and an automatic starting device which leaves the operator free to give his whole attention to the feeding of axles to the machine and removing them when finished. Pumps are provided to furnish a liberal flow of cutting compound to the saws. The machine is driven by 15-horsepower electric motors and weighs approximately 30,000 pounds.

NIAGARA DOUBLE CRANK PRESS

The large double crank press illustrated in this connection was recently built by the Niagara Machine & Tool Works,



Large Niagara Double Crank Press

Buffalo, N. Y. This machine is intended for punching and forming operations met with in steel car work, but the ma-

chine is also suitable for a wide range of heavy stamping operations. The bed, housings and arch are held together by means of four steel tie-rods 4½ inches in diameter which are a shrink fit in the parts which they connect. The same convenient method of adjusting the slide and gibs is provided that is employed on other large presses of this company's manufacture. The motion of the press is controlled by a hand lever operating a powerful jaw clutch. The working surfaces of the three jaws of the gear hub—as well as the clutch collar—are faced with hardened tool steel pieces. An automatic device is provided to stop the slide at the highest point of its stroke. Presses of this type are built in different sizes; the machine shown in the illustration measures 84 inches between the housings and has an approximate weight of 50,000 pounds.

* * *

STATUS OF THE PFAUTER PATENTS IN THE UNITED STATES

Referring to the note appearing on page 478 of February MACHINERY, engineering edition, in reference to the Pfauter patents on gear-hobbing machinery, we wish to state that this seems to have been misleading, some of our competitors assuming that they are now in a position to offer gear-hobbing machines with the differential for cutting spiral gears in the American market also. In order to correct this misunderstanding, we call attention to the fact that the United States patent which was granted to Herman R. Pfauter under date of January 2, 1900, has still about three years to run. Anyone selling or offering for sale gear-hobbing machines equipped with differential gearing for cutting spiral gears will infringe the existing Pfauter patents, and Mr. Pfauter is fully prepared to prosecute any such infringement.

New York City SCHUCHARDT & SCHUTTE

* * *

NEW MACHINERY AND TOOLS NOTES

Heating Forge: Word Brothers, San Francisco, Cal. A forge heated by oil which was particularly designed for heating rock drills; this forge is also adapted for general blacksmith work.

Roller Bearing: Royersford Foundry & Machine Co., 54 N. 5th St., Philadelphia, Pa. A new type of Sells roller bearing in which the sleeve is split and clamped over the shaft by two split collars.

Finishing Tool: Western Tool & Mfg. Co., Springfield, Ohio. A tool for finishing work in the lathe, shaper or planer which consists of a forged shank to which a steel disk which constitutes the cutter is bolted.

Drill Head: Edward Board, 619 Filbert St., Philadelphia, Pa. A four-spindle drill head designed for drilling four holes simultaneously at an angle of 45 degrees. This head is particularly designed for machining the burners of gas stoves.

Time Recorders: Baird Equipment Co., Chicago, Ill. Three types of time recorders intended for use in marking employe's weekly cards; daily job tickets; single, three or seven day job cards, or for use as a watchman's time detector.

Magnetic Chuck: O. S. Walker & Co., Worcester, Mass. A multiple pole magnetic chuck which is similar in general construction to previous types of magnetic chucks of this company's manufacture. Each pole is energized by an individual coil.

Punch and Shear: J. W. Grace Co., Burlington, Vt. A hand operated punch and shear equipped with two sets of blades. This shear will handle flat bars up to 3 by ½ inch in size. The punch has a capacity up to a ½-inch hole pierced through a ½-inch iron plate.

Facing Arm: H. B. Underwood & Co., 1024 Hamilton St., Philadelphia, Pa. A universal swiveling facing arm on which the tool-holder swivels through a complete circle and can be clamped in any position. The facing arm can be applied to either end of the bar.

Tool Racks: The New Britain Machine Co., 64 Bigelow St., New Britain, Conn. A line of steel tool racks with seamless sheet metal trays pressed from No. 16 gage steel. Racks of this type are mounted on wheels where it is desired to provide for moving them from place to place.

Circular Slide Rule: Lucien E. Picolet, 19 S. 9th St., Philadelphia, Pa. A circular type of slide rule particularly intended for performing the operations of multiplication, division and the extraction of square and cube roots. The results obtained with this rule are claimed to be as accurate as those obtained with three place logarithms.

Brazing Compound: Phillips-Laffitte Co., Philadelphia, Pa. A compound known as "Unifonte" for brazing cast iron. With this material any mechanic can braze broken cast-iron parts and produce a joint which is claimed to be stronger than the original material. "Unifonte" consists of a chemical paste which is used in connection with flux and spelter.

Pneumatic Drill: Ingersoll-Rand Co., New York City. The improved "Little David" pneumatic drill of this company's manufacture is equipped with roller bearings for the connecting rods and crankshafts which run in ball bearings. In other respects the drill is of similar design to the preceding model which has been manufactured by this company.

Cutting-off Machine: Grant Engineering Co., Detroit, Mich. A machine with a capacity for cutting stock up to 4 inches in diameter. The work remains stationary and is cut by a revolving cutter head which is worm driven. The speed of the head is automatically accelerated as the tools travel toward the center, thus maintaining a constant peripheral speed.

Thread Rolling Machine: The Waterbury Farrel Foundry & Machine Co., Waterbury, Conn. A reciprocating machine for rolling threads on very small screws. This machine has automatic feed, and the capacity is for blanks up to an approximate diameter of 1/16 inch. The feed mechanism is so designed that short work can be handled to excellent advantage.

Belt Pole: Edward Wilbur, 125 Summer St., Boston, Mass. A belt shifting pole designed to eliminate the use of ladders in shifting belts, and at the same time to facilitate the rapidity with which shifts can be made. The pole is 9 feet long, and has a fork at the upper end, one prong of which passes under the belt while the other acts as a fulcrum on the edge of the pulley.

Boring Mill: Cincinnati Planer Co., Cincinnati, Ohio. A boring mill of lighter construction than the machines previously built by the company. The features of the present machine are centralized control, complete guarding of all dangerous parts of the mechanism, a housing of increased rigidity, and double bearings for the table pinion. Machines of this type are built in 6, 7 and 8 foot sizes.

Planer Type Surface Grinder: Newton Machine Tool Works, Inc., Philadelphia, Pa. A line of heavy surface grinders intended for grinding locomotive radius links, tongue pins, armor plate, etc. The abrasive wheel remains in a fixed position while the work held in pneumatic chucks is traversed back and forth on the table. The wheel is adjusted for the full depth of cut and full width in one operation.

High-speed Hacksaw: Armstrong-Blum Mfg. Co., 343 N. Francisco Ave., Chicago, Ill. A high-speed hacksaw similar in design to the machine described in the June, 1911, number of MACHINERY. The present machine, however, is not provided with the cross-feed movement for advancing stock ready for a subsequent cut after a piece has been cut off. The capacity of the machine is for 6-inch square bars.

Plain Grinding Machine: Modern Tool Co., Second and State Sts., Erie, Pa. A small size grinder for manufacturing purposes. In designing this machine particular attention has been paid to features which will lessen the cost of production of work which requires grinding. The machine is known as a No. 8 size, and has the same capacity as the No. 1 universal grinding machine of this company's manufacture.

Self-opening Die: George Overton, 821 E. 167th St., New York City. A self-opening die of simple construction which has four chasers carried in blocks. In operation, the die travels over the work until the turret slide comes against its stop, when the die is opened through inertia. If preferred, an internal stop in the die shank can be set so that the end of the work will strike it and cause the die to be opened.

Two-speed Hacksaw: W. Robertson Foundry & Machine Co., Buffalo, N. Y. This company is now equipping its hacksaw machines with a two-speed mechanism designed to give suitable speeds for cutting tool and soft steels. In this way a maximum amount of service is obtained from the blades. The two speeds are obtained through a set of screws consisting of a twin gear mounted on a crankshaft which meshes with either of two pinions on the driving shaft.

Vertical Lathe: Bullard Machine Tool Co., Bridgeport, Conn. A 6-spindle vertical automatic lathe of the station type. The machine is equipped with independent work-tables, independent tool heads, cross feeds for all boring and turning cuts and a positive maximum feeding pressure for each tool head. All dangerous parts of the mechanism are adequately guarded and positive stops are provided for the tool head movements which work to 0.001 inch. A retarding mechanism is provided for indexing the spindle carrier and a controller interlocks all of the automatic movements. The

time of machining a piece on this vertical lathe is the time of the longest operation plus the time of one indexing. The weight of the machine is 16,000 pounds.

* * *

CENTRALIZED CONTROL RADIAL DRILLING MACHINE

Centralized control of machine tools has received a growing amount of attention of late years. High cutting efficiency is another equally important requirement. It has been the aim of Messrs. J. Archdale & Co., Ltd., Ledsam St., Birmingham, England, in the machine here illustrated and described, to develop these two features to the highest degree.

In the radial drilling machine illustrated in Fig. 1, centralized control has been achieved by the bold step of embodying all the speed changes in the saddle itself. The changes of speed are made by two levers operating steel sliding gears, a plate giving lever positions for the various rates of speed and feed being fixed to the saddle close to the speed change levers. It will be obvious that speed control is quicker and easier than on machines where the speed changes are made in a gear-box carried on the baseplate at the back of the column. The reversing gear is also carried on the saddle, and is operated by a convenient lever. Thus all speed changes can be made, and the spindle started, stopped or reversed without the operator changing his position. The fact that all transmission shafts and gears in this design run at a constant high speed, results in a greatly increased efficiency.

Another important feature bearing on the question of efficiency is the automatic lubrication of all gears, shafts, etc., in the saddle, which reduces the time and attention required for oiling to a minimum. Gear-driven feed motion is provided with changes made by lever, the friction clutch being operated by a lever which is always in the same position. An instantly adjustable automatic stop is provided. The spindle runs in phosphor-bronze bearings carried in a steel sleeve, is provided with a ball thrust bearing, and balanced by a compensated spring arrangement.

Naturally, the complete saddle is heavier than an ordinary saddle, but the rollers on which it is carried enable the

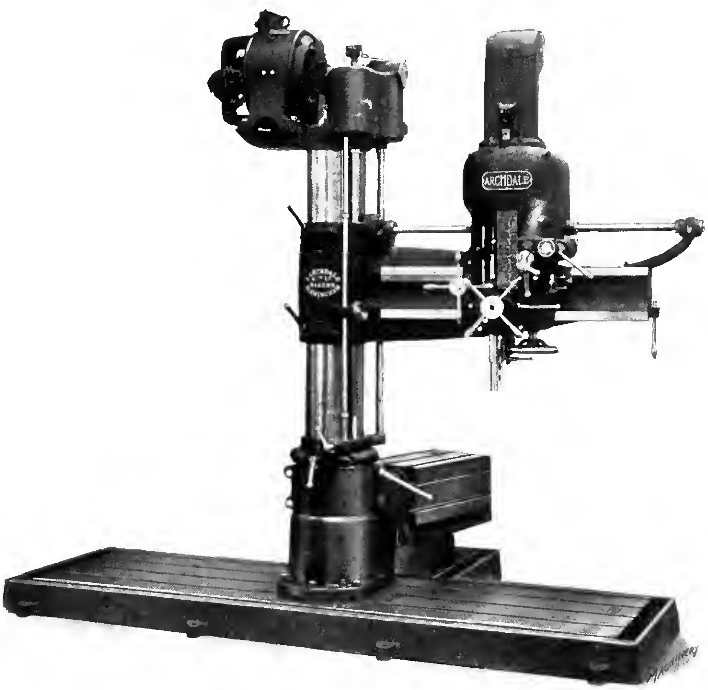


Fig. 1. Archdale Radial Drilling Machine

movement along the arm to be made with the greatest ease. The traversing wheel is shown at *F*, Fig. 2, which shows a view of the saddle mechanism with the front cover removed. The mechanism for sliding the spindle gears *A* and the back gears is clearly indicated, *J* and *H* being two levers operating the sliding gears through the helical pinions *C* and racks *B*.

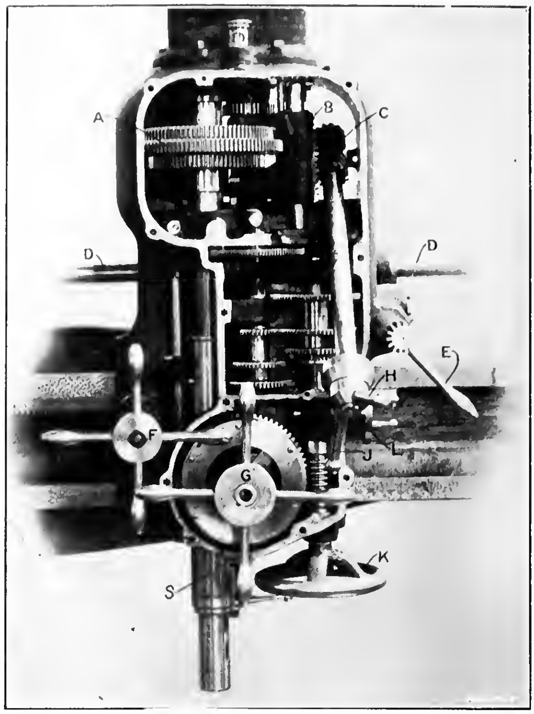

Fig. 2. View of Saddle Mechanism with Front Cover removed

The feed control is obtained at *L*. Quick and slow hand-feed motions are obtained by handwheels *G* and *K*. The reversing lever is shown at *E*.

The arm is of an oval box section, and it is claimed that this is superior to the ordinary composite section of a box with ribs top and bottom. Severe tests have shown that torsional deflection is so minute as to be practically negligible. The fixed column carries a rotating sleeve on which the arm is vertically adjustable, this sleeve being mounted on roller journal bearings and a ball thrust bearing, making the swinging of the arm extremely easy. A convenient lever is provided for rigidly clamping it to the fixed column. A friction gear-box at the top of the sleeve operated by a convenient handle controls the vertical movement of the arm, safety stops being provided to prevent over-running.

The base is double-ended and has an extension at the back. Thus, as drilling proceeds on one portion, work may be set up at either one or both of the two remaining positions. The operator, therefore, can be drilling practically the whole of the time, moving from one position to another. As setting up of work on drilling machines takes up a considerable portion of the whole time, it is clear that this is a valuable feature where a large output is required. The box table may be used in either of three positions or swung clear of the base. The motor, which rotates with the arm and sleeve, is at the top of the column, and therefore can never be an obstruction to work being set up on the baseplate. Where the work is such as requires lubricating, the pipe is taken up through the center of the column, fitted with swivel joint, and connected by flexible pipe to the saddle. The lubricant is thus available for all positions of the spindle or arm with-

out danger of fouling the pipe. The pump is, in this case, a separate unit, being connected to the machine by pipes, preferably under ground, in covered troughs.

AIR BRAKE TESTS, PENNSYLVANIA RAILROAD

Important improvements in the braking of heavy passenger cars were described in a paper read before the American Society of Mechanical Engineers at the Engineering Building, New York City, February 10, by S. W. Dudley of Pittsburg. Air brake tests were conducted jointly by the Pennsylvania R. R. and the Westinghouse Air Brake Co., and the results are considered the most important recent contribution to the subject. A train of twelve steel cars running at sixty miles per hour stores up 224,000,000 foot-pounds of energy. This is sufficient to raise the entire train 120 feet. With prevailing brake equipment such a train would be stopped by an emergency application in a distance of 1600 to 2200 feet, according to the truck rigging and brake shoe design. These tests showed that this distance has actually been reduced to 1000 feet or to within the length of the train. This was the result of improvements in the truck brake design involving the clasp brake, having two shoes per wheel, and the location of the brake shoes with reference to the horizontal center line of the wheels, in addition to improved methods of applying the air brakes quickly and simultaneously and at a high pressure. This concerns safety. These tests emphasized, as has never been done before, the possibilities of improvement in efficiency and economy in regular service operation by proper attention to design and installation in order to permit the realization of the flexibility of improved air brake apparatus. These improvements center in the electric control of the brakes, giving quick, simultaneous and responsive action. The electric control has opened the way for maximum effect in practice of improvements in practically all the factors involved in air brake apparatus, all of which were covered in the development represented by these tests. The tests constituted a progressive development of brake rigging and brake shoes in connection with the scientific study of the air brake as a whole. Fifteen years ago trains were stopped in about half the distances prevailing in the practice of today. Increased size and weight of equipment brought an entirely new brake problem. These tests showed that high-speed braking on the longest passenger trains can be accomplished with safety but at the expense of a somewhat complicated apparatus which responds to both pneumatic and electric impulses.

* * *

CLEVELAND AUTOMATIC FOR MACHINING BRASS NUTS

The Cleveland Automatic Machine Co., Cleveland, Ohio, recently installed two of its 3/4 to 1 1/4 inch model C "automatics" in the plant of the Metric Metal Works, Erie, Pa. These two machines are equipped with an air chucking device, a rotary tilting magazine, and special tools to adapt them for facing and tapping brass coupling nuts ranging from a very small size up to 2 1/2 inches in diameter. The machines have now been in operation long enough to show that they are exceptionally well adapted for nut work. The output is three times that which has ever been obtained by any other method.

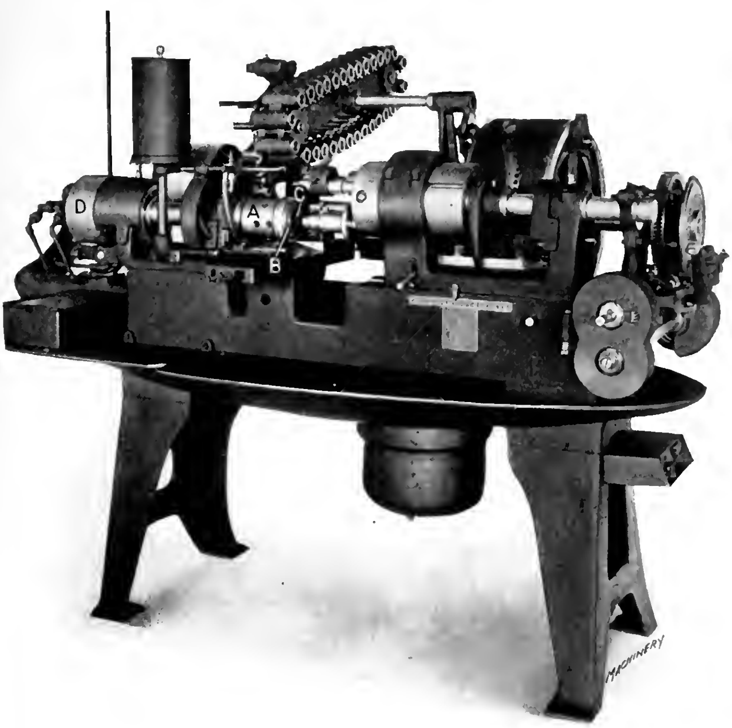

Fig. 1. Front View of Cleveland Automatic for machining Brass Nuts

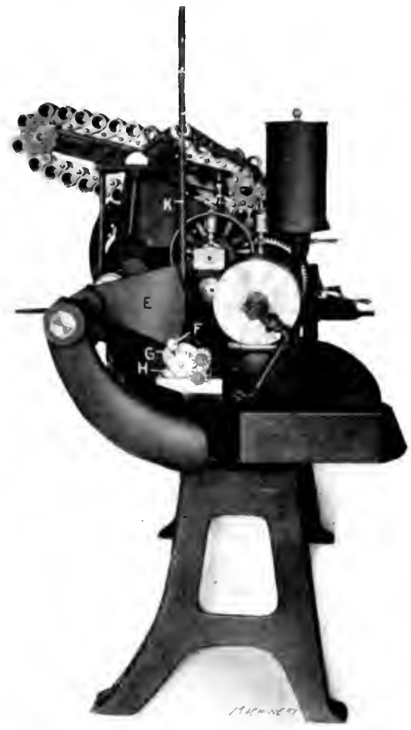

Fig. 2. End View of Machine showing Mechanism for controlling Air Chuck

The air chuck on the machine in Fig. 1 is shown at *A*. The chuck is screwed onto the spindle in place of the regular chuck hood and is fitted with three removable jaws *B* which, in turn, are provided with three pads *C* that can be shaped to suit various kinds of work. The rear end of the spindle is shortened and the air cylinder *D* is screwed onto it. A connecting-rod actuated by the piston in the cylinder *D* operates the chuck jaws *B*, the admission of air at each side of the piston opening and closing the chuck.

Fig. 2 shows an end view of the machine where the mechanism for controlling the admission of air to the cylinder *D* is clearly illustrated. The segment *E* is fitted with a roller *F* in contact with the lever *G* that operates the air valve to release the chuck. The geared lever *H* swings up as the lever *G* is carried down by the roller *F*; a second roller on the opposite side of the segment *E* then comes into contact with the lever *H* as the segment swings around and this moves the valve to its original position, closing the chuck and

at the same time exhausting the air on the opposite side of the piston. The air supply pipe K is fitted with a sight-feed lubricator (not shown) which thoroughly oils the piston and moving parts of the air valve.

The rotary tilting magazine L, Fig. 3, is equipped with a link belt M, each link being fitted with a bushing of suitable shape to hold the work. When the magazine L tilts up after the conveyor N has removed a blank, the lever P comes in contact with the pin R which indexes the link belt to bring another piece of work in line with the conveyor when the magazine swings down the next time. This rotary tilting magazine was described in detail in the February number of MACHINERY, so that further discussion of this feature of the machines which form the subject of the present article is unnecessary.

The conveyor N is fitted with a flanged sleeve S that comes in contact with a stop on the turret head (not shown) on the backward stroke of the turret after the chucking operation. Should the chuck fail to grip the work, the sleeve S strips the work off the conveyor, thus allowing the conveyor to remove another piece of work from the magazine without

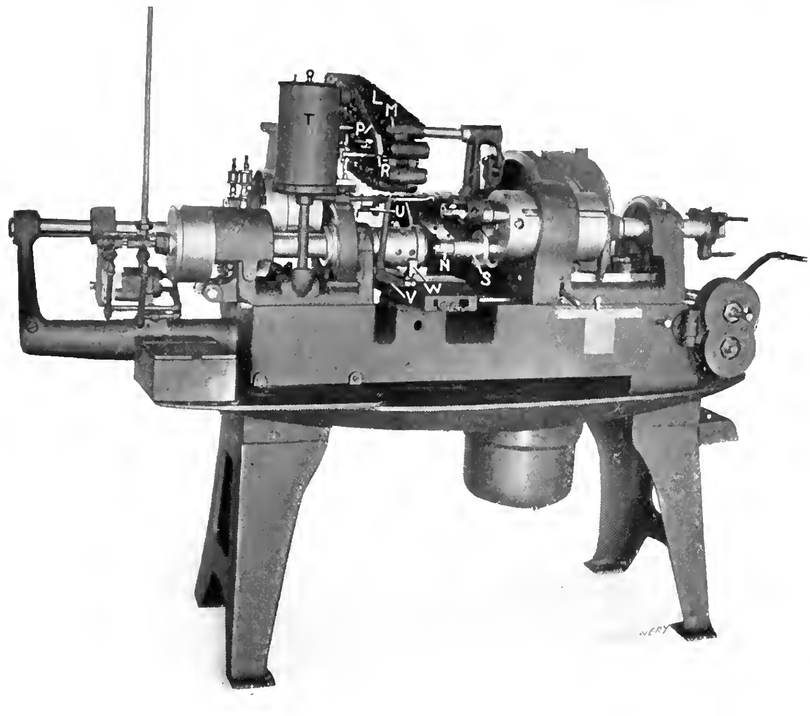

Fig. 3. Arrangement of the Magazine and Chuck Mechanisms

interference. If the finished work is not ejected from the chuck, the forward movement of the next blank carried by the conveyor comes in contact with it and compresses a spring in the shank of the conveyor N; this takes up the strain and avoids damaging the machine.

Fig. 3 also shows an oiling device used to drop oil onto the tap. This lubricating equipment consists of the tank T with suitable piping and a valve U which is operated by a lever V pivoted on the spindle head and operated by the tripping dog W on the cross-slide. As the cross-slide moves forward to allow the facing tool on the rear of the slide to operate, the tripping dog W strikes a V-block on the lever V, causing the valve U to open and drop the required amount of oil onto the tap. The amount of oil supplied may be varied from one drop to a steady stream, being under control of the operator.

It has already been stated that these machines were built to meet the special requirements of the Metric Metal Works, but "Cleveland" automatics equipped with this type of air chuck can be used for all sorts of work requiring drilling, counterboring, reaming, tapping, recessing and similar operations.

ADMINISTRATION BUILDING OF NEW DEPARTURE MFG. CO.

The New Departure Mfg. Co., Bristol, Conn., recently moved into its new Administration building, which has been in course of construction for the last twelve months. The demand for New Departure ball bearings has increased so rapidly that the company could not wait to build the required additions to its manufacturing plant, and as a result bought the factory of the Whitlock Coil Pipe Co., Hartford, Conn., which comprises 145,000 square feet of floor space. The office quarters were also inadequate and this deficiency has been met by the erection of the new Administration building, which is 62 feet wide by 220 feet long and six stories high. The building is modern in every detail of construction and is absolutely fireproof. The outer walls are of light grey brick in three shades, relieved by broad ribbons of blue and green colored tiles at the second and fifth stories. The entrance is reached by a broad flight of granite steps, and is flanked on each side by hand-carved limestone panels.

The ceiling of the main vestible of the building is decorated in Roman gold, and the side walls are panelled with marble. The floor is also of marble with a geometrical design worked out in tiles, and with the monogram of the company in green and white as a center piece. The main lobby, which is just beyond the vestibule, is 16 feet square; the floor is of Italian marble and the wainscot is relieved by ornamental capitals. The office is located on the fifth floor of the building and is reached by an electric elevator which runs from the lobby.

The private offices of the officials and heads of departments are located at the front and south side of the fifth floor. The workers in each department are directly opposite the private office of the head of that department. These offices are finished with panels of mahogany carried up to the height of the window sills. The partitions between the general offices are of plate glass above the wainscot. At the west side of the office there is a double fire- and burglar-proof vault. All equipment of this vault is steel and absolutely fire-proof. One of the features of the main office is a large leaded glass dome ceiling light 112 feet in length by 16 feet wide. In addition to the general offices there is a large foremen's conference room on this floor, which has a small kitchen attached to provide for serving luncheons.

On January 1 the following changes were made in the organization of the New Departure Mfg. Co.: Mr. Albert F. Rockwell, who was one of the founders of the company and who has taken an active part in the development of patents covering the product, has been relieved of certain managerial details, but continues as president of the company. Mr. DeWitt Page, who formerly held the positions of secretary, sales manager, purchasing agent and advertising manager, has been appointed general manager of the company. Mr. Charles T. Treadway, for some years past treasurer of the company, continues in that capacity, but also becomes chairman of the board of directors.

* * *

Tax factories and there will be fewer factories; tax trade and there will be less trade; tax machinery and there will be less machinery; but tax the value of land and of natural resources and there will not be any less land or natural resources.

A ROTARY CUTTING-OFF MACHINE

A machine which has accomplished some remarkable performances in cutting off bars and tubes has recently been built by Charles Taylor, Ltd., Birmingham, England. The cutter revolves around the bar or tube to be cut off, the work being held stationary in a vise. This avoids revolving long and heavy bar stock, and facilitates moving up and regripping the work. The cutters do not have to be stopped while the rod is being adjusted, thus reducing to a minimum the time lost in cutting off several pieces in succession.

The headstock consists of a substantial iron casting forming the main body of the machine and having massive split bearings in which runs a hollow spindle carrying the cutter-head. The cutter-head has two cutter-slides operated by a hand lever, which feeds the cutters in by means of chains passing through the spindle. These chains act in connection with an automatic balancing device to insure the cutters doing equal work. Fig. 1 shows how this is accomplished. In this illustration *A* is the cutter, *B* the slide carrying the cutter, *C* the chain which feeds the cutter in, and *D* a yoke which can oscillate on a cylindrical bearing in the piece *E*. Thus as one cutter is forced out, the yoke *D* moves on its bearing and draws the opposite cutter in until both cuts are exactly equal, and they remain so throughout the cut.

In most cutting-off machines it is highly important for both cutters to be set precisely alike to a gage, and this requires a skilled operator. In the machine under consideration, this is not of great consequence because if the cutters *A* are carelessly placed, even to the extent of 1/16 inch or more, as indicated by the dotted lines on the end of the cutters, the effect when the machine is at work is that one cutter retreats and the other advances until both cutters are working precisely alike. When this balance is obtained the cutters remain in position until they are again taken out for resharpening. An unskilled operator can handle this balancing machine.

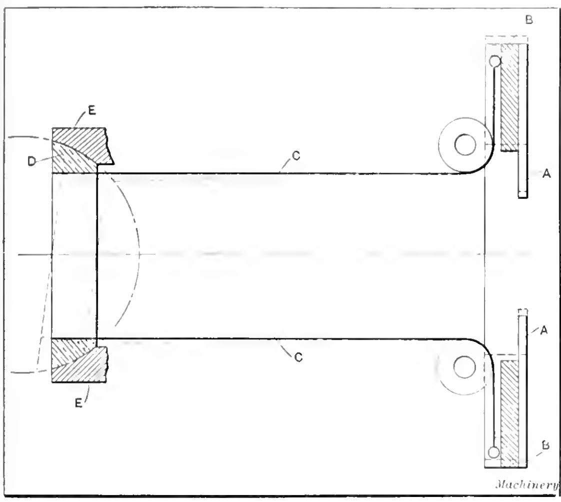

Fig. 1. Diagram illustrating Method of feeding Cutters to Work

The feed chains are protected by a steel liner running the whole length of the spindle, the spindle being driven by a balanced cast-iron pulley of 16 inches diameter, for a three-inch belt. The cutters are of plain oblong section and are rigidly supported throughout their length. As shown in Fig. 2, they are so placed as to have ample clearance at all points and require grinding on one face only. This is accomplished by having their bearings so shaped that when the cutters are clamped in place they lie in such a position that only the extreme corner of one side of each is in contact with the work, except, of course, the front cutting edge. All other parts have a liberal clearance. Moreover, the cutters are offset from each other so that each takes a cut of less width than the groove which is being cut. This allows the chips to swell, as all chips do, without binding in the groove. Also when the cutters are dull they simply yield slightly from the face of the groove and so touch without the slightest binding effect. As the cutters are of plain rectangular section set to cut their own clearance, they cannot wear narrow on the front or cutting edge and bind in the groove, which is a frequent and continuous trouble with the ordinary formed cutting-off tool. In Fig. 3, for instance, showing the usual formed tool, the points *A* and *B* break off causing the tool to bind in the groove on the sides *C* and *D* with consequent breakage.

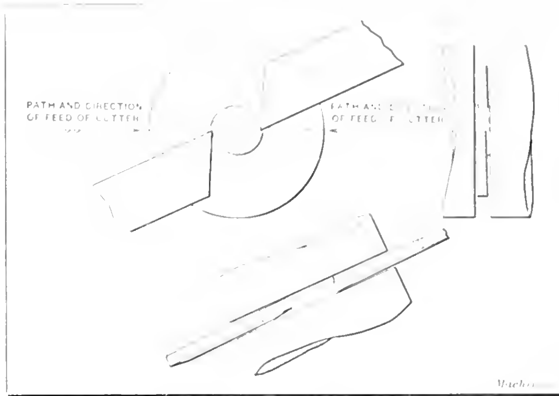

Fig. 2. Method of mounting Cutters that gives Ample Clearance

Other features of the machine include a lever stop with a spring plunger set to act in such a way that the spring is compressed as the stock is cut through, thus serving to retard the advance of the cutters at the last moment and to insure that the end of the stock is left clean. The stock is held in a self-centering vise in front of the cutters, and provision is made to support the stock which projects from the vise by means of an adjustable roller support, which facilitates the feeding of heavy stock through the vise. The cut off pieces are supported in the spindle on a long supporting member projecting into the spindle from the rear end. A two- or three-speed countershaft is provided enabling the speed to be changed, if necessary, while cutting is actually in progress.

The performance of this machine can be gaged as follows. The average time for cutting off solid bars is, for ¾-inch round mild steel, 11 seconds; 1-inch round mild steel, 12 seconds; 1½-inch square mild steel, 19 seconds; 2-inch round mild steel, 22 seconds; 3-inch round mild steel, 45 seconds; and 2-inch round cast steel, 65 seconds. In dealing with gas pipe, a 1½-inch pipe can be cut off in 5 seconds. J.

* * *

DELICACY OF THE CHEMICAL BALANCE

Those not familiar with the methods of chemical analysis have very little conception of the delicacy of the chemical balance and extreme care that must be taken when ascertaining weights to a fraction of a milligram. The balance is supported by the knife-edges only when actual weighing is in progress. When the substance to be weighed is being placed on the pan, and during all manipulations of the weighing, the rule is to raise the beam off the knife-edges by means

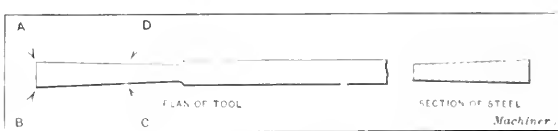

Fig. 3. Diagram illustrating Weakness of Formed Cutter

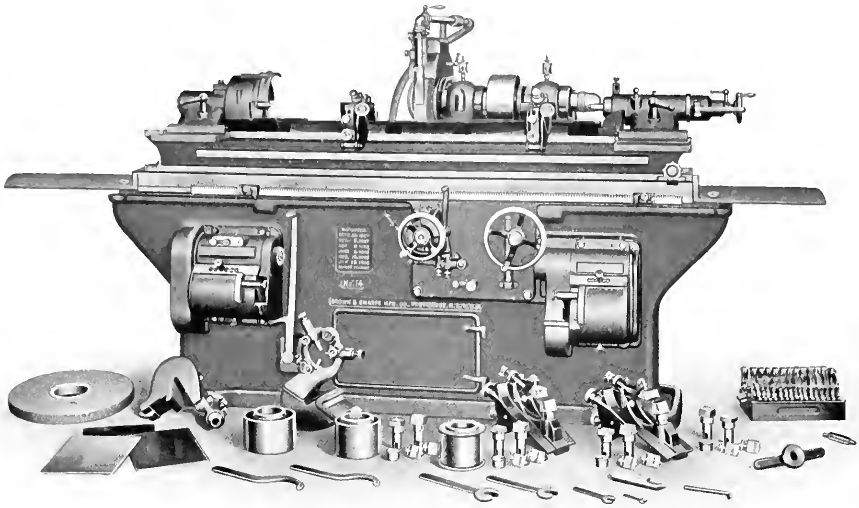
provided for the purpose. When not in use the beam is always supported by the auxiliary means provided. Extreme care must be taken to keep the knife-edges free from corrosion. A jar of unslacked lime or pure sulphuric acid is kept in the case to absorb atmospheric moisture. A warm object cannot be accurately weighed because the air currents set up a disturbing force sufficient to vitiate the accuracy of the work.

Grinding Time on This Work is



No. 14 PLAIN GRINDING MACHINE

You are probably familiar with some, if not all of the various types of machine parts represented in the case opposite.

It is the sort of work to be found in quantity in many manufacturing shops—work on which a small saving per piece means a worth while saving by the end of the day.

There are long, slender shafts requiring careful support, pieces of large diameter on which heavy cuts are taken, taper bearings on spindles, irregular shaped work as shown near top of case, etc.

We have developed the type of Plain Grinding Machine with quick change work speeds and table traverse, shown above, as particularly fitted for rapid production on such work.

PERSONALS

Henry Pollard recently took charge as superintendent of manufacturing of the Chicago plant of the Benjamin Electric Co.

E. E. Hendee, secretary of Joseph T. Ryerson & Son, returned to Chicago in the middle of February after a two weeks' trip to the South and Southwest.

Edward Blake, who for several years was sales manager of Wells Bros. Co., Greenfield, Mass., and for the past three years general manager of the J. T. Slocomb Co., Providence, R. I., has resigned his position with the company. Mr. Blake has made no definite plans for the future.

A. B. Hall, for the past fourteen years connected with the machinists' supply department of the Whitman & Barnes Mfg. Co., was elected a director and second vice-president of the company at the annual stockholders' meeting held January 28 at the general offices, Akron, Ohio.

William Miller has discontinued his connection as secretary of the firm of Henry Disston & Sons, of Philadelphia, after a service of thirty-seven years, and on February 1 associated himself with the Simonds Mfg. Co., Fitchburg, Mass., and Chicago, Ill. Mr. Miller is one of the most experienced and efficient men in the saw, knife and file-making business, and is well and favorably known in the hardware trade.

O. P. Wilson, of the purchasing department of the Westinghouse Electric & Mfg. Co., has resigned to take the position of assistant general manager of the Norma Company of America, 20-24 Vesey St., New York City, manufacturer and importer of high-grade ball bearings, precision instruments, etc. Mr. Wilson has been connected with the Westinghouse Electric & Mfg. Co. for fourteen years, and for the last ten years has been one of its head buyers.

C. S. Dundore, after thirteen years' service as treasurer and general manager of the American Die & Tool Co., Reading, Pa., has started in business for himself under the name of the Dundore Mfg. Co., 221 S. 9th St., Reading, Pa. The company will serve the tool and contract work trade, being equipped to make tools and dies and also to do contract work in the manufacture of machines and metal specialties. Special attention will be given to the manufacture of boiler and bridge builders' tools.

* * *

OBITUARIES

Neil W. Snow, president and general manager of the Detroit Twist Drill Co., Detroit, Mich., died January 22, aged thirty-four years.

William Colthar, proprietor and general manager of the Victor Vise Co., Springfield, Ohio, and a manufacturing machinist, died January 19, aged forty-nine years. Mr. Colthar acquired his mechanical training with the Mechanics Institute at Cincinnati, and after considerable experience in the machine tool industry in the latter city he undertook work on his own account, being the original designer of the Timken roller bearing. He did considerable work on the Paige typesetting machine, and designed many original machines. He is survived by his widow and one son.

Caleb Colvin, founder of the Caleb Colvin iron foundry, which later became the L. W. Pond Machine & Foundry Co., Worcester, Mass., died of bronchitis at his home in Worcester, February 17, aged eighty-five years. He was born in Cranston, R. I., and at the age of eighteen was apprenticed to the iron molder's trade. He went to Worcester in 1865 and established the iron foundry business, which was afterward made a partnership known as C. & J. A. Colvin. The business was incorporated in 1887 under the name of the L. W. Pond Machine & Foundry Co. Mr. Colvin retired from active business in 1905.

Erwin Starr Sperry, editor and publisher of the *Brass World and Platers' Guide*, died at Bridgeport, Saturday, January 31. Mr. Sperry was born in Ansonia, Conn., in 1866, and graduated from the Sheffield Scientific School of Yale University in 1887, where he afterward held a position as assistant instructor in chemistry under Prof. H. L. Wells. In 1891, he went to Bridgeport as chemist for the Aluminum Brass & Bronze Co., and afterward became superintendent of the Waldo Foundry. Ten years ago, he started publishing the *Brass World and Platers' Guide*. He was a member of leading scientific societies of this country and Europe. Mr. Sperry is survived by his widow.

David B. Hyde, one of the Hyde brothers who have been closely connected with the emery wheel manufacturing business since its inception, died February 14 at Riverside, Cal., of pneumonia, aged fifty-five years. He was born at Wilmington, Vt., in 1859 and at the age of thirteen was thrown upon his own resources. He and one of his brothers (mere boys at the time) showed great enterprise by placing on the market a patent inkstand, and thousands of these stands were sold in America and Europe. Mr. Hyde was one of the pioneers in the manufacture of emery wheels and grinding machinery. In 1880 he, with his four brothers and D. T. Homan, started the Springfield Glue & Emery Wheel Co. at Springfield, Mass., being the first to make emery wheels for water tool grinding in this country. In 1893 he and his brother, O. H. Hyde, and E. C. Gwynn, organized and started the Safety Emery Wheel Co. of Springfield, Ohio, and he introduced the safety collars used on emery wheels. Mr. Hyde also originated the "Champion" tool-holder now manufactured by the Western Tool & Mfg. Co. of Springfield, Ohio. He was later connected with the Pittsburg Emery Wheel Co., but on account of poor health sold out his business interests and went to California, where he was engaged in dry farming on an extensive scale at the time of his death. Mr. Hyde leaves a widow, two daughters and one son; also three brothers, E. R. Hyde of the Bridgeport Safety Emery Wheel Co. and O. H. and C. L. Hyde of the Safety Emery Wheel Co. of Springfield, Ohio.

Henry Brinton, president of the H. Brinton Co., Philadelphia, Pa., died at his home at Bala, January 30, after a brief illness with heart trouble, aged sixty-six years. He was born at Christiana, Lancaster Co., Pa., of a line of Quaker ancestry descended from William Brinton who came to America in 1684. He received a thorough training as a machinist in the shops of I. Broomell & Sons, now the Christiana Machine Co., and later spent about two and one-half years with Bement-Miles & Co., Philadelphia. From there he went to the Colt's Armory in Hartford, Conn., where he worked for a time on the Baxter engine. His next work was on the Branson knitting machine at Bellefonte, Pa. When the Branson Co. failed, Mr. Brinton went to the Lancaster Watch Co. at Lancaster, Pa., where he obtained experience in fine manufacturing methods which had a pronounced effect on his own designing later. When the Branson Co. was reorganized, Mr. Brinton went back to Bellefonte, only to meet another financial crisis. After a further experience at the Lancaster Watch Co., he joined Branson a third time in Philadelphia and was for some years the superintendent of the knitting machinery business under the Branson name. In 1888 Mr. Brinton started manufacturing knitting machines in the partnership of Brinton, Denney & Co., and five years later, Mr. Denney sold his interests to J. E. Longergan and the firm name became H. Brinton & Co. The business was incorporated in 1906 under the name H. Brinton Co. Mr. Brinton probably did more to improve and commercialize automatic cylinder knitting machines of the latch needle type than any one else. He took out patents on the knitting machine sinker mechanism with the sinker driven from below the stitch level. On ribbers, the Brinton design was revolutionary. The ribber pattern wheel mechanism built by Mr. Brinton twenty years ago, has not been surpassed or changed to this date. Splicing devices for inserting an extra thread is also of Brinton design and a ring in the dial cap for operating multiple-feed rib machines was another Brinton invention. In general, it may be said that the prime feature of Mr. Brinton's work was the beautiful simplicity of his mechanism for producing complex results. When he finally adopted a design, that design was usually as near to the perfection of mechanical simplicity as it was possible for it to be made. He was married in 1874 to Rachael Cawley, who with a daughter and two sons survive him.

COMING EVENTS

April 4-11.—First National Efficiency Exposition and Conference, Grand Central Palace, New York City. Walter H. Tallis, director, Efficiency Society, Inc., 41 Park Row, New York City.

April 29-30.—Annual meeting of the National Association of Cotton Manufacturers, Boston, Mass., in the Paul Revere Hall of the Mechanics Bldg. C. J. H. Woodbury, secretary, 45 Milk St., Boston, Mass.

May 1-October 31.—Anglo-American Exposition, London, England, to celebrate the centenary of peace between the United States and Great Britain. American executive offices: Woolworth Bldg., New York City. Charles J. Kiralfy and Albert E. Kiralfy, commissioners general.

June 15-17.—Annual convention of the American Supply & Machinery Manufacturers' Association at White Sulphur Springs, West Virginia; New Green Brier Hotel, headquarters. General offices of the association, Woolworth Bldg., New York City.

September 20-25 (1915).—International Engineering Congress, San Francisco, Cal., in connection with the Panama-Pacific International Exposition. W. F. Durand, chairman, Foxcroft Bldg., San Francisco, Cal.

NEW BOOKS AND PAMPHLETS

Copper Wire Tables. 69 pages, 7 by 10 inches Published by the Department of Commerce, Washington, D. C., as Circular 31 of the Bureau of Standards.

Standard Specifications for Incandescent Electric Lamps. 20 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Circular 13 of the Bureau of Standards.

United States Coast and Geodetic Survey. Annual Report of the Superintendent to the Secretary of Commerce. 100 pages, 6 by 9 inches. Published by the Department of Commerce, Washington, D. C.

High-frequency Ammeters. By J. H. Dellinger. 70 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Reprint No. 206 from the Bulletin of the Bureau of Standards, Vol. 10.

Electrolytic Corrosion of Iron in Soils. By Burton McCollum and K. H. Logan. 69 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as No. 25 of the Technologic Papers of the Bureau of Standards.

Latent Heat of Fusion of Ice. By H. C. Dickinson, D. R. Harper and N. S. Osborne. 32 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as No. 209 of the Scientific Papers of the Bureau of Standards.

Coal Washing in Illinois. By F. C. Lincoln. 108 pages, 6 by 9 inches. Published by the University of Illinois, Urbana, Ill., as Bulletin No. 69. Price 50 cents.

A great amount of data gathered from experiments made in the mining laboratory of the university, personal visits to the various coal washeries in the state and a thorough search of the scattered literature on the subject has been compiled and tabulated in this bulletin. The bulletin also contains an article by S. W. Parr on the moisture in washed coals and is a summary of tests made at the Experiment Station on carload lots of various washed coals.

Elementary Manual of the Steam Engine. By Ernest V. Fallier. 266 pages, 5 by 7¾ inches. 102 illustrations. Published by D. Van Nostrand Co., New York City. Price $2.

This work, as indicated by the title, is intended for the instruction of students and young men studying the elements of engineering. It treats of reciprocating steam engines, governors, engine calculations, the indicator, heat, boilers, pumps, Corliss engines, pipes and fittings, rotary engines, internal combustion engines and lubrication. Wherever possible, principles are illustrated with arithmetical examples, and questions are given at the end of chapters which may be used for self-examination to the student studying at home. The work is one that should be appreciated by the class generally for whom it is intended.

Factory Organization and Administration. By Hugo Diemer. 378 pages, 6 by 9 inches. 172 illustrations. Published by the McGraw-Hill Book Co., Inc., New York City. Price $3.

The first edition of this work was published in 1910. In rewriting the book, the author has rearranged the material in what appears to be more logical order. The subjects treated comprise: Principles, Field and Methods of Industrial Management; Industrial Finance; Organization and Control; Typical Factory Organizations; Factory Accounts; Departmental Reports; Factory Location; The Planning of Factory Buildings and the Influence of Design on Their Productive Capacity; Employment of Labor and Labor Problems; General Office; Order Department; Bills of Material; Drafting Department; Pattern Department; Purchasing Department; Stores and Stock Department; The Production or Planning Department; Foundry Systems; The Machine Shop and Tool Department; Shipping and Receiving Departments; Time Taking; Cost Department; Aids in Taking Inventory; Inspection Methods in Modern Machine Shops; Rate Fixing and Time Studies; Wage Systems; Principles Underlying Good Management; and A Bibliography of Works Management.

Welding—Theory, Practice, Apparatus and Tests. By Richard N. Hart. 210 pages, 6 by 9 inches. 127 illustrations. Published by the McGraw-Hill Book Co., Inc., New York City. Price $2.50.

The first edition of this work was published in 1910. The rapid progress of the last three years in apparatus and methods of welding has made a revision necessary, especially with regard to arc welding and oxy-acetylene welding. The work deals with the characteristics of iron, platinum, gold, silver, aluminum, copper, and nickel. The electric welding processes are described, including the La Grange-Hoho process, the Zerener electric blowpipe, the Bernardos arc-welding process, the Slavianoff arc-welding process, combination Slavianoff and Bernardos processes, and the Thomson process. Part III is devoted to hot-flame welding, treating of the oxy-acetylene and oxy-hydrogen processes. The torches and apparatus in general are illustrated and described. A chapter is devoted to the thermit process, illustrating its apparatus and application to rail welding, marine repairs and other characteristic jobs for which it is especially suited. A chapter is given up to soldering and miscellaneous processes including the Lafitte welding plate, the "ferrofix" brazing process, brazing and soldering, the Blaugas process, etc. The work is one to be recommended to all desiring to become acquainted with the characteristics of the various welding processes developed within the past few years. While the treatment of the subjects is by no means exhaustive, it leaves comparatively little to be desired by those who wish to gain a general knowledge of the modern welding art.

NEW CATALOGUES AND CIRCULARS

Massachusetts Institute of Technology, Boston, Mass. Catalogue for 1913-1914.

Stevens Institute of Technology, Hoboken, N. J. Annual catalogue 1914-1915.

Technical Supply Co., Scranton, Pa. Booklet describing the Levi automatic blueprint finisher.

Polytechnic Institute, Brooklyn, N. Y. Annual catalogue of the College of Engineering, 1914-1915.

Alston Saw & Steel Co., Folcroft, Pa. Circular of the Alston process improved hacksaw blades made for all purposes.

Laidlaw-Dunn-Gordon Co., Cincinnati, Ohio. Bulletin 22 on air compressor efficiency and the factors controlling it, with special reference to the Cincinnati air gear.

Brown Hoisting Machinery Co., Cleveland, Ohio. Pamphlet C on "Brownhoist" safety crabs and winches. Provision is made so that the handles cannot fly back and the load cannot drop.

Hannifin Mfg. Co., Chicago, Ill. Circular illustrating and describing Hannifin air-operated chucks, including master hinge air-operated collet chucks, and two- and three-jaw universal chucks.

H. A. Lowe, 1374 E. 88th St., Cleveland, Ohio. Circular of the Lowe universal test indicator weighing 1¼ ounce and magnifying 100 times. The dial is graduated to thousandths inch.

Northern Engineering Works, Detroit, Mich. Crane catalogue 26 illustrating electric traveling cranes, hand power traveling cranes, electric and pneumatic hoists, overhead track systems, bucket handling cranes and railway cranes.

Railway Roller Bearing Co., Syracuse, N. Y. Catalogue of the roller journal boxes, electric motor bearings, etc. The construction of the bearing is shown and examples of applications to electric locomotives, street cars, motors, etc., are included.

Simplex Wire & Cable Co., 201 Devonshire St., Boston, Mass. The "Simplex" manual containing, in addition to information regarding "Simplex" products, tables and data for the ready reference of electrical engineers, contractors, wiremen, etc.

Greenfield Machine Co., Greenfield, Mass. Catalogue No. 5 of the "Greenfield" universal tool and cutter grinder and its attachments. The uses of the attachments are illustrated and other matter is contained of value to users of tool grinding machines.

Mesta Machine Co., Pittsburg, Pa. Bulletin M of the Mesta improved pickling machines for pickling metal objects of any shape. The Mesta machine brings mechanical action into play to such an extent that the material is pickled with about one-half of the acid and labor required in hand pickling.

Webster & Perks Tool Co., Springfield, Ohio. Circulars of Nos. ¾ floor or bench type grinder, 1¼ "P" self oiling grinding and polishing machine, 1⅜, 1½ and 1⅝ direct-current electrically driven floor type polishing and buffing lathes, and 1¾ alternating current direct connected electrically driven type grinder.

Gould & Eberhardt, Newark, N. J. Catalogue of high duty shapers and attachments, details of construction and general specifications. The line comprises 14-inch, 16 inch, 20 inch, 24-inch and 28-inch sizes. Shapers with direct current and alternating-current motor drives are shown, and accessories for same.

Winfield Electric Welding Machine Co., Warren, Ohio. Catalogue of Winfield electric welding machines, comprising spot and butt welding machines, which are illustrated and described. The catalogue contains information on electric welding useful to manufacturers employing the electric welding process.

Royersford Foundry & Machine Co., 54 N. 5th St., Philadelphia, Pa. Catalogue "Saving the Friction Loss—'Sells' Roller Bearings," containing a description of the construction, operation and application of "Sells" roller bearings. The catalogue is illustrated with halftone and sectional views, the latter showing the design in detail.

Wood Turret Machine Co., Brazil, Ind. Catalogue of the "tilted turret" lathe, a feature of which is that the turret is so made and placed that the stock can pass clear through, thus giving unlimited capacity in length of work. The machine is made in six sizes, ranging from 1 inch to 4½ inches automatic chuck capacity.

National Lead Co., 111 Broadway, New York City. Pamphlet on electro-plating zinc alloy die-castings, giving practical methods for cleaning, polishing and electro-plating the various alloys used in die-casting. The information contained will be particularly acceptable to electro-platers who have experienced difficulty in doing this class of work.

Pawling & Harnischfeger Co., Milwaukee, Wis. Pamphlet entitled "Difficult Drilling and Boring Made Easy," illustrating work done by the Pawling & Harnischfeger drill presses in machine shops. Manufacturers having to drill large structural work, castings, etc., should find the illustrations and descriptions of these drilling machines of interest.

National Tube Co., Pittsburg, Pa. Bulletin No. 18-A entitled "National Reamed and Drifted Pipe." This bulletin contains a complete description with illustrations of this product, together with a short introduction explaining the processes of well drilling and information relative to the various accessories necessary for the drilling and pumping of wells.

Cutler-Hammer Mfg. Co., Milwaukee, Wis. Pamphlet on door safety switches for use with electric elevators. A great majority of accidents on all kinds of elevators are the result of setting the elevator machine in motion before the doors are closed and locked and the passengers clear. With the ever-increasing number of passengers the safety feature is of the utmost importance.

National Tube Co., Frick Bldg., Pittsburg, Pa. Bulletin 19, listing the products of the company. An idea of the extent of the products manufactured can be gained from the fact that the bulletin has eight pages, two columns to the page, filled with small type. Of "Kewanee" products, 852 are listed; of "National" pipe products, sixty-four, and of Shelby seamless steel tubing products, thirty-seven.

Niles-Bement-Pond Co., 111 Broadway, New York City. Catalogue of Niles electric traveling cranes, showing the equipment of Niles standard traveling cranes and details of construction. Grab bucket trolleys, electric wall cranes, gantry cranes, traveling hoists and hand power frames are also shown. The catalogue is beautifully illustrated with numerous views of works in which Niles bridge traveling cranes are installed.

Curtis Pneumatic Machinery Co., 1568 Kienlen Ave., St. Louis, Mo. Catalogue of air compressors, air hoists, air cranes, pneumatic and hydro-pneumatic elevators, trolleys, trolley systems and sand blasts. The company has specialized in pneumatic hoisting appliances for over twenty years and has developed the simple air cylinder into a straight-line motor with wonderful speed control and dependability, capable of the widest application to hoisting problems.

Gardner Governor Co., Quincy, Ill. Circular "The Gardner One Tool Plant," consisting of a vertical self-oiling air cooled compressor, 2 by 2½ inches, driven by ½ H. P. electric motor, mounted on a four wheel truck. A tool box is provided and a rack for hose. The machinery is enclosed in a removable cover and the outfit forms a compact, portable compressed air plant. While primarily designed for stoneworkers, monumental work, etc., it should serve in many other situations where compressed air is required.

Yale & Towne Mfg. Co., 9 East 40th St., New York City. Pamphlet entitled, "History of the Trade-mark 'Yale,'" which is a record of cases in which the company's rights have been sustained and confirmed in litigation involving a legal right in trademarks, catalogue numbers, distinctive designs and other indications of the origin of patterns. The pamphlet is one that should be read with interest by all concerned with trademarks, and it should also be found interesting by readers in general because of the matter contained on the origin of locks.

Titanium Alloy Mfg. Co., Niagara Falls, N. Y. Rail Reports Bulletin No. 4 on open hearth steel. This bulletin contains a summary of chemical and physical results as reported in bulletins 1, 2, 3 and 4 on standard open hearth A rails and titanium open hearth treated A rails. It was found that the average hardness of standard rails is twenty-four per cent greater in the webs than in the heads and flanges while in the titanium treated rails, the average difference is only five per cent. The impact resistance of titanium rails averaged thirty-five per cent higher than of standard rails in the heads, four per cent in the webs and fifty per cent in the flanges. Titanium rails in the White-Souther endurance test averaged fifty per cent greater endurance than standard rails. The value of these reports on extensive rail tests is evident to all metallurgists and users of rails.

H. W. Caldwell & Son Co., Western Ave., 17th to 18th Sts., Chicago, Ill. Catalogue No. 38 on elevating, conveying, power transmitting and general machinery, containing 797 pages, 6 by 9 inches. The company makes helicoid conveyors, machine molded gears, friction clutches, ice handling machinery, specialties for flour mills, grain elevators, cotton seed oil mills, alfalfa plants, starch works, linseed oil mills, breweries, distilleries, malt houses, sugar refineries, glucose works, cement works, phosphate works, lime works, gypsum works, chemical works, tanneries, etc. The catalogue is one of the most complete in the line of power transmission elevating and conveying machinery. It is copiously illustrated, printed on high-grade paper and completely indexed. It should be in the hands of every engineer and manufacturer having use for the line of machinery and parts listed.

R. K. LeBlond Machine Tool Co., Cincinnati, Ohio. Catalogue of LeBlond engine lathes which are furnished in various styles, with such combinations of equipment as may be desired, as follows: regular stud lathe, 14 to 20 inches swing; regular standard engine lathe, 12 to 24 inches swing; regular quick-change engine lathe, 12 to 24 inches swing; heavy-duty manufacturers' automobile lathe, 17 to 21 inches swing; seventeen-inch rapid production lathe; heavy-duty standard engine lathe, 25 to 33 inches swing; heavy-duty quick change engine lathe, 17 to 33 inches swing; heavy-duty quick change engine lathe, 25 to 33 inches swing; heavy-duty quick change sliding bed gap lathe, 19-38, 25-50 and 30-60 inches swing; regular plain chucking lathe, 12 to 24 inches swing; heavy-duty quick change combination turret lathe, 17 to 27 inches swing; heavy-duty manufacturers' complete turret lathe, 24 to 27 inches swing—with triple gear single pulley drive, 31 inches swing; heavy-duty quick change universal turret lathe, 17 to 33 inches swing; motor-driven engine lathes of any size or type. A line of accessories is shown comprising turrets, turret toolposts, compound rests, relieving attachment, multiple automatic length stop, belt shifter, draw-in attachment and collets, translating gears for metric threads, etc.

TRADE NOTES

Warren Forge & Tool Co., Warren, Ohio, has elected James Robertson, president; M. J. Konold, vice-president and secretary; George E. Warner, treasurer; and George F. Konold, general manager.

Walcott & Wood Machine Tool Co., Jackson, Mich., has bought the patent rights, patterns and good-will of the Melling-Northrup die-sinking machine manufactured by the Melling-Northrup Co., Jackson, Mich.

Gem City Machine Co., 429 East First St., Dayton, Ohio, was destroyed by fire during the last week in January. Three days later, however, the firm was operating in other quarters, delivering orders and contracting for new work.

Buffalo Forge Co., Buffalo, N. Y., has opened offices at 176 Federal St., Boston, Mass., for its fan, ventilating and pump department. The company is represented in the New England territory by B. R. Andrews, formerly with the B. F. Sturtevant Co.

J. T. Slocomb Co., Providence, R. I., maker of machinists' micrometers, centering drills, etc., has been sold to J. H. Drury, sales manager of the Union Twist Drill Co., Athol, Mass. J. T. Slocomb, who organized the business, will remain for a short time.

Eveland Engineering & Mfg. Co., 2324-2328 Market St., Philadelphia, Pa., has been authorized by its

MANUFACTURING "AMERICAN" STEEL PULLEYS*

TOOLS AND METHODS EMPLOYED IN PRODUCING BELT PULLEYS FROM SHEET STEEL

BY FRANKLIN D. JONES†

Fig. 1. "American" All-steel Split Pulley—Arms Integral with Hub

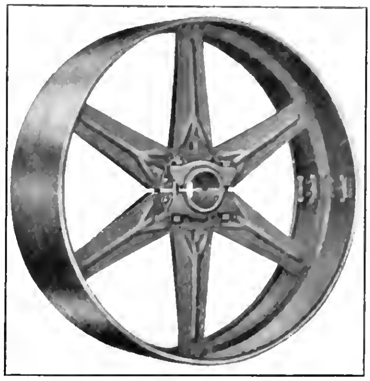

Fig. 2. "American" All-steel Split Pulley—Arms Riveted to Hub Flange

At the plant of the American Pulley Co. at Philadelphia, the normal monthly output of pressed steel pulleys of various sizes is about 22,000. To manufacture this number of pulleys from sheet steel and secure a strong, accurate, well balanced product, requires highly specialized machines and constructional methods, many of which are interesting not only from a mechanical viewpoint, but as a study in efficient means of production. In this article the principal operations connected with the manufacture of the American pulley will be described. It should be mentioned that the order and nature of some of the operations for different sizes and designs of pulleys vary somewhat, as this company makes pulleys ranging from 3 to 72 inches in diameter; most of the operations which will be referred to, however, are common to all medium and large sizes and represent the most important processes.

Two types of "American" pulleys which have been widely used are shown in Figs. 1 and 2, these designs being for medium and large sizes, respectively. The hub of a half section of the type of pulley shown in Fig. 1 is integral with the arms, whereas the arms of the pulley illustrated in Fig. 2 are securely riveted to half an annular hub ring of angle section. In each case, the outer hub is riveted to an inner hub shell. Sizes varying from 44 to 72 inches, inclusive, have eight arms instead of six and the arms are bifurcated or forked where they are riveted to the hub ring. The forked ends which overlap are also riveted together, thus forming a rigid pulley especially adapted for heavy duty. The rim sections of all the pulleys are joined at the center by flanges, to which the arms are riveted, and the rims are beaded around the outside edges to stiffen them and make a safe rounded edge.

Forming Pulley Arms and Hub

The method of forming a half spider (including half the hub and three arms) for a pulley of the type shown in Fig. 1 is illustrated in Fig. 3. First, the flat steel stock is sheared to length and is then slit, as at *A*, in a die to form the three arms. The three arms are then corrugated, as at *B*, to stiffen them, in a hydraulic press equipped with suitable dies. (This operation for some pulleys is done later.) The flat, corrugated plate is next flanged in a V-shaped die, as at *C*, which is the first step in the formation of the hub, the latter being shaped in three operations. After the plate is flanged, the three arms are spread apart and the hub roughly formed as at *D*; then this roughly formed part is placed in another die where the hub is made round and the arms are spread and convexed to the proper degree, as at *E*. The die for the spreading operations *D* is shown in Fig. 4. This die is so arranged that the central arm of the slit plate is held by block *A* while the other two arms are being spread by the action of

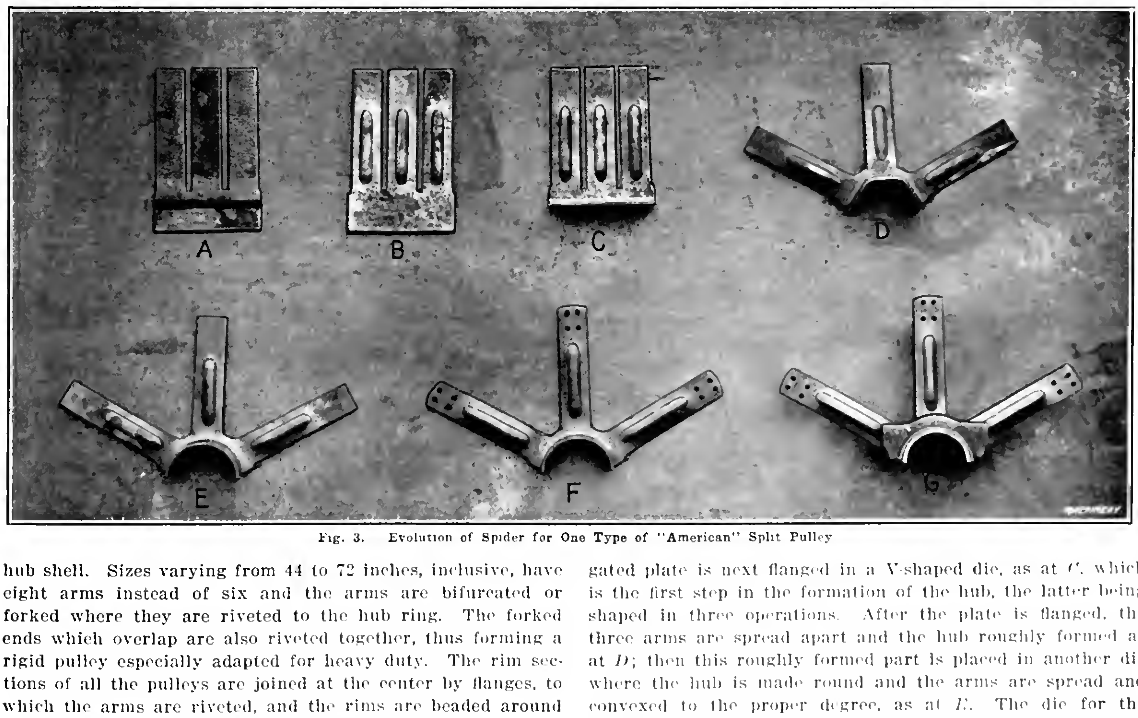

Fig. 3. Evolution of Spider for One Type of "American" Split Pulley

* For other articles on the manufacture of steel pulleys see "Making the Philips Pressed Steel Pulley in the November, 1913, number of MACHINERY.
† Associate Editor of MACHINERY.

a cylindrical shaped punch B which compresses the straight flange and roughly forms the hub.

After the hub has been formed and the arms are spread to the proper angle, the outer ends of the arms are pierced for the rim flange rivets, as at F, Fig. 3. The dies used for piercing these holes are shown in Fig. 5. The spider is clamped against locating plug A by lever B which operates a clamping slide, and the arms are located in relation to the punches by stop C. The extreme ends of the arms are next rounded in another die to approximately the curvature of the rim and are beveled on one side to avoid interference with the fillet of the rim flange. This beveling is necessary, for the ends of the arms which are milled to a uniform radius, as described later, must come in contact with the flange to insure an accurate pulley. Each arm is located for beveling by the pierced rivet holes which engage pins on the die. Holes are next drilled in the hub for the rivets which hold

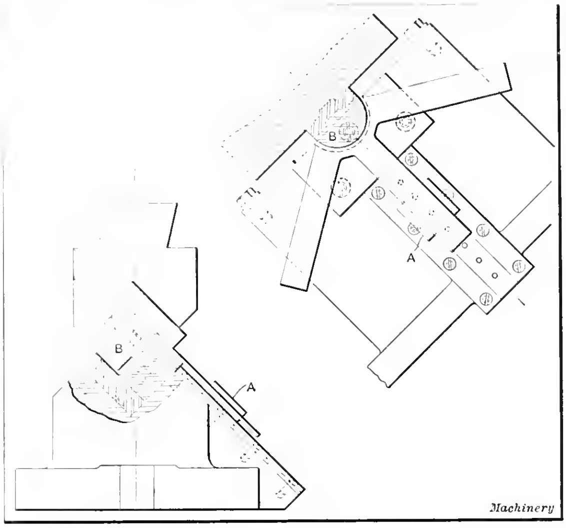

Fig. 4. Die for spreading Arms of Spider and roughly forming Hub

the inner shell. This drilling is done on the special multiple drilling machine shown in Fig. 6, the spindles of which are fed inward simultaneously, by the action of levers B operated by a cam at the rear. The work is held by three magnetized locating plugs C which engage the arms at the rear. These plugs hold the work securely enough for drilling, but it

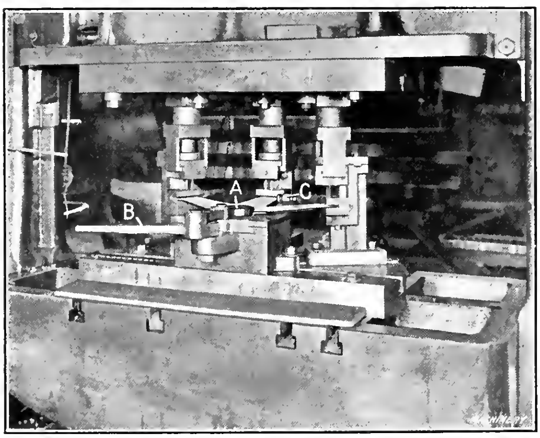

Fig. 5. Press and Dies for piercing Rivet Holes in Spider Arms

can be removed without demagnetizing the plugs. The location of the holes in the hub, relative to the arms, is controlled by pin A which engages a hole in the central arm, as shown.

The hub clamp shown attached to the hub at G, Fig. 3, is also formed of flat steel stock. This clamp, which is for the bolts that tighten the pulley hub on the shaft, is first blanked and then bent to a U-shape in a simple form of die; finally, the clamp is rounded to fit the hub and finished in the die illustrated in Fig. 7. This die has a rounded seat which conforms to the curvature required for the clamp, and a curved punch A. As the punch descends, the wedge-shaped plates B and B_1 at the sides engage plates C and C_1 which are forced inward, thus preventing the work from spreading or buckling while the forming operation takes place. As the punch

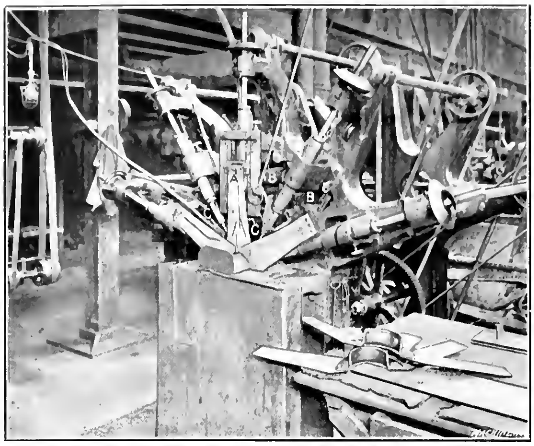

Fig. 6. Multiple Drilling Machine for drilling Rivet Holes in Hub of Spider

ascends, these plates loosen so that the work is easily ejected.

The assembling of the hub, hub clamp, and hub shell, to form the part shown at G, Fig. 3, is a riveting operation, hydraulic machines being used. The final operation on the pulley arms is shown in Fig. 8. Two half-sections or spiders are bolted around an accurately made bushing A which is not a part of the pulley but is a tool that represents the maximum shaft for which that particular pulley is adapted; this bushing is left in place until the pulley is completely assembled, riveted and tested. For the operation illustrated in Fig. 8,

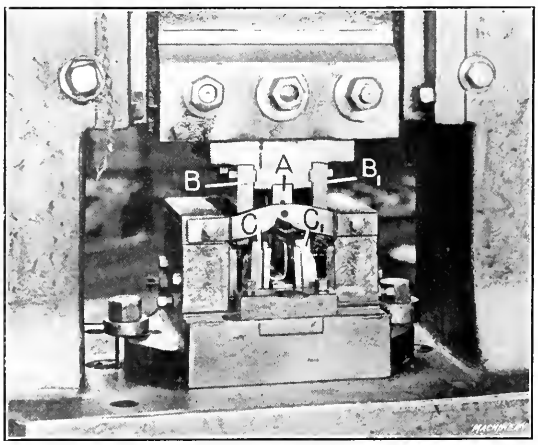

Fig. 7. Die for Final Forming Operation on Hub Clamp

which is that of milling the ends of the arms, this bushing is placed over a close-fitting plug and the arms are milled to a uniform radius by cutter B, the work being fed by simply turning it by hand. These milled surfaces insure a true pulley, as the rim sections are forced against them and are riveted in this position. Thus it will be seen that the accuracy of a pulley formed of sheet steel depends upon the design as well as upon the way in which it is manufactured.

Forming the Pulley Rim

The complete rim is composed of four sections, there being two sections in each half, joined by flanges at the center, as previously mentioned. These sections are first sheared approximately to length and then trimmed to an exact length in a die. At the same time, the corners are beveled slightly

so that the edges of the bead and flange will be radial after they have been formed, and the rim is made circular. These flat pieces are next passed through the rolls shown in Fig. 9, where they are roughly formed. The bead at the edge is partially turned over, as at *A*, and the flange is bent nearly at right angles. The last pair of rolls *B* is equipped with a crinkling device which uniformly corrugates the flange as shown at *C*, so that when the flange is pressed at right angles the bending action will be uniformly distributed and buckling prevented.

One of the large hydraulic presses used for finishing the rim sections is shown in Fig. 10. The rims are given the required shape by dies, and two sections are pressed simultaneously. This press has two large vertical plungers, one

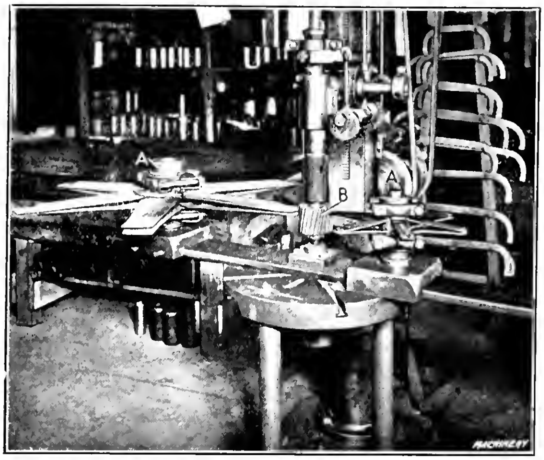

Fig. 8. Machine for milling Ends of Spider Arms to a Uniform Radius

being above the central inner die and one below it; in addition, there are four horizontal plungers located radially and 90 degrees apart. Two rough-rolled and crinkled rim sections the central die. The upper vertical plunger then descends and forces the crinkled flange down flat and at right angles, when the flange is pressed and while the rims are held se-

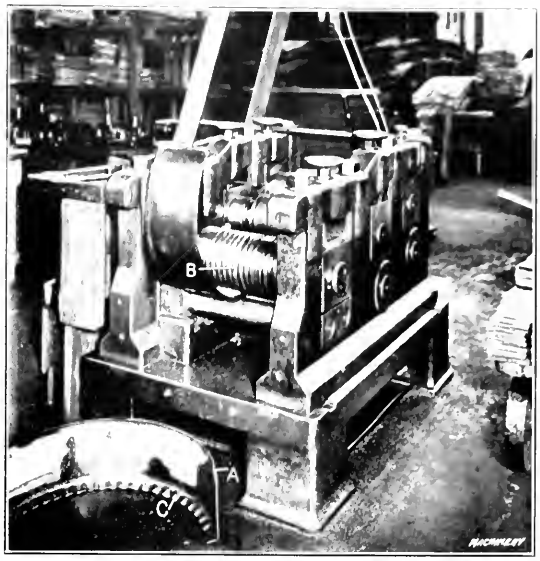

Fig. 9. Rolls for rough-forming Sections of Pulley Rim

curely, the lower plunger ascends and a curved beading die on it engages the edge of the rim (which it will be recalled was partially formed in the rolls) and rounds it, thus giving the rim a stiff outer edge. These operations are performed quite rapidly and the rims leave the press smoothly and accurately formed. The plungers are moved to and from the work by a pressure of about 150 pounds per square inch, but when the dies come into contact with the rims, the pressure is increased by an intensifier to 1000 pounds per square inch or more, in order to give the stock a permanent set. The rims

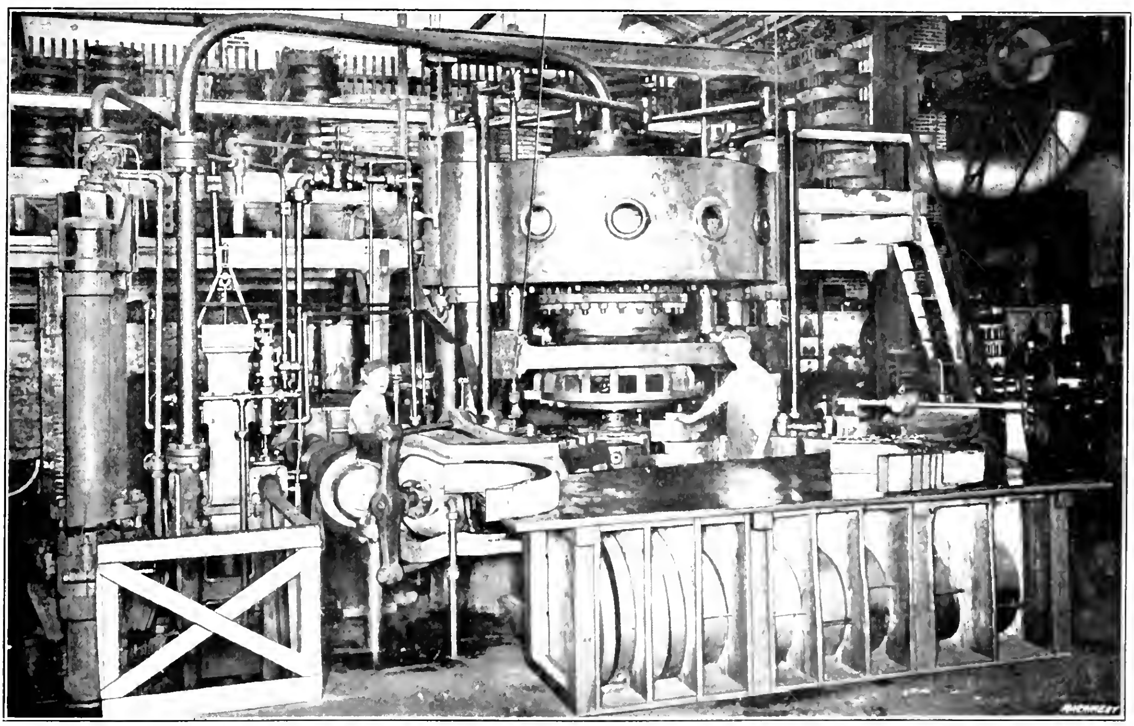

Fig. 10. Large Hydraulic Press equipped with Dies and used for finish-forming Rim Sections

are first inserted by two men standing one on each side of the press. The four radial plungers equipped with dies of the proper radius next move inward and press the rims against for pulleys larger than 18 inches in diameter are not formed in a hydraulic press with dies, but are rolled to the required size.

The rim ends and flanges are next pierced for rivet holes, which complete the rim section. The dies for piercing the central flanges are shown in Fig. 11. It will be noted that the dies for each pair of holes in the rim are independently attached to a circular faceplate or platen *B* having radial T-slots. The die bases are tongued to fit these slots which are also engaged by the clamping bolts. Each die is accurately located radially by plugs *A* which pass through it and enter holes that extend parallel with the slots. With this simple construction, one die is made to cover a wide range of sizes. The punches are, of course, also adjustable on the upper platen. The dies used for piercing the arms (illustrated in Fig. 5) are also constructed on the same principle, so that they can be adjusted for pulleys of different diameters.

Assembling the Pulleys

The pulleys are assembled on stands as indicated in Fig. 12. A spider having arms milled to a uniform radius and a tool bushing bolted in the hub, as previously mentioned, is placed over the vertical stake of an assembling stand and loose rivets are inserted through the arms, rim flanges and bolt clamps. One half of the pulley rim is accurately aligned with the other half, by short dowel pins *A* which were previ-

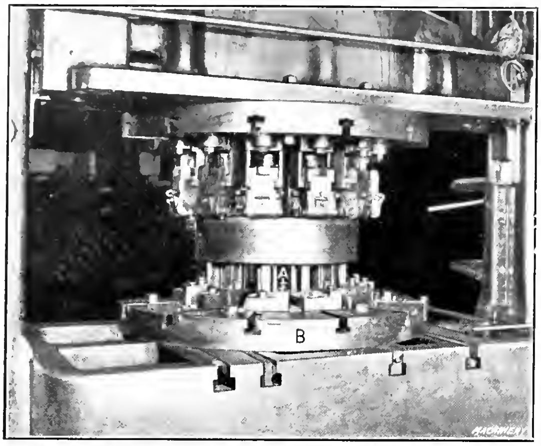

Fig. 11. Press and Dies for piercing Rivet Holes in Central Flange of Rim Section

ously inserted in the beaded edges. The assembled pulley is now taken to one of the hydraulic riveters (see Fig. 13) where the rivets are set. Before the riveting begins, the rim is firmly held against the ends of the milled arms by segments *A* which are forced in radially by an outer cam-ring *B*. This machine is used for setting rivets in the flange and arms. The rivets for the bolt clamps at the rim joint are set in the

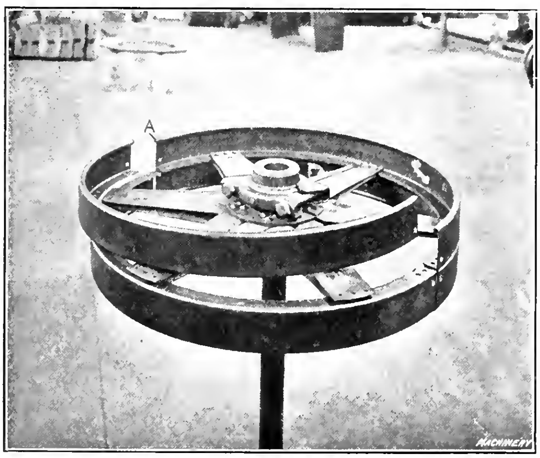

Fig. 12. Spider and Rim Sections being assembled prior to Riveting

special hydraulic riveter shown in Fig. 14. A heavy bar *A* passes through the pulley and provides a backing for the riveting dies *B* which receive the thrust of the lower plunger and dies *C*. When the rivets are set, the pulley is removed by simply pushing the bar back through bearing *D*.

Testing, Balancing and Inspecting

All finished pulleys are subjected to careful tests for accuracy and balance. The test for accuracy is made by the use

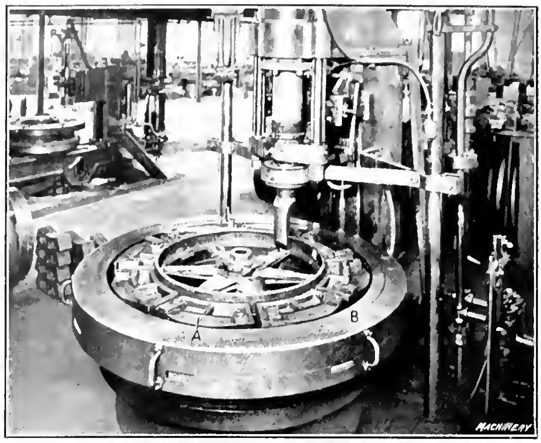

Fig. 13. Hydraulic Riveter equipped with Special Clamping Fixture for holding Rim against Milled Ends of Arms

of stands similar to that shown in Fig. 15. The spindle on which the pulley is mounted is revolved by a belt, as shown, and the stationary pointers *A* show whether the rims are circular and concentric or not. Screws *B* and B_1 at the sides show the accuracy in a lateral direction and are also used to force the pulley one way or the other, as may be required. Any slight local distortion of the rim is corrected by the

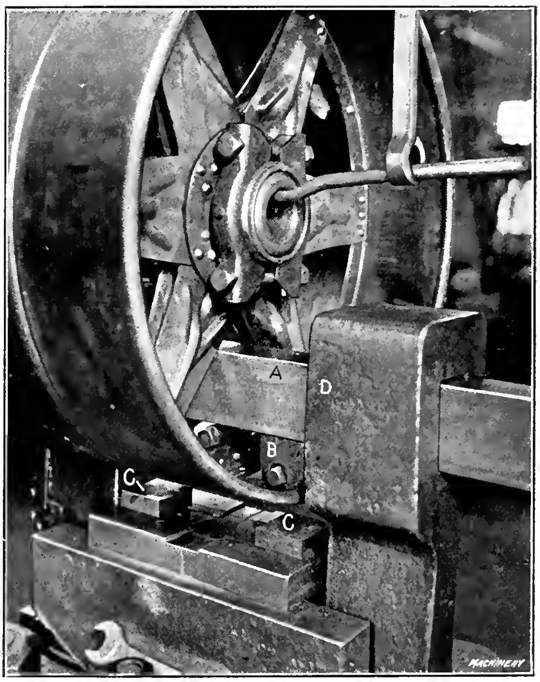

Fig. 14. Special Hydraulic Riveter for setting Rivets in Bolt Clamps at Rim Joint

special clamp tongs shown on the floor just in front of the stand. Most pulleys are very accurate, considering that the rim is not machined and that all the forming operations are effected by the use of dies.

After the accuracy test, the pulleys are tested for balance. In making this test, the pulley is mounted on an arbor and the latter is placed upon thin disk rollers of the testing stand shown in Fig. 16. These disks are free to revolve so that any unbalanced or heavy part of the pulley will turn to the

bottom. This balance test is very sensitive as a slight irregularity in the distribution of the weight will cause the pulley to turn. As the pulley rim is of uniform section, the balance is, in most cases, very accurate and the use of counterweights is unnecessary.

Crowning Pulley Rims

"American" pulleys are made with either straight, cylindrical rims or with "crowned" rims which slope away from the center. The crowning is done on sizes above 48 inches, after the pulley is assembled and riveted together. The hydraulic press for doing this work is shown in Fig. 17. This press is equipped with sectional dies *A* which fit into a tapering seat in the outer ring *B* which is attached to the lower platen *C*

Fig. 15. Stand for testing Accuracy of Finished Pulley

of the press. The dies are also tapered on the inside to conform to the crown or taper required for the pulley rim. The pulley *D* to be crowned is first drawn up against the top platen of the press and is held there by a wire cable *E* operated by an overhead electric hoist. The lower platen or plunger then moves upward and the crowning dies are forced

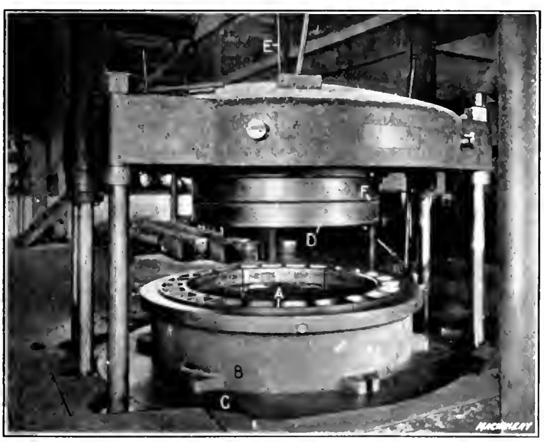

Fig. 17. Large Hydraulic Press and Dies used for crowning Pulley Rims

over the pulley, thus tapering one-half the rim. The platen is then lowered and the pulley is released by raising the sectional dies in their tapering seat. The opposite half is then crowned in the same way, the position of the pulley being reversed. Crowned rims are recommended for pulleys carrying non-shifting belts, and straight, cylindrical rims for belts that must be shifted.

The weight of one of these steel pulleys is about 45 per cent of the weight of a cast-iron pulley, and it is claimed that the strength is sufficient for any duty not so severe as to demand a special pulley. The annular groove *F* (Fig. 17) around the center of the rim face, formed by the curvature of the inner rim flanges, is said to greatly increase the efficiency of the pulley as a transmitter of power, owing to the fact that the air which is trapped between a rapidly moving belt and the pulley rim can escape through this groove, thus giving better belt contact.

* * *

CATALOGUE WASTE IN CENTRAL AMERICA

Special agent Garrard Harris writes that the waste of catalogues, trade circulars and form letters addressed to

Fig. 16. Stand for testing Balance of Pulley

merchants and business men of Central America, as well as other countries of Latin America, is enormous. Mails are loaded with beautiful catalogues that are works of art in every respect, exhibiting the most experienced thought and ability of experts. Most of the publications are illustrated and in the United States would prove valuable and effective

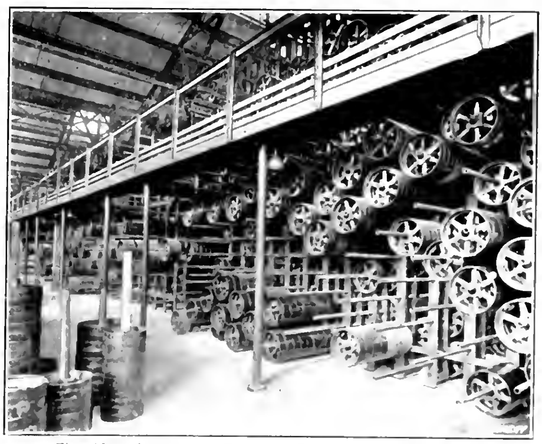

Fig. 18. View in Store-room of American Pulley Co.—Note Arrangement of Pulley Racks

trade getters. Yet in the Latin-American countries they are ineffective. Trade circular letters so prepared that a trained observer could hardly detect the mark of the mimeograph or the fact that each one was not an original personal letter also go to the waste basket. One reason is that all this trade literature is in English. Another is that Latin-American merchants prefer to do business with traveling men. Catalogues printed in Spanish, however, may be used effectively to introduce goods to the notice of possible buyers

THE CLEVELAND AUTOMATIC SCREW MACHINE—1*

DESIGN, CONSTRUCTION, OPERATION, TOOL EQUIPMENT AND ATTACHMENTS

BY DOUGLAS T. HAMILTON†

The Cleveland Automatic Machine Co., Cleveland, Ohio, made the first model of the Cleveland automatic screw machine in 1891. This machine is constructed on the single spindle principle and incorporates many interesting features in design, construction and operation. One feature which

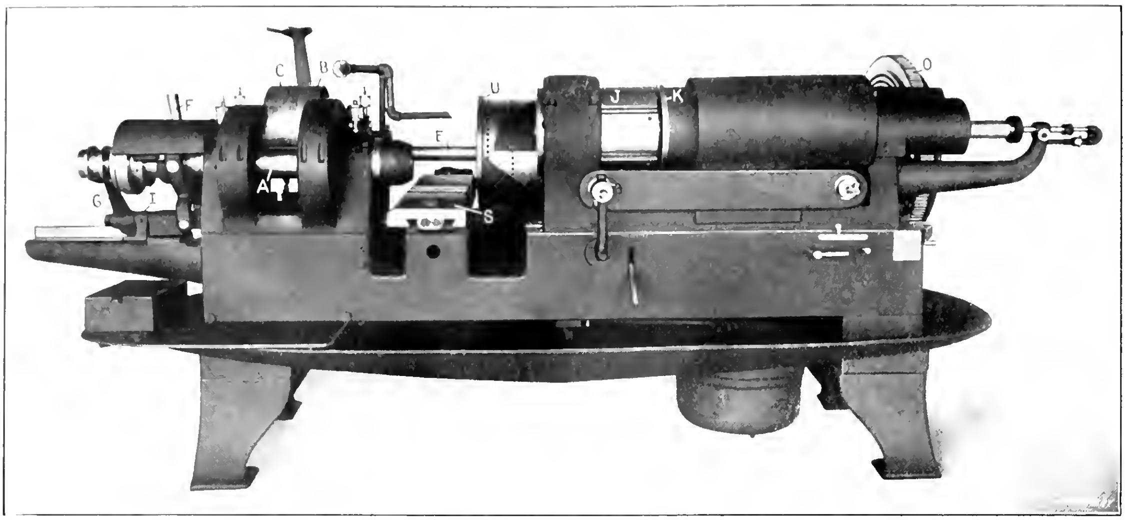

Fig. 1. Front View of $3\frac{1}{4}$-inch Cleveland Full Automatic Screw Machine

characterizes it is the method of obtaining the variation in the feed of the turret and cross-slide tools. A regulating drum on which adjustable strip cams are held is used for this purpose; these cams operate a bell-crank lever which shifts the position of a roll located between two driving friction disks and thus changes the speed of the driving shaft operating the turret through spur gears, an epicyclic train and a worm and worm-wheel. This mechanism provides for a wide

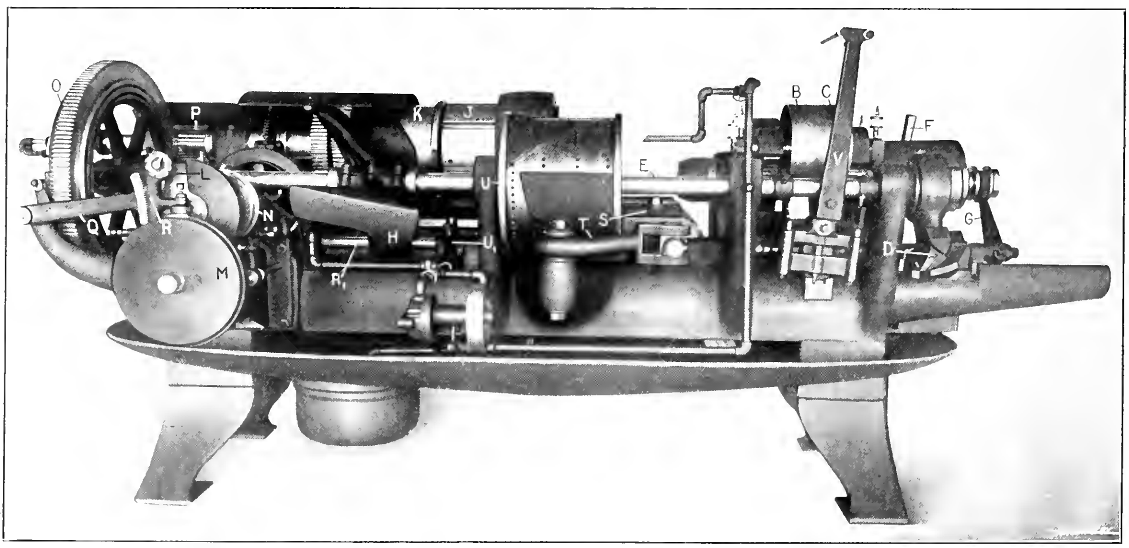

Fig. 2. Rear View of the Cleveland Full Automatic Screw Machine

range of feeds to the individual turret and cross-slide tools and can be regulated while the machine is in operation. The latest improved model of the Cleveland automatic screw machine is shown in Figs. 1, 2, 3 and 4, which present front, rear and end views, respectively, of the $3\frac{1}{4}$-inch full automatic turret type of machine.

Types of Cleveland Automatic Screw Machines

In addition to the full automatic type of machine shown in Figs. 1, 2, 3 and 4, which is known as model A and is built in sizes ranging in chuck capacities from $\frac{3}{8}$ inch to $7\frac{3}{4}$ inches, the Cleveland automatic is also built in several other types adapting it to a large range of work and variety of purposes. The full automatic machine is provided with a turret having five holes on sizes from $\frac{3}{8}$ inch to $2\frac{1}{4}$ inches inclusive, and six holes on the machines of greater capacities.

The next type of machine is the plain automatic known as model B. This machine has no turret but is provided with one tool spindle which can be used for holding a box-tool, drill or tools of a similar character. The range of this machine, however, can be greatly increased by the addition of simple attachments on the cross-slides and tool spindle. The model C machine is of the full automatic type and is half-way between models A and B. It is provided with only three holes in the turret and resembles model B in construction.

* For information on automatic screw machine practice previously published in MACHINERY see "Examples of Screw Machine 'Set-ups,'" November, 1913, and articles there referred to.

† Associate Editor of MACHINERY.

The type of machine known as model D is similar to model A, but is built to handle castings, forgings, etc., and hence is semi-automatic in its operation. The turret of this machine is provided with four holes and both the turret and spindle heads are adjustable along the bed. A modification of the plain machine is the double-spindle plain automatic which is provided with two opposing work-spindles located in a parallel line and with the chuck mechanism of both heads acting simultaneously. This machine is particularly adapted for finishing both ends of a piece of work, thus obviating the necessity of a second operation to complete the part.

Principles of Design and Operation

Before proceeding with the description of the construction of the Cleveland automatic screw machine, the general principles of operation will be briefly outlined. The following description given pertains particularly to the full automatic type of machine known as model A, as this machine incorporates all the principal points of design and operation common to this make of automatic screw machine. The work-spindle A, Fig. 1, is driven from the overhead countershaft through two pulleys B and C and three pinions (one being intermediate) and gears, two pinions being carried on the same shaft as the pulleys, one on an intermediate shaft, and the gears on the work-spindle. Pulleys B and C are separated by a loose pulley so that when the belt is thrown onto it no power is transmitted to the spindle. Pulleys B and C can be rotated both forward giving two speeds, or one forward and one reverse for threading. The chuck which is of the push type is operated by a sleeve that passes through the spindle and is actuated by adjustable cams held on the arm D, Fig. 2, located on the rear shaft E. Lever F is provided for opening and closing the chuck when setting up.

The feeding of the stock is accomplished by a feeding finger and tube passing through the work-spindle and operated by an arm G, see Figs. 2 and 3, which receives power through a rod R_1 actuated by the cam H. Variation in length of feed is accomplished by shifting the position of roll carrier U_1 along rod R_1. The turret J, which is of the drum type and is provided with holes for carrying six end-working tools, is mounted on a horizontal shaft located parallel with the spindle. It is operated back and forth by cams held on a separate drum K, which is rotated by spur gears, a worm and worm-wheel, epicyclic train and friction disks L and M; this mechanism receives power from a pulley N driven by a belt from the overhead works. The turret is indexed by a rod passing through the drum K which, when the turret moves back, comes in contact with pins held in its rear face, thus transmitting a rotary movement to the turret after the locking pin is withdrawn from the slots in its periphery by a cam held on drum K.

The feed given to the tools in the turret and on the cross-slides is governed by adjustable strip cams held on the regulating drum O, see Fig. 4, which is mounted on shaft E and rotated by a gear P held on the turret shaft. The cams on this drum operate a friction roll running between disks L and M through the medium of a bell-crank lever Q and rack arm R. The indexing of the turret is accomplished at a much higher speed than that used when cutting and this is effected by dogs carried on the regulating drum O which operate a tooth clutch, changing the drive direct to the pulley N instead of through the epicyclic train of gears mentioned.

The cross-slide which is a single casting S, carrying both the front and rear forming and cutting-off tools, is operated by a lever T. This lever receives its motion from cams held on drum U mounted on the rear shaft E. On the Cleveland automatic, as ordinarily equipped, the front and rear cutting tools cannot be operated independently, that is, they cannot be brought to work on the bar at the same time. However, for work which can be better handled in this way, a double cross-slide can be furnished as will be described later.

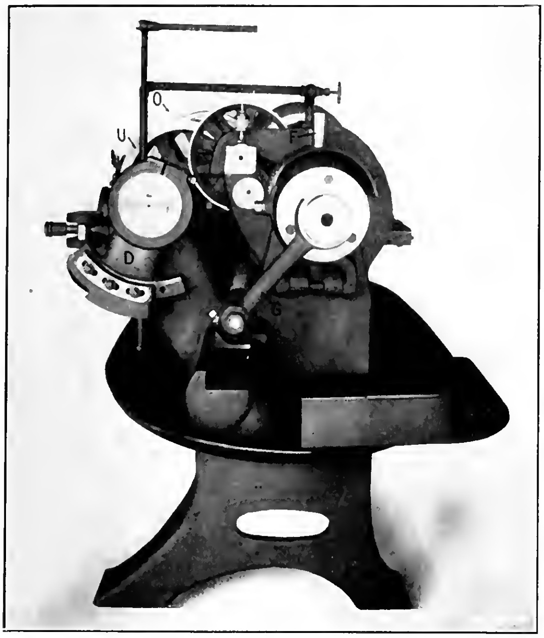

Fig. 3. End View of Cleveland Automatic showing Chuck Closing and Stock Feeding Mechanism

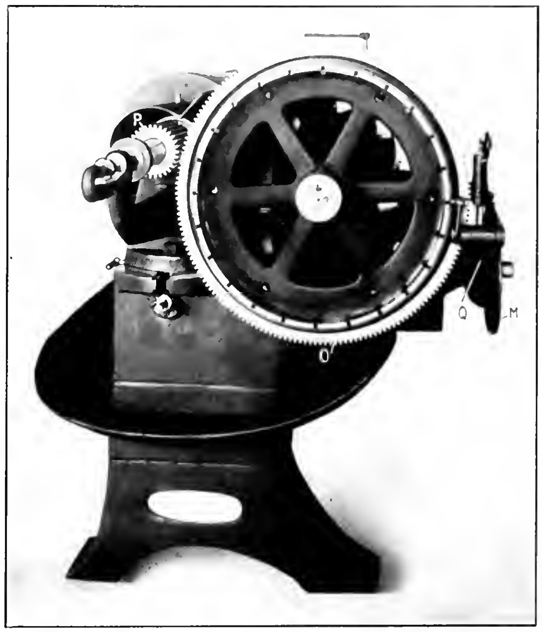

Fig. 4. End View of Cleveland Automatic showing Regulating Drum and Auxiliary Mechanism for changing Feed of Tools

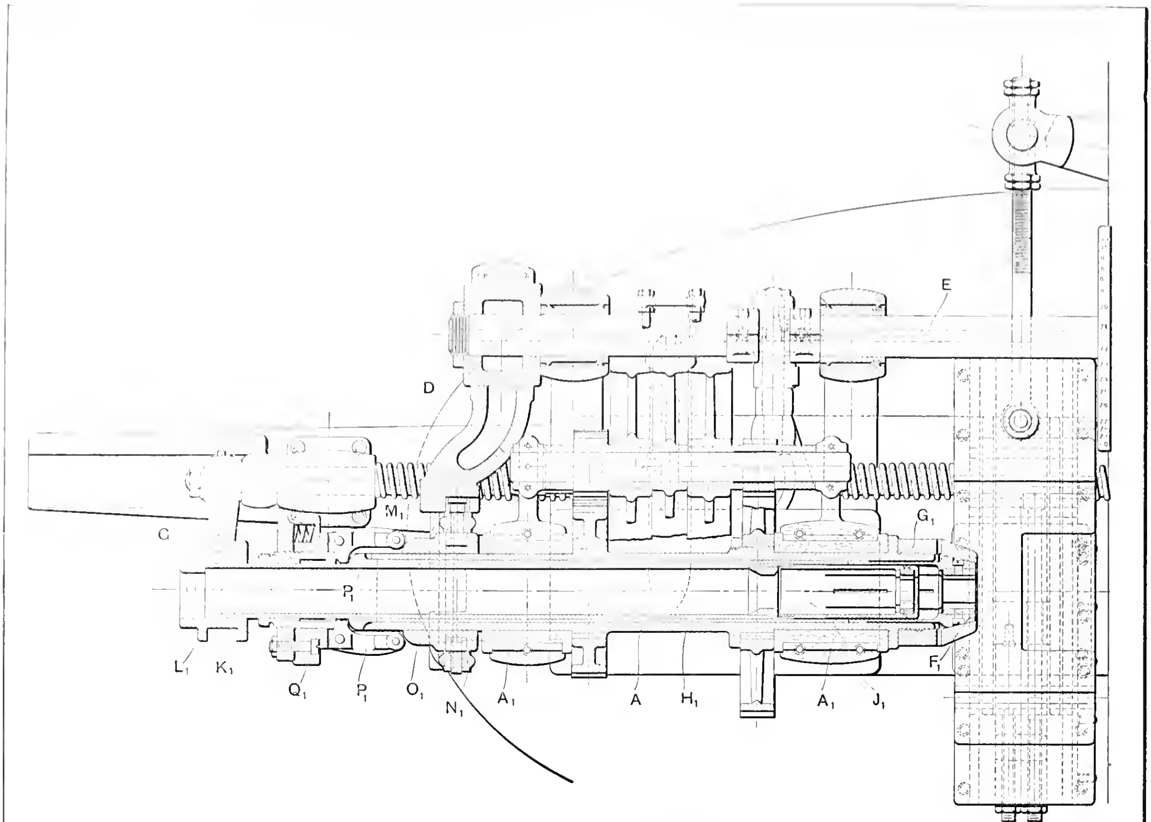
Construction and Operation of the Work-spindle

The work-spindle A is a 0.40 per cent carbon steel forging that rotates in special journal metal bearings A_1, see Figs. 5 and 6. With the standard type of drive the spindle is rotated forward by pulley B through a pinion B_1 and gear C_1. It is revolved backward by pulley C through pinion D_1, an intermediate pinion and gear E_1. There are several other types of drives employed for special purposes, as will be described in a subsequent article.

The shifting of the driving belt from one pulley to the other is accomplished by an ingenious positive-acting belt shifting device V, which is shown in detail in Fig. 7. This device consists primarily of a bracket a fastened to a boss on the machine and carrying a swinging member b fulcrumed on a pin carried in the bracket. The device is operated to shift the belt to the different pulleys by means of cam fingers I_1, see Fig. 8, which are carried on the rear shaft E and are adjustable. The fingers, as the shaft rotates, come in contact alternately with spring operated plungers c and d, depressing them, and through the medium of levers e withdraw the wedge f from the slots in plate g. When the wedge f is withdrawn from one slot in the plate, the shifter is thrown instantane-



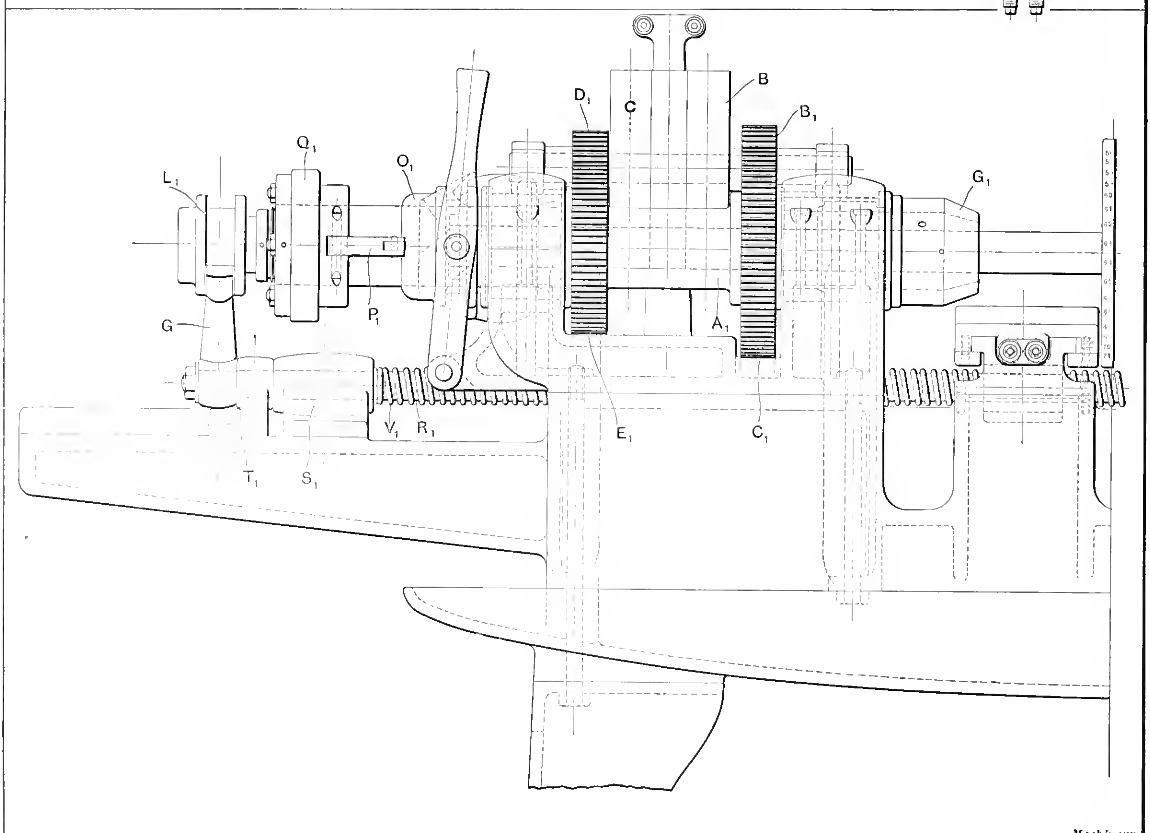


Fig. 5. Sectional Plan View showing Construction of Spindle, Spindle Driving Mechanism, Chuck Closing, Stock Feeding and Auxiliary Mechanism
Fig. 6. Front Elevation of Work-spindle End of Machine

ously into the next slot and thus shifts the belt or belts by means of the arm *h*. There are different combinations of these arms for the various types of belt drives and they can be easily changed by taking out the screw *i*. In Fig. 7, *h* is the arm and finger for the third speed drive, *j* for the double belt drive and *k* for the single belt drive.

Chuck Closing and Stock Feeding Mechanism

The chuck F_1, Fig. 5, which has a tapered nose, is of the push type and is held in the cap G_1 screwed onto the nose of the work-spindle. It is operated by a sleeve H_1 that receives power from the arm *D*. A detail of this arm is shown in Fig. 10, which illustrates its adjustable features. In addition to being split, enabling it to be clamped in any position on the shaft, this arm is provided with adjustable cams *m*, *n* and *o*. Here *m* is the chuck opening cam, *n* the safety cam and *o* the chuck closing cam which is cast integral with the arm *D*. Cams *m* and *n* comprise the same casting and are adjustable on the arm *D*, being held in the desired position by three clamping screws fitting in elongated slots. There are also additional tapped holes in the arm allowing for further adjustment.

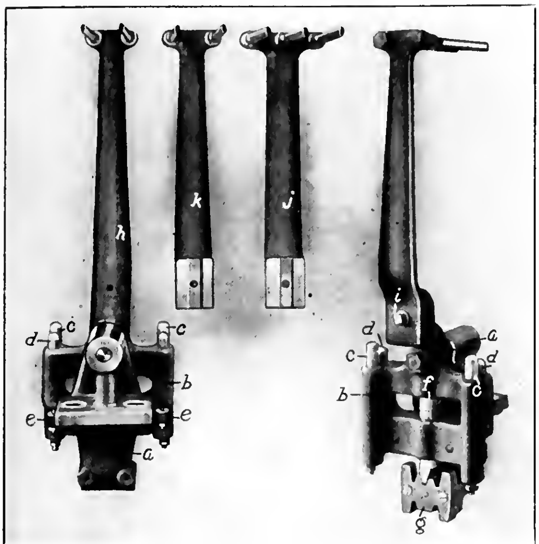

Fig. 7. Details of Positive-acting Belt Shifting Device

When smooth stock is being held in the chuck the adjustable cams *m* and *n* are set tightly up against cam *o*, thus giving a quick closing and opening action to the chuck and allowing a short space of time for feeding the stock. When rough bar stock is being handled, and for magazine work, it is necessary to keep the chuck open much longer; for this action the cams *m* and *n* are separated from cam *o* in order to allow sufficient time to handle the work successfully.

Fig. 10. Detail of Adjustable Cam Chuck Closing Segment

The action of closing the chuck is simple and is accomplished in the following manner: As arm *D* rotates, cam *m* comes in contact with a roll M_1, Fig. 5, held on the fulcrumed yoke N_1. This yoke, in turn, carries two rolls that work in a circular groove cut in sleeve O_1. As the cam forces this sleeve in a direction away from the chuck it acts upon two fingers P_1 provided with rolls at their outer ends, the rear ends of the fingers bearing against the rear end of the chuck closing sleeve H_1. This action forces the split chuck into the hood closing it on the work. As cam *o*, Fig. 10, comes into action, it reverses the operation of yoke O_1 and removes the pressure from the sleeve H_1, allowing the chuck to open, due to spring tension. Pressure bushing Q_1 acts as a medium for holding the fingers P_1 up on the collar O_1.

The bar stock is fed through the spindle by a spring finger J_1 screwed into the front end of the tube K_1, the rear end of which is provided with a grooved collar L_1. Fitting in this grooved collar is a forked lever *G* which is carried on the rod supported in brackets S_1 and T_1, the former being fastened to and the latter sliding on the base or extended bracket on

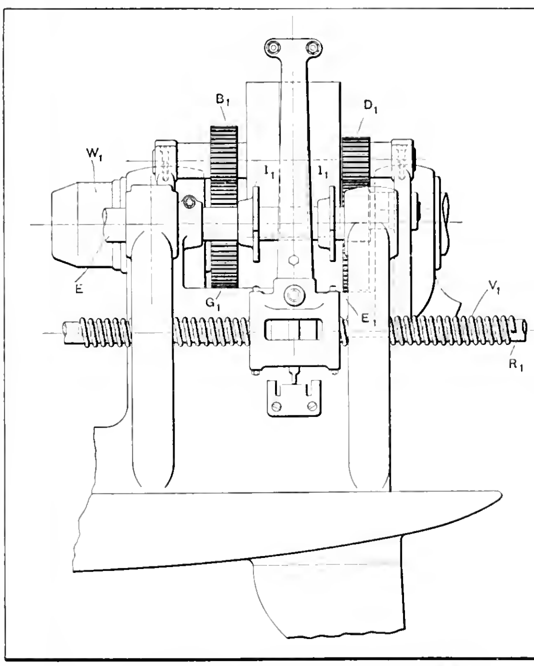

Fig. 8. Rear Elevation of Work-spindle End of Machine showing Drive and Belt Shifting Arrangement

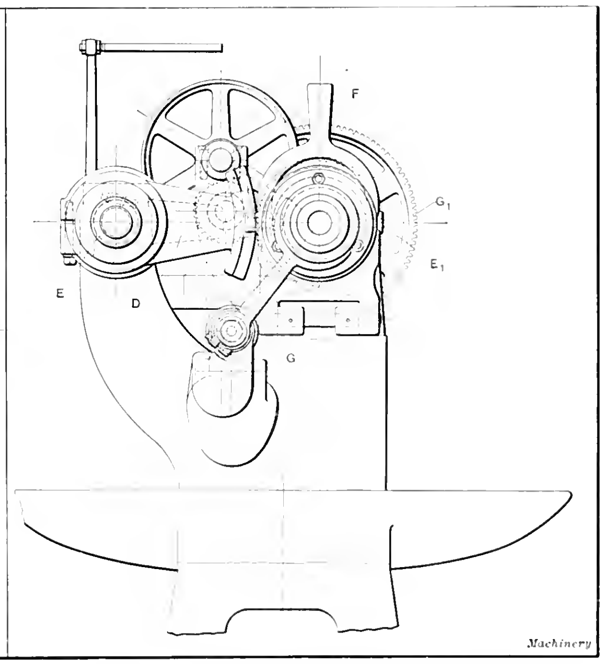

Fig. 9. End Elevation showing Chuck Closing and Stock Feeding Mechanism

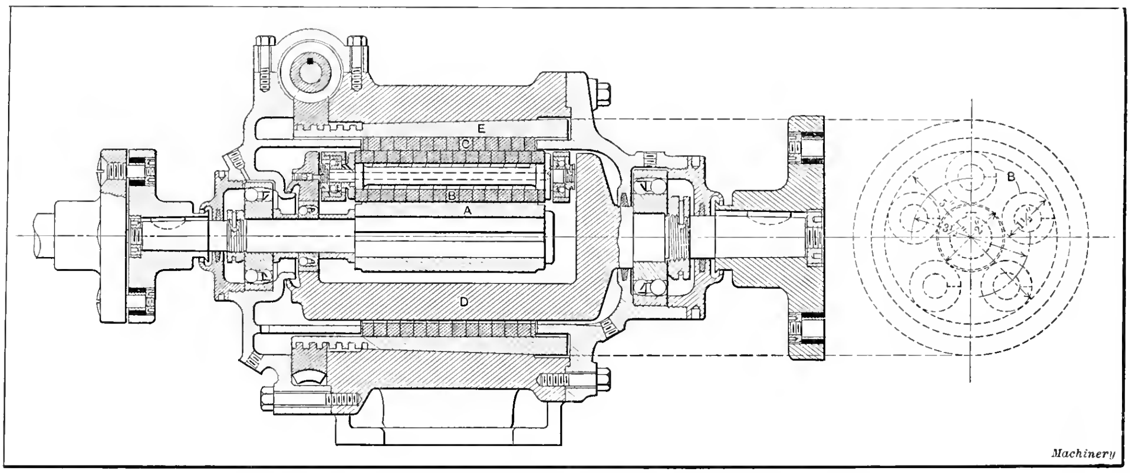
the machine. The movement of forked lever G is controlled by a cam H, Fig. 2, which contacts with a roll held on bracket U_1, clamped to rod R_1. Adjustment for length of feed is controlled by shifting the position of the bracket U_1 along rod R_1, and the timing is effected by shifting the cam H around the shaft E. An open wound coil spring V_1, Fig. 6, serves to keep the forked arm G and sliding bracket T_1 up against the stationary bracket S_1, when the rod R_1 is not acted upon by the cam. For double feeding, a drum is provided carrying two cams, allowing for feeding the stock twice for every revolution of the cam-shaft.

* * *

"FAST" SPEED REDUCING MECHANISM

The accompanying illustration shows a new type of high-speed "transformer" or speed reducing mechanism invented by Mr. Gustav Fast. As will be seen, this device is an application of the friction gear principle. The motion is transmitted from the cylindrical sleeve A on the high-speed shaft, to five rolls B (see end view) which are carried by housing D connected with the low-speed shaft.

The novel feature of this mechanism is that the frictional rolls B are flexible, being made in the form of a helical spring in order to insure an even contact between the inner and outer members A and C against which they bear as they revolve. The outer part C is also made in the form of a helical spring and it is enclosed by a sleeve E that is tapering on the outside. When this sleeve is drawn in by means of the threaded end and worm gearing shown, the diameter of the flexible track for the rollers is reduced. This construction is said to insure a perfectly cylindrical surface even when this flexible lining is contracted to its limit, which equals a reduction in diameter of 1/16 inch. By means of the adjusting worm gear, sufficient pressure can easily be obtained for any load within the capacity of the mechanism.



Sectional View of Speed-reducing Mechanism equipped with Flexible Frictional Rollers

The speed reduction of the particular design illustrated is in the ratio of 3½ to 1, but this type of speed reducer can be designed for ratios varying from 2½ to 1 up to 10 to 1. It is claimed that the transformer runs very smoothly and quietly at speeds even as high as 6000 revolutions per minute and that it makes considerably less noise than a steam turbine or an electric motor running at the same speed. The total weight of the machine is 218 pounds. The maximum power that a speed reducer of the type here shown is capable of transmitting at various speeds is as follows:

Speed of "High-speed" Shaft, R. P. M.	Horsepower Transmitted	Speed of "High-speed" Shaft, R. P. M.	Horsepower Transmitted
1000	11	4000	34
2000	21	5000	38
3000	28	6000	40

In the construction of this speed reducer, heat-treated vanadium steel proved to be an important factor in making the device efficient and practicable. The high wearing qualities of chrome-vanadium steel tires led the inventor to use vanadium steel in this transformer for the driving roller, the friction rollers and the flexible track or casing. After using the transformer six months, the parts showed practically no wear and the surfaces were very hard and smooth. The vanadium steel used was made by the Halcomb Steel Co., and it is the type D, 0.50 carbon chrome-vanadium steel.

The heat-treatment given these parts is as follows: All of them were quenched in oil at 1650 degrees F.; the driving roller was then drawn at 650 degrees F.; the friction rollers at 450 degrees F.; and the flexible track at 800 degrees F. It is claimed that the efficiency obtained with this mechanism has been as high as 99 per cent and that it has never dropped below 97 per cent for any kind of a load. The mechanism has been loaded to 100 per cent above its capacity for a continuous run of three hours without being injured.

NEW DEPARTURE IN ENGINEERING EDUCATION

An interesting educational experiment will be made this year at the College of Mechanical and Electrical Engineering of the State University of Kentucky, where the thesis of the students of the senior class will consist of a complete design with specifications for a 15,000 kilowatt power plant, not worked out individually by each student, but by the students as a group of engineers. A location will be definitely decided upon and the young men will visit the spot, making an actual preliminary survey and boring a few test holes. They will also investigate the water supply and the climatic conditions where the plant is to be located. After the preliminary work has been done, the class will be organized into an engineering body working in a class drafting-room like in a modern engineering establishment, with a regular eight-hour working day. It is stated that even a time clock will be installed and that regular attendance to duties will be enforced. One of the professors will act as chief draftsman, the man being selected to act in such capacity having had experience in the office of a large power plant designing firm.

This new departure in engineering education is worthy of commendation. It seems to place the engineering college on more practical ground and to make the transition stage between school and practical engineering work easier than has been the case in the past, when many graduates have entered practical work with little or no knowledge of actual engineering conditions.

* * *

According to the *London Times*, a bill will shortly be introduced in the French Chamber of Deputies making legal the division of the quadrant of a circle into 100 parts, or grades, each divided into 100 centesimal minutes, each of these, in turn, consisting of 100 centesimal seconds. According to this division a complete circle will have 400 grades, 40,000 minutes, or 4,000,000 seconds.

ELECTROPLATING ZINC ALLOY DIE CASTINGS

Difficulty has sometimes been experienced in electroplating zinc alloy die castings, although they can be electroplated as easily as iron or steel if the proper methods are followed. The following, which is from a booklet on this subject issued by the National Lead Co., New York City, contains some practical methods whereby die castings can be cleaned, polished and electroplated.

Cleaning and Polishing

Die castings that are to have a polished surface should be "cut down" with the usual buff wheels and tripoli composition. The finishing should be done with white compositions of Vienna lime. After the parts have been polished, the excess of polishing material should be removed by the aid of benzine or gasoline, and they should be dried in maple sawdust. If the benzine or gasoline is dispensed with, hot alkaline solutions should be used for cleansing. The strong alkalies of caustic soda or potassium should never be used in cleansing zinc, as they have a reducing action upon the metal and produce oxides, thus destroying the polished surface.

The solution should be maintained at a temperature of 160 to 180 degrees F. Soda ash may also be used for the purpose, one pound of this material and one-quarter ounce of cyanide of potassium being used per gallon of water.

The articles should remain in the cleansing bath for a few minutes and then the excess polishing material brushed away, using an oval painter's sash brush for the purpose; the rubber-set variety is the most economical. After cleansing, immerse in clean, cold water and then into a cyanide dip. This dip should consist of 6 ounces of cyanide of potassium or sodium to each gallon of water and should be used cold. After re-washing the articles in clean, cold water they are ready for the plating bath.

Articles to be unfinished are cleansed in the same manner, if somewhat corroded due to the formation of oxide of zinc on the surface by contact with moisture. Immerse for a few seconds in a pickle consisting of one part of hydrochloric acid and four parts of water (this will dissolve the oxide); then rinse the die castings in cold water, immerse in the cleaning solution for a few seconds, re-wash in cold water and scratch-brush to bring up the color of the metal. Repeat the cleaning operations, using only the cleaning solution and the cyanide dip; the casting is now ready for plating. If the articles are to have a polished finish, the scratch-brushing may be dispensed with.

Copper-plating Die Castings

The solution for copper-plating should have the following proportions:

Water	1 gallon
Cyanide of copper	3 ounces
Carbonate of potash	1 ounce
Cyanide of potassium or sodium	4 ounces

To prepare the solution, the potash and copper should be dissolved in half the amount of hot water, the cyanide in the balance of lukewarm water; then mix thoroughly together. Use the solution at a temperature of 150 degrees F. and at 2 to 2½ volts pressure. Cast copper anodes give the best results, but the electrolytic variety may be used.

Brass-plating Die Castings

Prepare a solution exactly the same as for the copper bath; then dissolve equal parts of cyanide of zinc and cyanide of potassium in warm water. An addition of 1 ounce of zinc carbonate and the same proportions of cyanide should be added to the copper bath per gallon; then add ½ ounce of sal ammoniac per gallon of solution. If the color should be too deep a yellow, a little more zinc should be added to the bath to obtain the required shade. This bath should be used at a temperature of 120 degrees F. and at 2 to 3 volts pressure. The cleansing of the articles should be done as previously stated.

Nickel-plating Die Castings

Much trouble has been experienced in nickel-plating die castings with the ordinary solution, due to black streaks appearing in the deposit caused by local action of the ordinary solution upon the metal. The following formulas will give satisfactory results without the difficulties mentioned:

Nickel sulphate	10½ ounces
Potassium citrate	7 ounces
Ammonium chloride	10½ ounces
Water	2½ gallons

To prepare this bath, dissolve the nickel sulphate and ammonium chloride in half the amount of hot water prescribed; then dissolve the potassium citrate in the balance of the water and mix thoroughly. The voltage should be 2½ to 3 volts. This bath should always be kept neutral to avoid black streaks. For this purpose pure caustic potash dissolved in water should be added to the bath so that the solution is neutral to the test of red or blue litmus paper.

The following bath is used extensively in plating articles made from zinc and gives excellent results:

Double nickel salts	8 ounces
Chloride of sodium	1 ounce
Magnesium sulphate	2 to 4 ounces
Water	1 gallon

To prepare the bath, dissolve the nickel salts in half of the water at a temperature of 180 degrees, and dissolve the other salts in the balance of cold water; then mix thoroughly together. Use this solution cold, with anodes of cast nickel. The voltage should be 2½ to 3½ volts. The articles to be nickel-plated may be plated direct or be lightly coated in the copper or brass baths prior to nickel-plating. The time of immersion in either of the nickel baths should be according to the thickness of the deposit required, although thirty minutes gives a fairly good deposit in either case.

Silver-plating Die Castings

Cyanide of silver	3 ounces
Cyanide of potassium	4 ounces
Water	1 gallon

Use anodes of pure silver at about 1 volt pressure. Die castings for silver-plating should be previously copper-plated for a short time then amalgamated in a mercury dip consisting of the following proportions:

Water	1 gallon
Oxide of mercury	½ ounce
Cyanide of potassium	6 ounces

After copper-plating and washing in water, the articles are immersed in the dip for a second or two, or until uniformly coated with mercury. They should then be re-washed and immersed in the silver bath. The articles may also be nickel-plated in one or the other of the nickel baths and then quickly coated in the silver striking solution, after which they should be directly immersed in the silver bath without rinsing.

The silver strike should be as follows:

Cyanide of silver	½ ounce
Cyanide of potassium	6 ounces
Water	1 gallon

Use silver anodes with 3 to 4 volts pressure. The nickel surface must be immediately coated over for successful silver deposits.

Gilding Die Castings

In gilding die castings the articles must be previously coated with brass or copper and have a bright luster. The following formula will give excellent results:

Phosphate of soda	8 ounces
Sulphate of soda	1½ ounce
Cyanide of sodium	6 pennyweights
Chloride of gold	6 pennyweights
Water	1 gallon

To prepare the solution dissolve the cyanide and chloride of gold in part of the hot water and the sodium salts in the balance; then mix together thoroughly. Anodes of gold, platinum or carbon may be used, and the bath should be kept at a temperature of 180 degrees F. at 2 volts pressure. If the articles are previously coated in the copper bath they should afterward be flashed in the brass bath to save an excess of gold.

The usual lacquers should be applied to brass, copper, silver or gold finishes. In plating die castings or articles of zinc, it is a distinct advantage to use as little free cyanide as possible. If this is reduced to a minimum, very little difficulty will be experienced in the blistering of the deposit. In nickel-plating, the baths should be maintained at the neutral point, as previously mentioned.

WORM HOBBING ATTACHMENT FOR AUTOMATIC SCREW MACHINES

DETAILS OF THE DESIGN OF THE ATTACHMENT AND METHOD OF MAKING THE HOB

BY B. F. ALEXANDER*

The Warner Instrument Co., Beloit, Wis., now incorporated under the name of the Stewart-Warner Speedometer Corporation, was the first to use an attachment on a National-Acme automatic screw machine for hobbing worm and spiral gears from blanks formed from bar stock on this machine. The first idea of making such an attachment is credited to Mr. A. B. Cadman, superintendent of the Beloit factory of the Stewart-Warner Speedometer Corporation, and formerly of the Warner Instrument Co. It has since been developed into many different types, the latest of which is the one described in this article. To show that these attachments are quite practical and not in any sense experimental, I might add that the first attachment that was made is still in actual service, having been used over a period of four years. During this period it has hobbed thousands of spiral gears.

The following describes a drop feed attachment—the first of its kind to be made—and a glance at Fig. 1 will give the reader an idea of the worm. It will readily be seen that the design of this worm is such that it could not be handled by

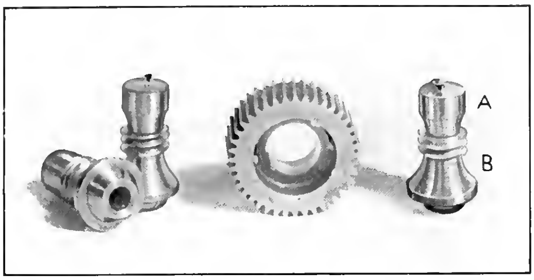

Fig. 1. Worm to be hobbed and the Hob

a circular hob fed longitudinally, and that is the reason a drop feed is used. By calculation, it was found that forty teeth would give a hob of the diameter that would clear the two high points on the worm blank, marked *A* and *B* in Fig. 1, and this number of teeth on the hob determines the entire gearing of the attachment. The worm being of the single threaded type, and the hob used to produce it having forty teeth, it follows that the worm must make forty revolutions to one revolution of the hob. Now then, the chucking spindle holding the worm blank must make forty revolutions to one revolution of the hob, which is driven by an extra shaft geared to the center spindle of the machine at the back or pulley end. Having the ratio given between the speed of the chucking spindle and the center spindle, which in this case is 29 to 36, the shaft *B* in Fig. 3 must revolve at the same speed as the chucking spindle. The 40 to 1 reduction is obtained through the worm on this shaft and the worm-wheel on the hob spindle. In Fig. 3, *D* shows the worm-wheel and *C* the worm keyed on the shaft *B*. On the No. 53 machine fitted up for this job, a 29-tooth pinion on the center spindle drives a 36-tooth gear on each chucking spindle. Therefore a 29-tooth pinion *A* is keyed on the center spindle on the back end of the machine and drives a 36-tooth gear *C* on the shaft *B* as shown in Fig. 4, with any idler *D* that conveniently meshes with the two gears *A* and *C*.

The Feed

The attachment is so designed that the hob starts hobbing the worm as soon as the forming tool begins to form the blank. Since the worm *C* and the worm-wheel *D*, Fig. 3, drive the hob at the required speed, and as their relative positions cannot be changed without altering the speed of the hob, it is evident that the center of the worm *C* must be the center about which the hob spindle oscillates. The worm can drive the worm-wheel *D* keyed on the hob spindle at the same speed in any position of the hob. The hob spindle is carried in bearings on an independent plate *H* which swings back and forth about the center of *C*, Figs. 3 and 5, on the surface of the casting *I* that is bolted down on the screw machine head. A cam *E* is mounted on the forming tool cross-slide to raise and lower the hob. An arm on the casting *H* has a roll *F* that fits in the cam *E*, and thus the raising of roll *F* by cam *E* lowers the hob and *vice versa.*

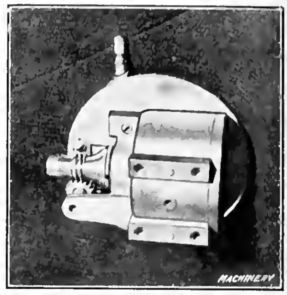

Fig. 2. Worm in Position on Case of Auto-meter

Fig. 6 shows the cam *E* more clearly. From *B* to *A*, the cam lets the hob drop quickly down to the surface of the worm, and this drop occurs when the cross-slide of the machine moves in quickly until the forming tool starts to cut. This action of the cross-slide reduces the time required to feed in by sliding in quickly to the point where the forming tool begins to cut. The tool then has more time to feed in and do the forming at a slower feed, thus producing a more perfectly finished blank. For this reason the cross-slide was selected to feed the hob on this attachment, and obtain the same action for the feed of the hob as for the feed of the forming tool. When the roller *F* has passed up the sharp incline *B*, Fig. 6, the cross-slide is just beginning to feed in slowly and the hob is just touching the blank; then the roller starts up the incline *A* at a slow speed, thus feeding the hob down into the blank to the required depth at a very slow feed. No spring or weight is required to lift the hob out of the hobbed worm, as the cam *C* performs this function by lifting the hob high enough to clear the machine's chucking spindle carrying the hobbed worm, allowing it to swing around a quarter of a revolution to its next position for the drilling operation.

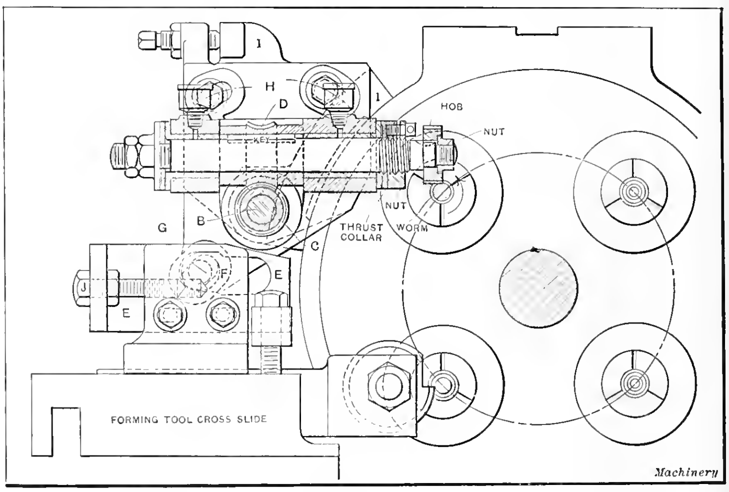

Fig. 3. Arrangement of Worm Hobbing Attachment on Automatic Screw Machine

Not being certain of the accuracy of the scaled dimensions of positions of the machine's parts and the outside diameter of the worm being subject to a change, the cam *E* was made adjustable. By sliding it in or out by the screw *J*, Fig. 3, various diameters of a 0.098-inch lead single threaded worm may be hobbed, providing that the variation does not amount to enough to change the spiral angle sufficiently to interfere

* Address: 1115 East Grand Ave., Beloit, Wis.

with the angle the teeth in the hob are cut on. However, considerable variation in the diameter of the worms to be hobbed can be taken care of. The face of the hob being flat and tangent to the worm, there is considerable clearance between the sides of the teeth on the hob and the sides of the threads on the worm in back of the cutting surface of the hob. This clearance increases as the curvature of the worm gets farther from the toothed face of the hob. This is evident, in that the teeth get narrower at the top, and the space between becomes wider.

The hob spindle is made adjustable to compensate for the regrinding of the hob. By loosening the nuts on the back end of the spindle from the steel thrust collar, the clearance may be taken up by tightening the lock-nut on the hob end, thus pulling the spindle forward. The key for the worm-

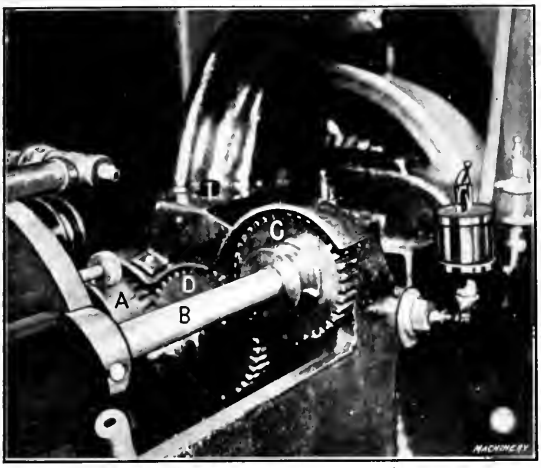

Fig. 4. Arrangement of the Gearing

wheel is solid in the spindle and has ample room between the bearings to allow it to slide in the worm-wheel either way. The spindle runs in hardened steel bushings, the back bushing being clamped in the casting *H* while the front bushing is pressed in. The back bushing is clamped in place because in changing the spindle or taking it down for repairs, this bushing must be readily withdrawn to permit the key in the spindle to be drawn through the bearing boss.

The Making of the Hob

To make the generating hob another hob is required to cut the teeth with, this hob being similar to the one used in hobbing a worm-wheel. In fact, the relation between these two hobs is the same as between a worm and worm-

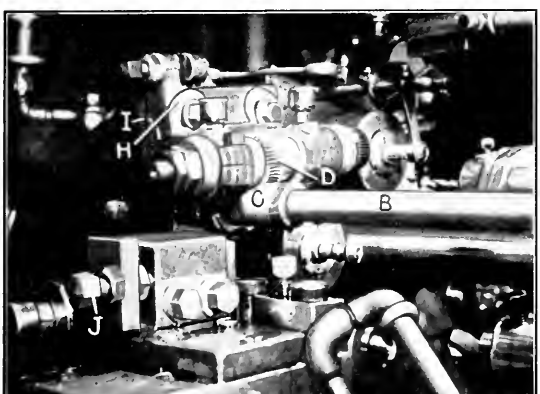

Fig. 5. Hobbing Attachment in Place on Automatic Screw Machine

wheel. This hob for producing the teeth in the generating hob used on the fixture is made to the same dimensions as the worm to be hobbed. It is thus evident that the generating hob will reproduce a worm of the same form of thread as that of the hob that produced the teeth in it. We have, however, a slight exception in this case, in that the hob takes a drop cut in the worm blank, thereby leaving a curve on the threaded length of worm with a radius equal to half the diameter of the hob—in other words, producing a worm somewhat of the Hindley form. No advantage in this shape of worm is gained, however, as the worm-wheel driven by the worm is much smaller in diameter than the generating hob.

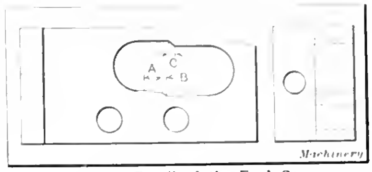

Fig. 6. Detail of the Feed Cam

Fig. 9 shows the worm shaped hob for producing the teeth in the generating hob. It is made up with a standard taper shank to fit the milling machine spindle, and is very substantial at the hob-end to prevent any vibration or spring, although the center may be used when the tool is in operation, thus eliminating all chance of chatter. The threaded length of the hob must be the same as for a hob used for hobbing a worm-wheel of the same dimensions as the generating hob. In other words, if the threaded length of the hob were shorter than the length engaged by the teeth in the generating hob, good results would not be obtained. The thread was cut in a lathe with a 29-degree formed tool, the lead of the thread being 0.098 inch and the depth 0.068 inch. The thread is single, the same as the finished worm. After the thread was cut, the hob was fluted and the top of the teeth and the bottom of the spaces relieved by hand. It was then hardened and tempered. The next step was to make a gashing cutter to gash the generating hob blanks with. This cutter is circular and is of the 29-degree form—

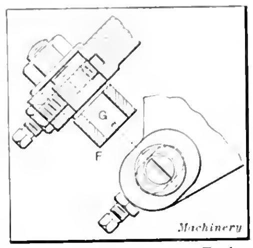

Fig. 7. Detail of the Feed Roller and Arm

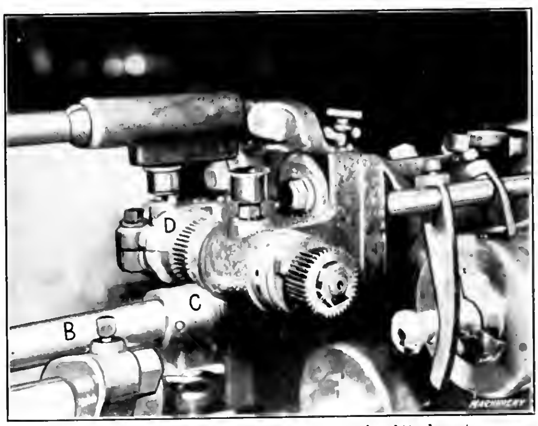

Fig. 8. View of the Hob in place on the Attachment

14 degrees, 30 minutes on a side—with the calculated width of face. Teeth were cut and relieved in it and the cutter was then hardened and tempered ready to gash the blank.

Having the hob and gashing cutter made, we may go ahead and make the generating hob blank. The finished piece is to have forty teeth and the circular pitch is the same as the lead of the worm. The pitch diameter can be found by calculation, but the outside diameter cannot be determined by the calculation used in finding the throat diameter of a worm-wheel of 40 teeth and 0.098 inch circular pitch. This is due to the fact that the dedendum of the worm must be added twice to the pitch diameter of the hob to obtain the outside diameter. In brief, the dedendum of the worm is the addendum of the hob. The hob is designed to stand considerable regrinding. It will therefore "stand up" comparatively long and hob thousands of worms before it must be discarded. Stock is left on to grind by, making the toothed face wider than the length of the spindle bearing

through the center. The difference of the two widths equals the amount that may be ground off before the hob must be discarded. In this case 3/16 inch was left on the flat face to be ground. The toothed face is 9/16 inch wide and the length of the spindle bearing in the center ⅜ inch, thus leaving a counterbore 3/16 inch deep and large enough in diameter to clear the flanged nut that holds the hob on the spindle.

The grinding of the hob after the edges of the teeth have become dull is a very simple matter. Simply lay the hob flat on a magnetic chuck on a surface grinder, with the cutting side up, and grind across the surface. About 0.002 to 0.005 inch is generally sufficient stock to grind off; this will sharpen the cutting edges of the teeth and the hob will be as efficient as ever. A good feature of this method of grinding is that the two faces of the hob are always parallel after grinding; consequently the cutting edge runs true with the spindle. It must be clearly understood that the toothed face has no clearance, being made parallel with the spindle hole in the center. Otherwise the grinding would be a detriment, as the hob would be smaller in diameter after each grinding, and would, therefore, require readjustment of the hobbing fixture. Clearance on the face would also complicate the cutting of the teeth of the hob with the equipment of an ordinary tool-room. I doubt if it could be done successfully. However, it is not necessary, and not enough advantage would be obtained to balance the extra expense and trouble in making a hob of this type. I might add that the Stewart-Warner Speedometer Corporation grinds all hobs of this type on magnetic chucks and has not yet experienced any serious trouble from the hobs becoming magnetized from the chucks.

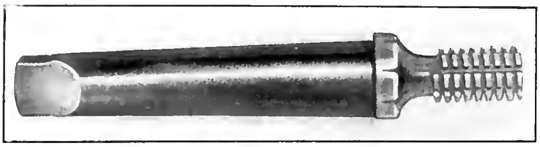

Fig. 9. Worm-shaped Hob for producing the Teeth in the Generating Hob

The gashing of the blank can be done by the usual method employed for gashing worm-wheels with flat faces. This consists of moving the table of the milling machine around to the required gashing angle and feeding the blank across the gashing cutter. When greater accuracy is required, this company employs a different method, as given in the following: Put a plate under the index head, leaving the table set at zero, and swing the plate with the index head around to the required angle. This arrangement allows the table to be fed across in the same plane as the gashing cutter. If the gashing is done by swinging the table around, the blank is fed against the cutter on an angle, thereby getting a gash that is not of the same form as that of the gashing cutter. It must be understood that the face of this hob is flat and not concave, and that it has to be gashed across the entire face at the same depth.

After the blank has been gashed, the index head is set back on the table in its usual position, and the gashed blank placed on an arbor and set up between centers so it can turn freely without any end-play. Put the hob for cutting the teeth in the spindle, raise the blank up to it and enter for the full depth of teeth; then feed across the hob. It is understood, of course, that the worm-hob carries the gashed blank around, similarly to the way a worm carries a worm-wheel around. A mark should be scratched on the blank, so that every time the blank has made one revolution the table can be fed in about 0.020 inch. This method gives a tooth of uniform shape across the entire face. All that is now left to be done is to harden the hob and temper it. It is then ground on the flat cutting surface, ready for use.

* * *

It is stated that liquid air can be produced at the rate of from 3 to 8.5 cubic inches per horsepower hour, according to the apparatus and arrangements employed.

SLIDING ACTION IN BALL BEARINGS

BY M. TERRY*

The popular impression regarding ball bearings is that in order to secure rolling contact, the contact points of the balls on the races should be points on a cone of rotation, the apex of which lies in the center line of the shaft, or that they should be points on the surface of an imaginary cylinder, the elements of which are parallel to the center line of the shaft. These purely geometrical considerations constitute a very elementary analysis, and when our theory is extended to embrace a few laws of mechanics and elasticity of materials, it becomes apparent that there is, perhaps, no such thing as pure rolling action, but only an approach to it; and—other things being equal—the degree of approach to the true rolling action determines the quality of the bearing.

Cup and Cone Bearing

Fig. 1 shows a cup and cone type of bearing with points of contact a satisfying the geometrical requirements. A point may be considered as an area of a circle of an infinitesimal diameter. If the load be applied and the points of contact are to remain mere points we shall have the condition of a measurable load distributed over an infinitesimal area which would result in an infinite stress per square inch. Such a condition is, of course, impossible, and deformation of balls and races will take place with the points of contact gradually widening into measurable areas of contact—probably circular or elliptical in shape.

In Fig. 1, b and c are the limiting points of contact, and whether the line bac be a straight line or a curve, the symmetry of the design suggests that points b and c are equally distant from the axis of rotation of the ball. The ball has a motion similar to that of the earth, *i. e.*, it revolves in an orbit determined by the inner and outer races and at the same time it rotates about its own axis. Assuming that in completing one revolution about the axis of the shaft the ball makes N rotations about its own axis $x—x$ and that there is absolutely no sliding, we can write the following equations:

$$2\pi rN = 2\pi R_1; \text{ and } 2\pi rN = 2\pi R_2.$$

Therefore R_1 should be equal to R_2, which in this type of bearing is a constructive impossibility, and hence sliding proportional to the difference between R_1 and R_2 must take place. Similar sliding action also occurs on the inner race.

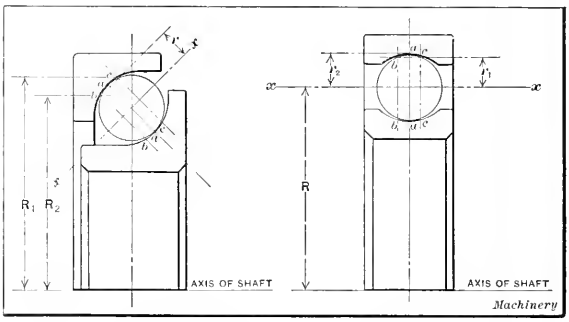

Fig. 1. Cone and Cup Bearing   Fig. 2. Radial Bearing

Radial Bearing

Fig. 2 shows a radial bearing under load. If the lines of contact bac were straight lines, pure rolling action would be possible, but as a rule lines bac are curves the radius of curvature of which increases with the size of the ball. The amount of sliding in this type of bearing depends largely on the ratio $\frac{r_1}{r_2}$; the closer this ratio approaches the value of unity, the less is the sliding action. Let N, as before, represent the number of rotations made by the ball about its own axis while revolving once about the axis of the shaft. Then, from Fig. 2 and assuming pure rolling of points b and a on the outer race, we have:

$$2\pi r_1 N = 2\pi\,(R + r_1) \quad (1)$$

and

$$2\pi r_2 N = 2\pi\,(R + r_2) \quad (2)$$

* Address: 1063 Manning St., Flint, Mich

Dividing (1) by (2) we obtain:

$$\frac{r_1}{r_2} = \frac{R + r_1}{R + r_2} \qquad (3)$$

This condition of equality can occur only when either $R = 0$ or $r_1 = r_2$. The first is a practical impossibility; the second can be only approached by a good design, fine workmanship, careful selection of materials and their proper treatment. It should be observed that

$$\frac{r_1}{r_2} < 1, \text{ and } \frac{R + r_1}{R + r_2} \text{ is also less than unity.}$$

Applying the same analysis to the inner race we find that for true rolling action

$$\frac{r_1}{r_2} = \frac{R - r_1}{R - r_2} \qquad (4)$$

Since r_1 is less than r_2, we have in practice:

$$\frac{r_1}{r_2} < 1, \text{ but } \frac{R - r_1}{R - r_2} > 1.$$

Thus the greatest amount of sliding occurs on the inner race. In practice r_1 approaches r_2 so closely as to make the amount of sliding almost nil.

Now, to compare the bearings illustrated in Figs. 1 and 2, let us assume workmanship, materials, etc., equally good in both bearings. Then, for the same amount of distortion of the ball the sliding action in Fig. 1 is proportional to $R_1 - R_2$, which is a fairly appreciable quantity, whereas in Fig. 2 it is proportional to $(R + r_2) - (R + r_1)$ or $r_2 - r_1$, which is almost negligible in amount. Thus, so far as sliding action is concerned, the radial type of bearing possesses a great inherent advantage over the cup and cone type, due entirely to the location of the points of contact, whereas a simple geometrical analysis would place the two bearings on a par. There are, of course, other points of difference between the two bearings, but they have nothing to do with either rolling or sliding.

* * *

EXPERIMENTS ON ROPE DRIVING

Very extensive experiments have recently been conducted under the auspices of the Society of German Engineers at the Charlottenburg laboratory. These researches cover a wide field, and of especial interest are those which relate to the influence of velocity. The efficiency in per cent is given under various tensions, showing a considerable decline at low loads. With a tension of 286 pounds in a rope of two-inch diameter, which is somewhat below the tension of 200 pounds per square inch commonly employed in calculations, the efficiency is 98 per cent at 2540 feet per minute and 96 per cent at velocities of 7680 feet per minute. These experiments conform so nearly with discoveries which were made many years ago as to make it fairly certain that with a properly designed installation and with a good grade of cotton rope the high point of efficiency, which by many tables is indicated to be at from 4500 to 4800 feet per minute, may be moved a considerable distance beyond these figures. They also indicate that rope drives can be used to advantage at much higher speeds. Another matter definitely established by the Charlottenburg tests is that idler or jockey pulleys produce a marked loss in efficiency.

The evidence from actual experience, as well as from tests, indicates that it is safe to use proper installations of rope drives up to 7000 feet per minute, and that the power up to this speed will be approximately in direct ratio to the increase in speed. As an example, it may be mentioned that nine ropes of two-inch diameter are regularly conveying a normal load of 880 horsepower at 7200 feet per minute in a large steel works in Germany. This is double the amount allowed by many tables in which too much allowance was made for centrifugal force by the compilers. It therefore would appear that the high speed permissible with rope drives is not limited so much by the rope efficiency and endurance, as by the material in the pulleys being able to resist the centrifugal stresses.

AUTOGENOUS WELDING OR AUTOGENOUS SOLDERING

In a paper read before a recent meeting of the Engineers and Shipbuilders of Scotland Mr. C. B. Desch compared the process of autogenous welding with that of other processes for joining metals. The following paragraphs contain a summary of the remarks made by Mr. Desch. As will be noted, an interesting distinction is made between welding and autogenous soldering, the latter name being preferred by the author of the paper. The term "welding," it was stated, is now somewhat loosely applied. It meant originally the union of two pieces of metal within their plastic range, but below their melting-point, as in an ordinary blacksmith's forge weld. It is now applied, in the term "autogenous welding," to denote a process of union by fusion, either of a part of the metal to be united or of a separate piece of metal used as a solder. Such a process is really autogenous soldering, not welding.

The ideal condition to be reached in a weld is that in which the crystals are continuous from one side of the weld to the other, with no change in the average dimensions of the crystal grains in passing through the weld. This condition requires the complete absence of intervening layers of impurities, especially of oxides, and also the absence of a zone of overheated metal. In true welding, which can take place at as low a temperature as 1150 degrees F., but which, of course, proceeds with much more rapidity and certainty at higher temperatures, there is mutual interpenetration, and, if oxidation is completely prevented, there is no reason why the weld should be weaker than the remainder of the metal. In practice, the weakness so frequently observed is due to incomplete union, readily seen under the microscope. The conditions are somewhat different when any of the high-temperature methods of autogenous soldering are applied. In electric resistance welds, the presence of oxide may be clearly traced along the plane of union, and a zone of very coarse crystallization is obtained.

The process of autogenous soldering with a blow-pipe flame introduces new conditions. Should the flame contain an excess of oxygen, oxide films are produced; with acetylene in excess, a carburized layer may be formed. In either case the joint is bordered by a zone of coarse, over-heated metal. In welding by a carbon arc, local carbonization is still more likely to take place, and the union is often extremely local. There remains the process of thermit welding, in which the two pieces of steel are united by a layer of almost pure molten iron, which alloys perfectly with the adjoining metal. Here, also recrystallization goes on in the immediate neighborhood of the joint, but to a less extent.

The evil effect of overheating may be largely overcome by hammering or forging the weld, followed by a short annealing process. Annealing alone is not usually successful. Imperfect union through the presence of gas cavities or inclusions of slag or oxide, and heterogeneity due to a highly carburized zone, are defects which are not removed by subsequent treatment.

It is not the intention to suggest that autogenous soldering is a process to be condemned. On the contrary, it has a wide field of usefulness, and is, in fact, a necessity for certain classes of work. It must be admitted, however, that a joint made in this way has not the same qualities as the original steel. It is not sufficient to show that fracture does not commonly take place in the plane of union when a mechanical test is made. It is not the weld, but the zone immediately near it, which is injured. Neither are tensile tests conclusive on this point, as the injury to the steel does not always affect the tensile breaking strength, but is revealed when the welded steel is subjected to shock or fatigue. Accounts have been published of boilers which have cracked in places in the course of use, after being repaired by autogenous soldering. When it is intended to use the same pressure as before, and to regard the plates as retaining their original strength, such a practice seems very undesirable. A systematic series of fatigue tests on such repaired plates would be interesting and valuable.

THE "FIVE BROTHERS"

Typhoid fever increases the weight of a patient, if he recovers from that malady; and a somewhat similar effect may be produced on the business of this country by the flood of legislation which has been recently enacted. A considerable number of these laws are good and should work out beneficially for the country. The trusts and big corporations have been curbed, which most of them needed; but we have reached the time when working people, among whom may be classed a good many machinery manufacturers, are anxious to saw wood again. Probably only a small number of the readers of MACHINERY are familiar with the legislation known as the "Five Brothers," kin in name only to the "Seven Sisters," a series of bills passed by the New Jersey legislature while President Wilson was governor of that state.

Some of the "Five Brothers" will accomplish desired reforms, and others will interfere with legitimate business, including the machinery business; although recent reports from Washington indicate that several objectionable features will be omitted or changed. One, which at this writing still stands, would prevent a manufacturer from giving his exclusive agency to a dealer and protecting that dealer in his territory so that he can educate his men on the mechanical and selling points of a machine and safely assume the expense of working up a sale. Another clause requires a manufacturer to sell his product at the same price (allowing for freight) in all parts of the country, making him liable if a dealer or agent should grant any concession from the price, such as taking a second-hand tool in part payment. A law of this character might be welcomed by manufacturers if they were allowed to make an agreement for the maintenance of prices with each other and with their agents; but such an agreement would throw them into the clutches of the Sherman law, which expressly prohibits it. These provisions were doubtless intended to prevent discrimination against competitors by trusts and powerful combinations, but some other way should be discovered to accomplish this object that will not harass legitimate manufacturers.

* * *

THE SPIRAL BEVEL GEAR

The development of the spiral bevel gear generating machine primarily for automobile manufacture will probably lead to the use of this type of gearing in other machinery. The spiral bevel gear has the same characteristic as the spiral spur gear as regards smoothness of action. The double spiral or herringbone gear is being used extensively now in machine construction, because of its efficiency and noiselessness. Improved machinery that produces this type in one piece has reduced the cost so that its use is feasible where once it was out of the question.

The spiral bevel gear made by the generating process is nearly noiseless, and when designed for drive in one direction only can be made highly efficient. This high efficiency is partly due to the spiral form of tooth, the inward thrust of which balances the outward thrust because of the pressure angle and angle of face.

The spiral bevel gear may be used in preference to ordinary spiral or helical gears for right angle drives, first because the shafts are in the same plane, and second because of the practical absence of thrust. Whether they will show as high efficiency as the best worm-gears of the same velocity ratio remains to be seen, but probably they will. The matter of lubrication is not so important as with worm-gears, and when there is doubt of the ability to lubricate properly, the spiral bevel type will be at a decided advantage.

* * *

THE STATUS OF GEAR GRINDING

The improvements in automobile design and construction have led to demands for gear durability and accuracy far exceeding anything that had been previously required of gear makers. They soon found that gears made by old-time methods from the ordinary grades of steel would not meet the close limits of accuracy and the physical tests imposed. When it was found that gears hardened by the time-honored methods were sprung out of shape, the natural remedy was to grind the teeth after hardening and thus restore them to true shape. Several gear-grinding machines were built and put into use, but with varying degrees of success.

While the grinding of spur gears is being done, the grinding of bevel gears for rear axle drives is now believed to be unnecessary. The improvements made in steel and in the design of bevel ring gears have produced a practically non-changing shape when hardened in machines provided for holding the gears between plates when dipped. The saving of time and labor is so great and the results are so uniformly satisfactory that the grinding of bevel gears has been abandoned by at least one large concern which had designed and built a machine for the purpose at heavy cost.

There is, however, a field for gear-grinding machines of some importance outside of the automobile industry. Cast spur and bevel gears can be made true and smooth by grinding at small cost, and in the case of cast steel gears used on electric railway motors, the cost is well repaid.

* * *

SPECIALIZED MACHINE TOOL BUILDING

The demands of the large automobile builders for special machine tools will apparently have a marked effect on the trend of American machine tool design within the next few years. Machine tools will be graded in three general classes: First, there will be the adaptable machine tool used in jobbing shops for all kinds of repair work and machine building. These tools will comprise the present types of engine lathes, planers, drilling machines, shapers, milling machines, gear-cutting machines, grinding machines and slotting machines. Second, there will be the more specialized machines, adaptable, it is true, but better suited for manufacturing than jobbing work which may give a dozen different kinds of work to a machine in a week. These machines will comprise the automatic screw machines, semi-automatic chucking lathes, automatic gear-cutters, bevel gear generators, hobbing machines, multiple-spindle drilling machines and broaching machines. Third, there will be purely specialized machines designed and built solely for the rapid production of machine parts of a given size, shape and material. These machines will be built around the past, as it were. The designer will study the part, and design a machine to produce it at the least possible cost of time and labor. Drilling machines that drill forty or fifty holes in four motor cylinders *en bloc* in several directions simultaneously are examples.

ETHICS OF CONTRIBUTING

The position of the editor of a technical journal like MACHINERY as regards publicity of methods, tools and processes is difficult to fill with satisfaction to all classes of readers. The ambitious mechanic wants to learn all about the methods and tools used in the most up-to-date manufacturing plants. The manufacturers, on the other hand, in some cases believe that it is distinctly to their disadvantage to have descriptions of up-to-date methods published. To steer a course that will avoid the objections of the manufacturers on the one hand without disregarding the wants of the ambitious readers on the other, is not always easy.

A letter was recently received from a prominent manufacturer referring to a contribution describing an improved trimming and shaving die. This contribution appeared to the editor to be only one of many good articles published describing improved punch and die equipment, but to the manufacturer whose practice was shown, the publication was a serious, if not a vital matter. He wrote as follows:

> We call your attention to an article by —— ————. This man was formerly employed by us as a toolmaker and had nothing whatever to do with designing the dies which he described. On the contrary, he simply worked to drawings made by our designers, and under the supervision of experts in our tool department. You will therefore understand how this article has been published without our consent, and that the drawings, which are the property of this company, have without doubt been copied and carried away by the writer of the article. You are doubtless aware of the fact that manufacturing methods and the designs of tools and fixtures are very often the result of long study and particular investigation, involving a large expenditure of time and money, and that information of this character must therefore be considered as a valuable asset and as such be carefully guarded and given out only through the proper channels. While we do not wish to imply that you would publish articles of this character were you aware of all the facts, nevertheless, you must agree with us that great injustice might be done to the rightful owners of designs, tools and fixtures if they were given publicity through the medium of trade journals. To our minds this raises a serious question and we shall be pleased to have you advise us whether you do not feel that careful inquiry should be made when an article is offered to you for publication to determine whether your correspondent has a right to use the information which forms the subject of the article.

To one familiar with the editing and publication of a technical journal it would be obviously impracticable for the editor to inquire closely into the antecedents of all contributors and contributions. We must rely on the honesty and good intentions of our contributors in general. MACHINERY is not a market for "stolen goods"; and most, if not all, contributors realize it. But what constitutes stolen goods in toolmaking practice? A toolmaker surely has the right to carry away with him from any plant where he has been employed good ideas in toolmaking, etc. His new employers have a right to expect that years of experience have given him knowledge of the best practice. How is it better for such a toolmaker to give to a competitor the best ideas he has gleaned from his experience than to publish them in a trade journal? In the case under discussion, the contributor probably did not consider that the design was in any sense proprietary, but only a development of punch and die practice right up to the minute. A history of this particular tool would undoubtedly show that hundreds of workmen and various plants had contributed ideas and resources which made its ultimate development possible. This seems to us to be a case where the editor must absolutely depend on the good faith of the contributor for the proper protection of "vested rights."

* * *

The Supreme Court handed down a decision February 27, giving the Wright Co. the exclusive control of ailerons or wing warping devices for aeroplanes. This decision apparently means that the company will absolutely control the aviation field and that none of the builders of heavier-than-air machines can build machines hereafter without a license from the Wright Co. The Wright Co. plans to collect royalties amounting to $1000 for each machine, taxing each machine about twenty per cent of its cost.

BEARING PRESSURES DUE TO THE ACTION OF BEVEL GEARS UNDER LOAD

BY RALPH E. FLANDERS*

The action of a pair of bevel gears under load produces a radial pressure on the bearings due to the tendency of the driver to climb onto the driven gear. The pressure angle of the involute teeth also produces a force tending to push the gears out of engagement. This angular thrust may be resolved into a radial bearing pressure and a direct end thrust on the shaft. The amount of radial bearing pressure and end thrust due to a given load on a given gear may be calculated by rules and formulas presented herewith. We must have the following data: The pitch diameter, with width of face, and the edge angle of the gear, which is the same as the pitch cone angle. These dimensions are shown in Fig. 1. It is also necessary to know the horsepower and revolutions per minute, or the torque in inch-pounds to which the gear will be subjected. The pressure angle of the teeth, *i. e.*, whether they are 11½ degree standard teeth, or whether they are 20 degree or other shape, must be known. It makes no difference whether the teeth are of standard length or of the "stub tooth" variety.

We will evidently get different driving pressures on the teeth, depending on whether we use the pitch diameter at the

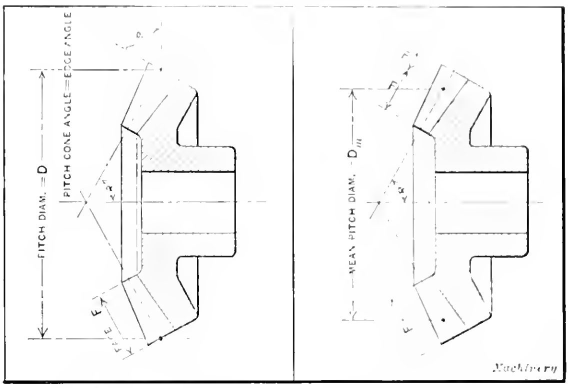

Fig. 1. Gear Dimensions required to determine Radial Pressure and End Thrust

Fig. 2. Mean Pitch Diameter defined for Purposes of Calculation

large end or at the small end of the teeth for our calculations. We should evidently use a diameter somewhere between to get correct results. An accurate calculation would require consideration of the elasticity of the tooth, which would be somewhat complicated. It will be well enough to locate our mean pitch circle at one-third the width of face from the large end of the tooth. The diameter thus located, as shown in Fig. 2, may be considered the mean pitch diameter for the purposes of this calculation. This mean pitch diameter may be obtained either by measuring an accurate drawing or by the following calculation:

RULE 1. *To find the mean pitch diameter multiply two-thirds the width of face by the sine of the edge angle, and subtract the product from the pitch diameter.*

RULE 2. *To find the tangential tooth pressure (which equals the direct radial pressure on the bearing) divide the torque in inch-pounds by one-half the mean pitch diameter.*

RULE 3. *The result obtained by* RULE 2 *can also be obtained by multiplying the horsepower transmitted by 126,050, and dividing by the product of the revolutions per minute and the mean pitch diameter.*

The next step is to find the thrust, due to the tooth pressure and the angularity of the gear, in the direction x x in Fig. 3. This may be done by the regular parallelogram of forces or by calculation as follows:

RULE 4. *To find the angular thrust of the gear, multiply the tangential tooth pressure by the tangent of the pressure angle of the tooth.* (Note: For a 14½-degree tooth the tangent is 0.2586; for 15 degrees, 0.2680; for 20 degrees, 0.3640; for 22½ degrees 0.4142.)

* Address: Jones & Lamson Machine Co., Springfield, Vt.

This angular thrust, as shown in Fig. 3, may be resolved into two components: one, the direct thrust on the shaft (which may be taken care of by a thrust bearing); and the other, an additional radial pressure on the bearing. These quantities may be derived by the parallelogram of forces or by the following calculation:

Rule 5. *To find the direct thrust on the shaft, multiply the angular thrust by the sine of the edge angle.*

Rule 6. *To find the additional bearing pressure due to the angular thrust, multiply the angular thrust by the cosine of the edge angle.*

It is evident from Fig. 4 that the bearing pressure due to the angularity of the teeth is at right angles to that due to the tangential tooth pressure carrying the load. The re-

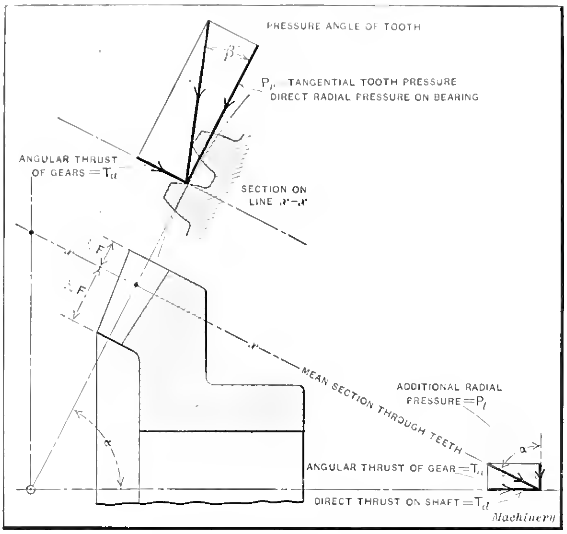

Fig. 3. Determination of Direct Thrust and Additional Radial Bearing Pressure

sultant total pressure on the bearings may be obtained by the parallelogram of forces or by calculation as follows:

Rule 7. *To find the total radial pressure on the bearings, add the squares of the tangential tooth pressure and the additional radial thrust on the bearing due to the angular thrust, and extract the square root.*

The foregoing rules may be expressed in the formulas:

$$D_m = D - 2/3\,F \times \sin\alpha \qquad (1)$$

$$P_r = \frac{2\,M}{D_m} \qquad (2)$$

$$P_r = \frac{126{,}050\,H}{R\,D_m} \qquad (3)$$

$$T_a = P_r \times \tan\beta \qquad (4)$$

$$T_d = T_a \times \sin\alpha \qquad (5)$$

$$P_t = T_a \times \cos\alpha \qquad (6)$$

$$P_b = \sqrt{P_r^2 + P_t^2} \qquad (7)$$

in which

D = pitch diameter;
F = width of face;
α = edge angle (same as pitch cone angle);
D_m = mean pitch diameter;
M = torque or turning moment in inch-pounds;
H = horsepower transmitted;
R = revolutions per minute;
P_r = radial bearing pressure = tangential tooth pressure;
β = pressure angle of involute tooth;
T_a = angular thrust of gears;
T_d = direct thrust on shaft due to angular thrust of gears;
P_t = additional radial pressure on bearings due to angular thrust;
P_b = total radial pressure on bearings.

As an example, take the case of the gear shown in Figs. 3 and 4, whose dimensions are as follows: pitch diameter = 6 inches; face = 1¼ inch; edge angle = 63 degrees 26 minutes; horsepower = 19 or torque = 1500 inch-pounds; pressure angle of tooth = 20 degrees. The radial pressure and thrust on the bearing are found by calculation from the above rules and formulas, as shown below. Graphical calculations giving the same results by the parallelogram of forces are indicated in Figs. 3 and 4.

$$D_m = 6 - \tfrac{3}{4} \times 0.8940 = 5.330 \text{ inches.} \qquad (1)$$

$$P_r = \frac{3000}{5.33} = 562 \text{ pounds.} \qquad (2)$$

$$P_r = \frac{126{,}050 \times 19}{800 \times 5.33} = 560 \text{ pounds (approximately).} \qquad (3)$$

$$T_a = 560 \times 0.3640 = 204 \text{ pounds.} \qquad (4)$$

$$T_d = 204 \times 0.8940 = 182 \text{ pounds.} \qquad (5)$$

$$P_t = 204 \times 0.4470 = 91 \text{ pounds.} \qquad (6)$$

$$P_b = \sqrt{560^2 + 91^2} = 567 \text{ pounds.} \qquad (7)$$

It will be seen from calculation No. 7 that the pressure angle of the tooth has a practically negligible effect in increasing the radial bearing pressure. In the case of spur gears, this effect is so small that the angular pressure need not be reckoned with; and in bevel gears the effect is even smaller, since a good share of the angular pressure is transmitted into thrust. It is, therefore, not necessary in practice to carry the calculations beyond the fifth rule or formula. The total radial bearing pressure thus found is, of course, distributed between the bearings of the shaft, usually two in number, in accordance with the principle of moments (see Machinery's Handbook, pages 338 and 339). The pressure on each bearing resulting from the gear action, as previously calculated, must be combined by the parallelogram of forces in the same way as shown in Fig. 4 with any other pressures arising in these bearings from other gears, belts, pulleys, brakes, or similar loads on the same shaft.

* * *

The first mention of platinum by name was made by Antonio de Ulloa in 1748. The great Ural fields of platinum were discovered in 1803 and then platinum became recognized as a metal of interest and use. Since then the interest and use have been increased by leaps and bounds so that within the last five years the price has increased from $20 to $46 per ounce. The United States now imports $4,000,000 or $5,000,000 worth a year. Platinum is an extremely useful

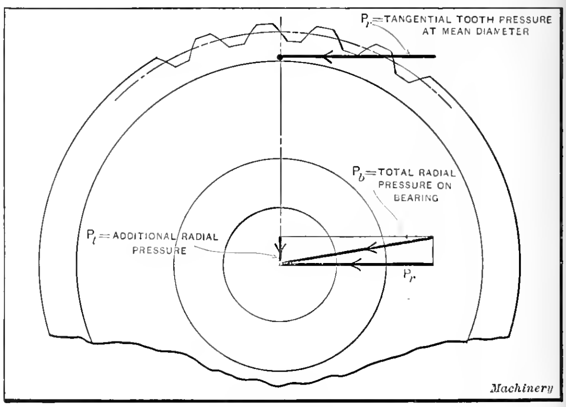

Fig. 4. Determination of Total Radial Pressure on Bearing

metal in the arts and chemists would be helpless without it. Liebig said, not many years ago, that without platinum the composition of most minerals would have remained unknown because the acids that will dissolve the minerals will also dissolve glass or porcelain and the heat required would melt gold or silver. Platinum is melted in a lime crucible, using an oxy-hydrogen blow-pipe. Its specific gravity varies. The higher the specific gravity, the more lasting the polish. Ordinary re-melted platinum has a specific gravity of about 20.3 and a cubic inch weighs 0.72 pound, but the best platinum has a density of 22.669 and the weight of a cubic inch is 0.798 or approximately four-fifths of a pound. Platinum is hardened with iridium, but as iridium costs nearly double as much as platinum, or $85 per ounce, it is used sparingly.

MAKING SPITZER BULLETS*

MACHINES, DIES, TOOLS AND METHODS USED BY THE FRANKFORD ARSENAL

BY DOUGLAS T. HAMILTON†

The methods used in the manufacture of Spitzer bullets or 0.30 caliber cartridges are of an unusually interesting nature. The point of the bullet must be absolutely concentric with the body if good results are to be obtained. If the point is slightly eccentric, the bullet is erratic in its flight and cannot be depended upon to shoot accurately. It is therefore not only necessary to exercise the greatest care in the final operations on the bullet, but the same exactness and careful attention must be followed from the initial operation through to the finished product. The cup, in fact, has to be started just right. The walls must be of equal thickness and drawn straight, as any difference in the length of the cup means, as a rule, a variation in the thickness of the wall. This variation in the thickness of the wall will be apparent in the finished jacket and is somewhat exaggerated in each successive operation, so that the care that must be exercised in drawing makes this work rather unusual in its character.

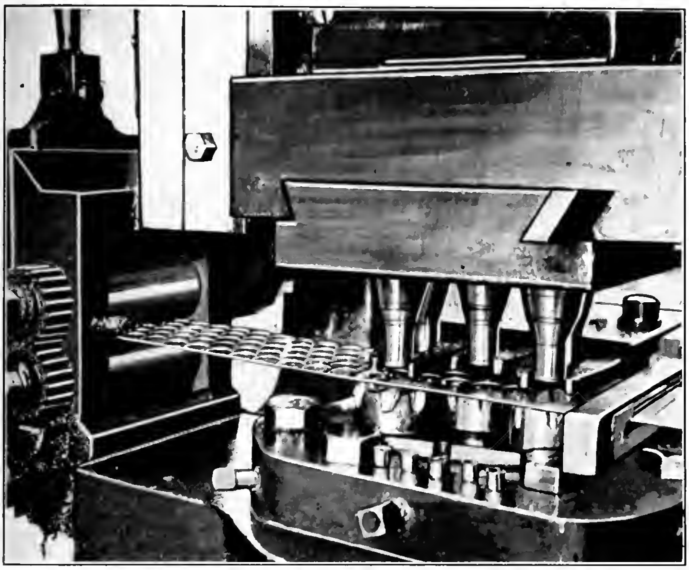

Fig. 1. Blanking, cupping and drawing the Nickel Case for Spitzer Bullets at the Rate of 470 per Minute, using Five Combination Punches and Dies

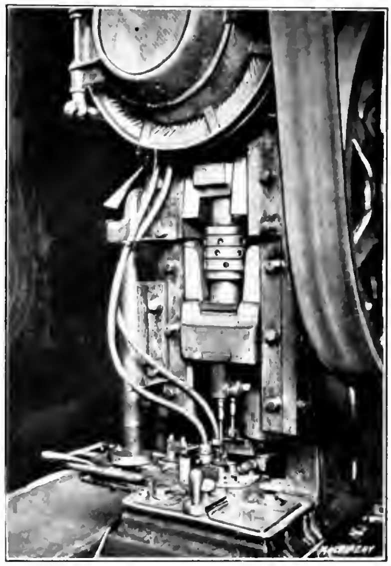

Fig. 2. Type of Drawing Press used for redrawing Nickel Jacket Cases for Spitzer Bullets using Two Punches and Dies

Making Cups for Spitzer Bullets

The cups from which Spitzer bullet jackets are made are produced from stock composed of 85 per cent copper and 15 per cent nickel. This material is purchased in sheet form and comes in rolls about 12 or 14 inches in diameter. In operation, the roll is held on a stand, as was described in connection with the making of the brass cartridge case in the March number, and is fed into a double-action press. When making the cups for the Spitzer bullet, five combination punches and dies, as shown in Fig. 1, are used. These are of the same shape and type as those shown in Fig. 10 of the article referred to, and the press is operated at a speed of ninety-four revolutions per minute, giving a production of 470 cups in this time. In addition to blanking out and cupping, this machine also performs the first drawing operation on the nickel cup. Before any further operations are performed, the cups are annealed, washed and dried and are then ready for the redrawing operation.

Redrawing Nickel Jacket Cases for Spitzer Bullets

The redrawing operations on the nickel jacket cases for Spitzer bullets are accomplished in a drawing press of the type shown in Fig. 2. This machine carries two punches and two dies as illustrated. The punches are carried in a head operated by a crankshaft, and the feeding mechanism is actuated by a cam, receiving power from the crankshaft through a pair of bevel gears and the vertical shaft shown. The cups are placed in a hopper located at the top of the machine in which a wheel carrying pins rotates. These pins pick up the cups and carry them to a receiving chute, from which they pass down through brass tubes made from close-wound brass springs, which carry the cups down to the feeding mechanism of the machine. The feeding mechanism consists of a slide in which fingers are held that grip the cups and carry them forward to the punches, which as the ram descends force the cups out of the fingers and through the redrawing dies. There are three redrawing operations on the nickel jacket case as shown by *A*, *B* and *C* in Fig. 3; this illustration also presents the three redrawing punches and dies used. The redrawing operations are accomplished in a press of the type shown in Fig. 2, which operates at 112 strokes per minute and turns out 224 cups in this time.

Making Lead Fillings or Slugs for Spitzer Bullets

The lead fillings or slugs for Spitzer bullets are made from wire which is produced in the hydraulic press shown in Fig. 4. This lead wire is made from large billets of a composition metal consisting of 30 parts lead and 1 part tin. A group of these billets just as they come from the mold may be seen in the foreground of the illustration. These are cast in an iron mold and are $1\frac{3}{4}$ inches in diameter by $13\frac{3}{4}$ inches long. The machine in which the billets are placed is operated on the hydraulic principle, water being used as a medium for obtaining the desired pressure, and is capable of exerting a pressure of 1000 tons per square inch.

In operating this machine the lead billet is placed on the stand *A*, and as the plunger of the machine ascends after forcing out the metal, this stand also rises until the billet comes almost level with the chute *B*. The operator then disaligns the plunger, as will be described later, dumps the lead billet off the chute, dropping it down into the die of the machine, aligns the plunger, starts up the machine, and as the plunger again descends, it forces the metal out through sizing dies. The metal, in passing out from the large die or billet container of the machine, passes through sizing dies

* For additional information on cartridge making, see "Drawing Cartridge Cases" in the March, 1914, number of MACHINERY and articles there referred to.
† Associate Editor of MACHINERY.

which form the wire to the correct diameter, in this case, 0.280 inch. When the machine first starts to force the lead wire out, the gage indicates a pressure of 600 tons, which gradually drops down to 550 tons as the metal begins to heat up and become softer.

As the lead wire is squirted out of the dies, it passes over a roll *C* and thence through a box *D* filled with constantly running water. This serves to cool the wire and harden it to some extent. From the box of water the wire passes over another roll and up through an adjustable mechanism which is used for winding the wire on the spool *E*. The mechanism for locating the wire on the spool is controlled by a double-pitch worm cut right- and left-hand which guides the arm of the feeding or winding attachment. As the wire in being wound up travels over to one side of the spool, the direction of the feeding or winding arm is changed by a dog which throws the nut into the groove in the worm running in the opposite direction. The worm is driven by gears from the pulley *F*, and the spool is driven from the same pulley through a friction clutch.

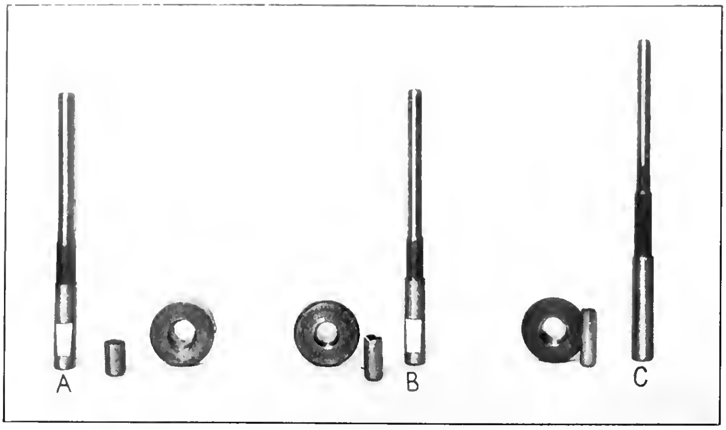

Fig. 3. Sequence of Three Drawing Operations for Nickel Jacket Case for Spitzer Bullets; also Dies and Punches used

To insert the lead billet in the central die of the machine it is necessary to throw the punch out of line with the die so that the billet can enter. This is done in order to decrease the amount of punch travel that would otherwise be necessary, and allows the machine to be operated much more quickly. The mechanism for disaligning the punch is of very simple construction, but is fool-proof. The plunger *G* is thrown out of line by operating the handle *H* and is brought back into line by operating the handle *I*. By looking carefully at this illustration, it will be seen that handle *I* is connected with the mechanism operating the valve of the hydraulic pump, and hence it is impossible to start the plunger on its downward stroke until it is in perfect alignment with the die. This attachment prevents any accident which might happen should the operator fail to align the punch accurately with the die and then start the machine.

Swaging Lead Slugs for Spitzer Bullets

The lead wire produced in the hydraulic machine shown in Fig. 4, after it has been wound on the spool, is taken to the swaging machine shown in Fig. 5, the spool being placed on a stand as illustrated at *A*. The wire passes from this roll down over a number of other small guiding rolls and is forced up by a feeding device located under the machine. This feeding device lifts the wire at each stroke an amount sufficient to produce two slugs. The machine is provided with two dials *B* and *C*, one over the other. The dies in these dials are not used for forming the slugs, of course, but merely act as feeding, or in other words, carrying members. One die in each of the dials *B* and *C* is successively in perfect alignment with the corresponding one in the other dial when the machine is indexing properly. The top dial, which is geared to the lower one, is one-half the size and carries one-half as many dies as the lower one. The lower dial indexes two positions for one index of the upper dial, the latter serving to feed each second successive hole in the lower dial.

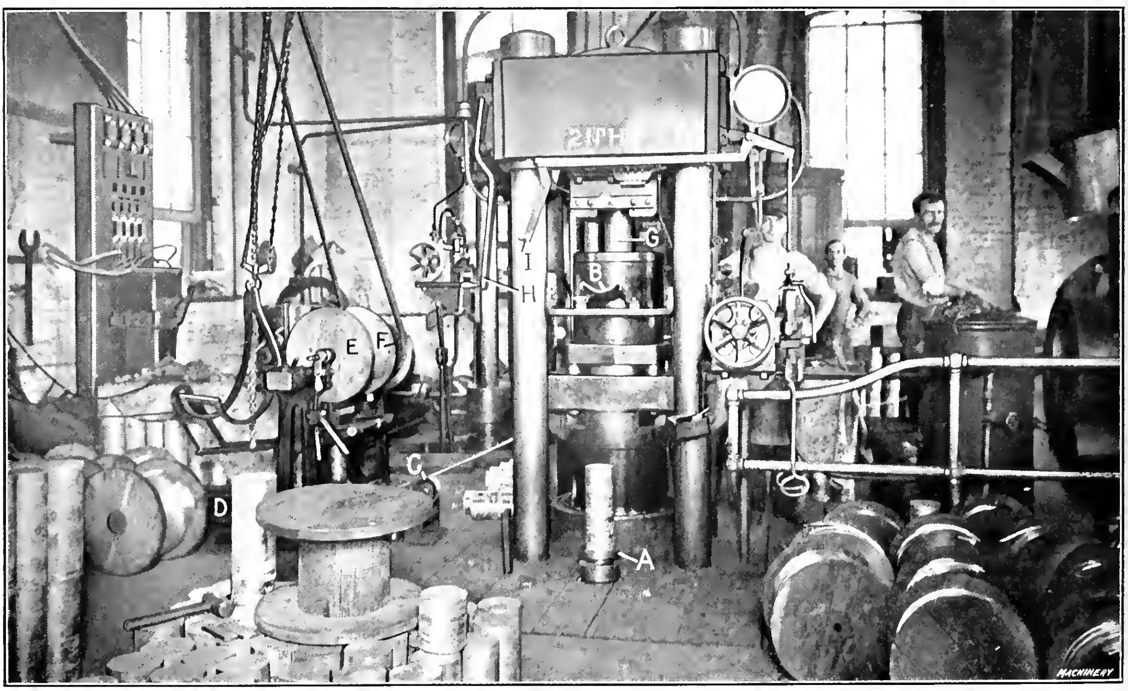

Fig. 4. Hydraulic Press for making Lead Wire, which is used as Filling for Spitzer Bullets

The lower dial, which makes two indexes for every one made by the upper dial, is used for carrying the slugs to the various punches and dies that are used for forming them to the proper shape. There are two sets of punches and dies; the first two punches *D* are used for forming the slugs, the second punches *E* force the formed slug out of the dies,

while the two punches *F* are used as a means of safety. The punch *G* is attached to the knock-off and stops the machine should the wire be feeding short. The last punch *H* knocks out any scrap that may remain in the top dial, and keeps the dies clear. The dies held in the lower dial are used in conjunction with bushings in the machine for cutting off the wire as it is fed up; then the amount of wire fed at each stroke is again subdivided by the dies held in the top and lower dial that work against each other as they rotate. This machine works entirely automatically and when properly set up produces slugs at a rapid rate.

Finish-forming Spitzer Bullets

The most difficult operation in the production of Spitzer bullets is finish-forming them, which consists in pointing the nickel case and making the point absolutely concentric with the body. The type of machine used for this purpose is shown in Fig. 6, where the sequence of operations on the bullet is

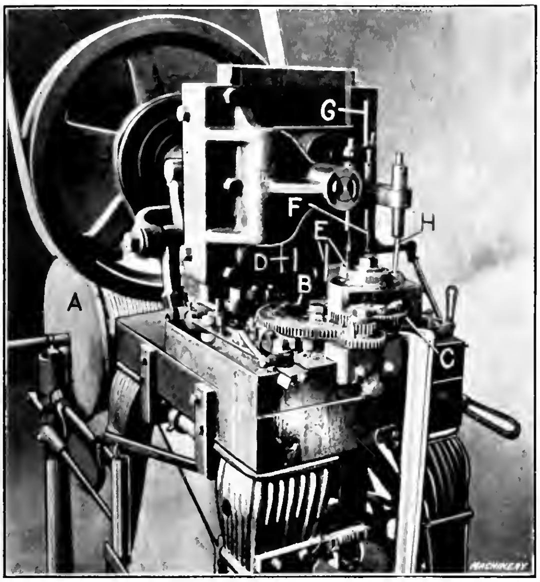

Fig. 5. Swaging Press used for making Lead Fillings for Spitzer Bullets

clearly shown by the samples on the dial. This machine is of the ratchet dial feed type. The nickel cases are located in bushings held in the dial *A* by the operator and are carried around by this medium. The slugs which are held in a hopper at the back of the machine are fed down to the second dial *B*, through a close-wound spring tube. Dial *B* is indexed in a similar manner and in unison with dial *A* and the slugs which are carried in it are forced out and located in the nickel case in the lower dial by means of punch *C* held in the ram of the machine.

Fig. 7 shows the sequence of operations followed in the production of the Spitzer bullet, and also the dies, punches and knock-out pins used. The dies in this case have been sectioned so that their shape can be clearly seen. Fig. 8 shows diagrammatically the operations performed on the

Fig. 6. Machine used for forming the Nickel Cases of Spitzer Bullets and assembling the Lead Fillings in them

Spitzer bullet. Here the relations of the forming punches and knock-out pins to the dies are clearly illustrated. By referring to this illustration, the sequence of operations on the Spitzer bullet will be clearly understood. At *A* the shell is partly reduced in diameter at the point. At *B* the point of the shell is still further reduced and the rounding of the body is commenced. At *C* this operation is carried still further, while at *D* the case is completely formed. In all the operations up to this point, the shell is formed to the shape shown by the punch and die working in conjunction with each other; that is to say, the punch is the same shape as the die, but is smaller in diameter an amount equal to twice the thickness of the walls of the case. At *D* the punch is relieved and only fits the case at the lower or curved portion; however, it follows the case right to the point and is used in connection with the die for forming the point concentric with the body.

At *E* the lead slug is inserted in the nickel jacket case, and it will be noted that the punch cannot pass down into

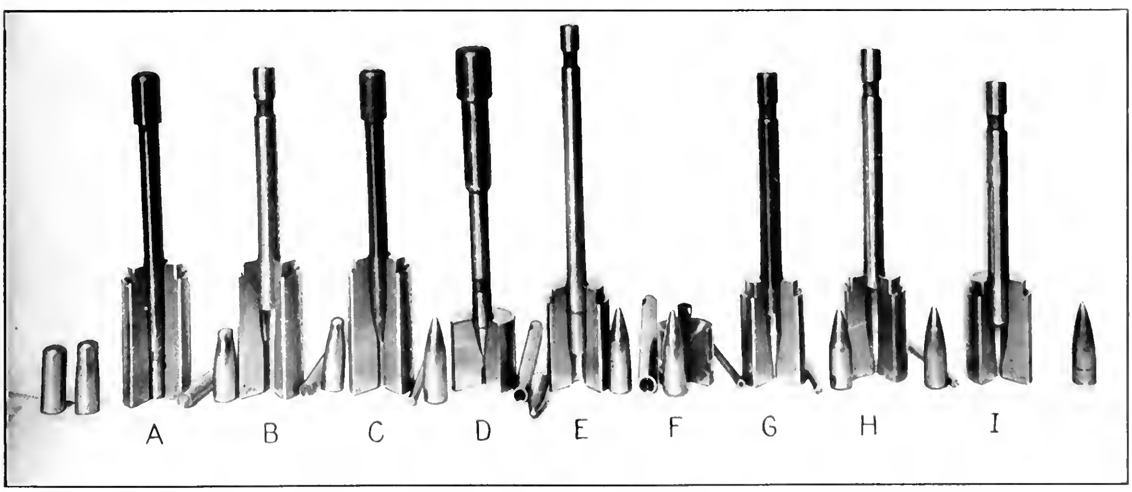

Fig. 7. Illustration showing the Type of Dies and Tools used in the Machine shown in Fig. 6 for making Spitzer Bullets

the shell, but merely rests on top of the lead slug. At *F* the operation accomplished is known as "coning." This is one of the most important operations, as it is intended to make the point of the bullet perfectly concentric with the

body. The die *a* which is used for this purpose only forms the extreme point of the bullet, and does not bear at all on the curved part of the body. These pointing dies are only allowed 0.002 inch float in the holder and must be perfectly in line with the punches. The punches and dies shown from *G* to *I* are used for forming the base of the bullet. These operations consist in turning over the top edge of the nickel case and flattening it down on the lead slug—*J* and *K* show the condition of the nickel case before and after pointing, whereas *L* shows the lead slug and *M* the finished bullet.

The proper setting up of the machine shown in Fig. 6 is an operation that requires some skill. The punches which are held in the ram of the machine must be in absolute alignment with the dies. The pointing dies are only allowed 0.002 inch float in the holders in which they are retained and are set as exact as it is possible to get them. After the machine has been set up, a number of trial bullets are run through; these are then taken out and tested in a special type of high-speed lathe in which the bullet is held true. When put under this test the point of the bullet must run perfectly concentric with the body before the machine can be started on a "run." This test of the bullet is also made

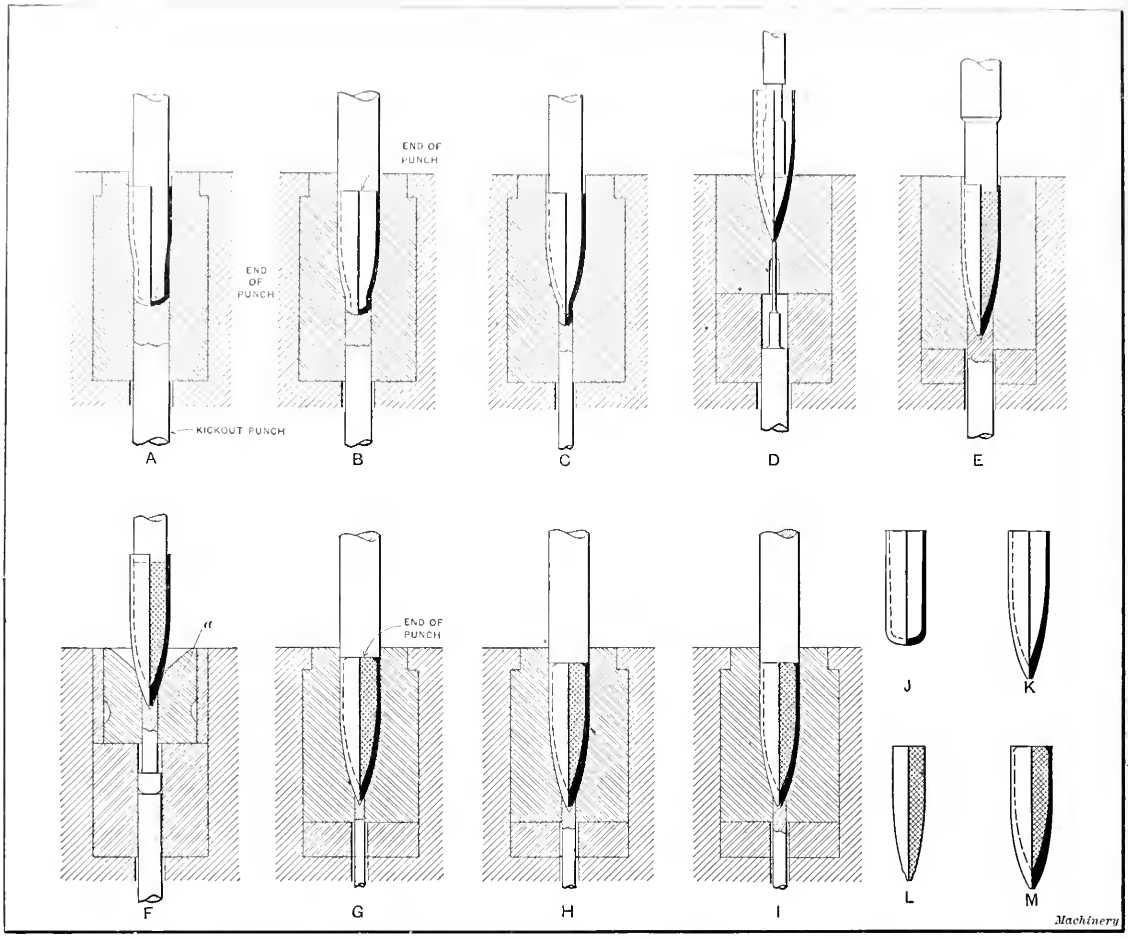

Fig. 8. Diagrammatical View showing the Sequence of Operations in the Production of Spitzer Bullets, and how the Various Tools act in Relation to each other

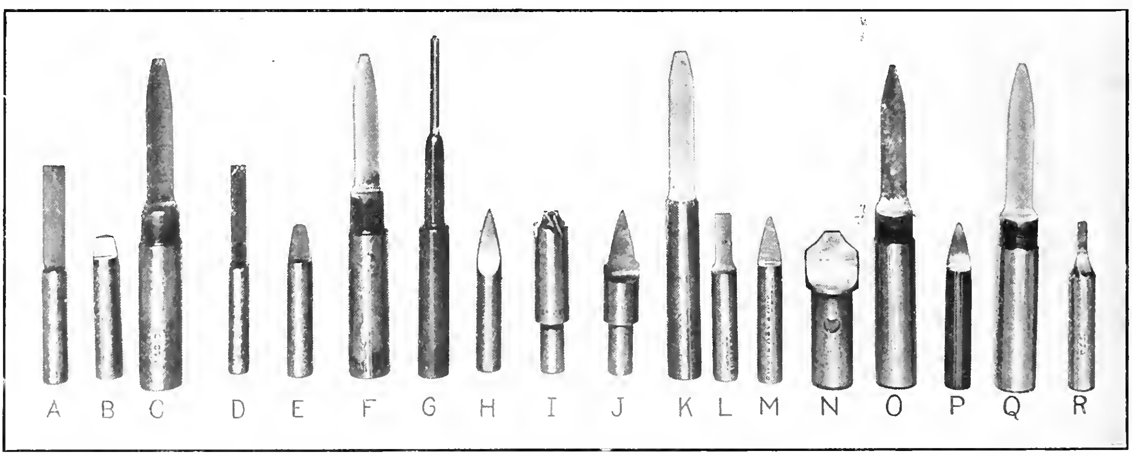

Fig. 9. Type of Tools used for making the Dies for producing Spitzer Bullets, these Dies being used in the Machine shown in Fig. 6

from time to time so that any variation in the setting of the dies will be detected before many scrap bullets have been run through. The making of the dies for bullets of the Spitzer type is considered by cartridge makers to be one of the most difficult propositions in cartridge making. It requires the most excellent tool work and also special care in using the tools, setting them up in the machine and keeping the machine in absolute alignment and perfect running order.

Canneluring and Sizing Spitzer Bullets

In order to provide a means for holding the Spitzer bullet in its proper position in the cartridge case, the bullet is provided with a knurled groove around its periphery near

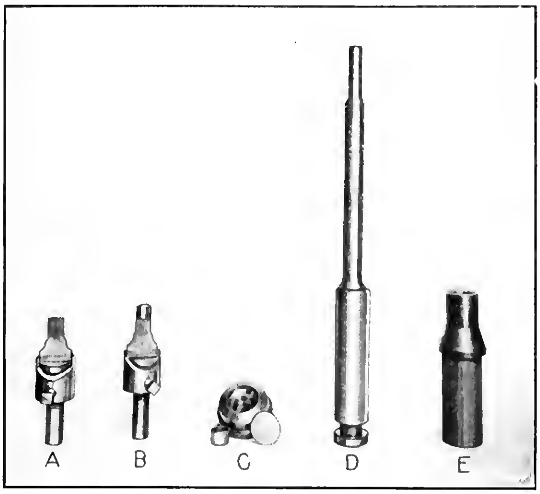

Fig. 10. Combination Blanking Punches and Dies used for making the Nickel Jacket Cups and Tools used for making the Die

the base. This operation is known as canneluring, and is accomplished in the machine shown in Fig. 12. The bullets are dumped into the hopper *A* from which they are conveyed by means of a tapered conveyor screw *B*. Conveyor *B* is rotated by means of a belt *C* running over the pulleys illustrated. The conveyor carries the bullets up to the entrance of the chute *D* which is a close-wound spring, connected with the small hopper forming an auxiliary to the six-hole turret *E* located above the canneluring dial *F*. Turret *E* in which the bullets are dropped rotates and carries the bullets around so that they can be inserted in the dial *F* by means of punches. Dial *F* is also rotated and carries the bullets past

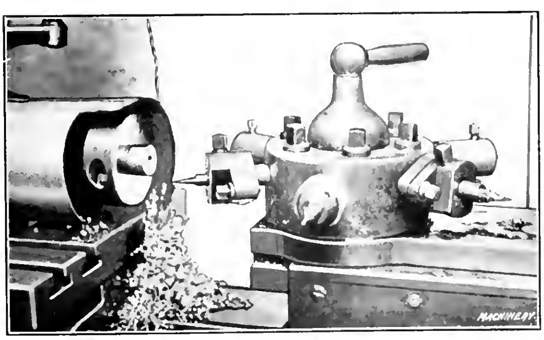

Fig. 11. Making the Pointing Die for a Spitzer Bullet in a Hand Screw Machine

a knurling segment, which produces the small groove in the circumference. As the bullets are cannelured they are forced out of the top dial *F*, pass down through a tube and are located in the lower dial *G*. This lower dial carries the sizing dies, which resize the bullets, this operation being necessary owing to the slight distortion produced during the canneluring operation. The punches for forcing the bullets through the dies held in dial *G* are carried in the slide *H* which is operated by crankshafts *I*. The dial *G* is rotated by a ratchet mechanism receiving power from a fulcrumed lever *J* which carries a roll working in and receiving motion from a groove in cam *K*.

Making Combination Blanking, Cupping and Drawing Dies for Spitzer Bullets

The type of tools used for making combination blanking, cupping and drawing dies for Spitzer bullets is shown in Fig. 10. These tools are of a similar type to those illustrated in a former article. Here *C* is the combination blanking, cupping and drawing die, *E* the blanking punch, and *D* the combination cupping and drawing punch, while *A* and *B* are the roughing and the finishing reamers, respectively, for the die. The information given in regard to the dies for making the brass case also applies to these dies.

Tools used for Making Pointing Dies for Spitzer Bullets

Fig. 11 shows how the pointing dies for Spitzer bullets are made. Sanderson hammered steel is used for making these dies because of its "shock resistance" and also the great hardness that can be obtained without danger of cracking or breaking. The operations in the making of this die which are shown at *D*, Figs. 7 and 8, are as follows: Drill large portion of hole; drill small portion of hole with a No. 68 drill, and insert roughing and finishing pointing reamers.

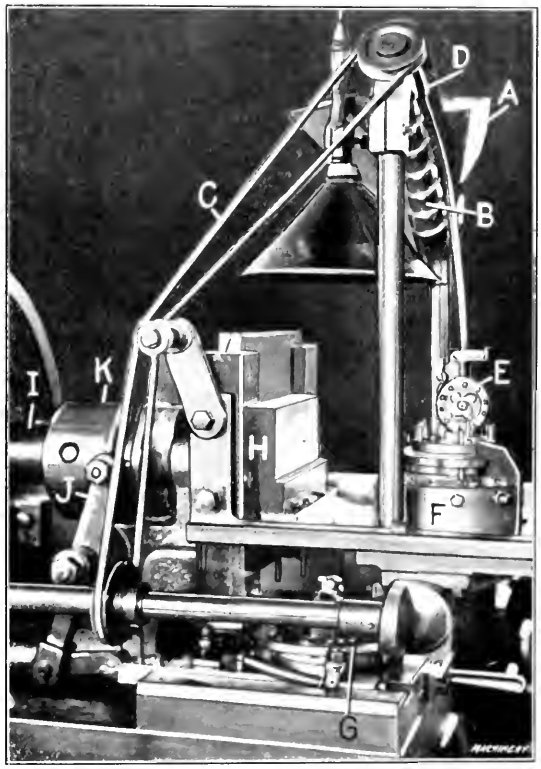

Fig. 12. Machine used for canneluring Spitzer Bullets; also for sizing them

The making of this die represents an excellent example of tool work, as the holes must be in absolute alignment with each other, and the entire curved portion of the hole perfectly concentric throughout.

Fig. 9 shows all the reamers that are used for making the pointing dies shown in Figs. 7 and 8. The names of these are as follows: *A* is the reamer for the first die; *B* is the first and second operation stem reamer; *C* is the reamer for the first and second die shown at *A* and *B* in Fig. 7; *D* is the second operation die reamer; *E* is the second operation stem reamer; *F* is the third operation die reamer, *G* is the reamer for the small hole in the third operation die; *H* is the first pointing die reamer; *I* is the countersink for the mouth of the pointing die; *J* is the pointing die finishing reamer; *K* is the "slug die" reamer; *L* is the slug die stem reamer; *M* is the coning die stem reamer; *N* is the coning die reamer; *O* is the hump die reamer; *P* is the hump and base

stem reamer; *Q* is the base die reamer; and *R* is the base die stem reamer. It will be noticed by referring to this illustration that practically all the reamers are of the "spoon" variety. This type presents only one cutting edge to the work, but is easily made and can be gaged with less difficulty than a fluted reamer. It is also readily sharpened, being stoned only on the top flat face.

COMBINATION HEAT-TREATING FURNACE

BY ALLOY

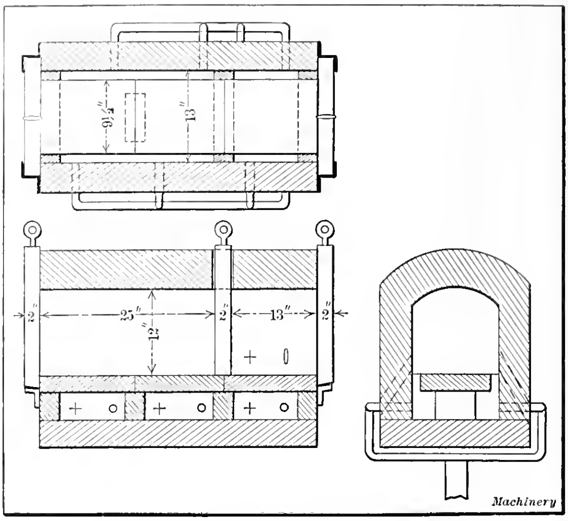
The company by which the writer is employed went to considerable trouble in looking over standard types of heat-treating furnaces in the hope of finding an equipment which would meet existing requirements. We were badly in need of space, and as the range of our work to be heat-treated is quite extensive it appeared that two furnaces were really necessary. At the same time, we were trying to find one furnace which would meet all requirements. The conditions will be better understood when it is known that the range of work to be handled includes milling cutters $6\frac{3}{4}$ inches in diameter by $1\frac{1}{4}$ inch face width and arbors 30 inches in length as well as the general small jobbing work usually encountered in repair shops. The cutters to be hardened are of high-speed steel, while the arbors are to be carbonized.

We considered the case from various angles. It appeared possible to meet the requirements with two standard furnaces, using a casehardening furnace for pre-heating the high-speed steel cutters, and having a second furnace for the high temperatures required for hardening. We also considered the possibility of saving space by eliminating the pre-heating process and using a single furnace for all the work. Allowing for the use of carbonizing boxes, it would require a furnace 40 inches long to handle the arbors, and it soon became evident that this idea was useless because of the excessive cost of fuel when treating small work and of maintaining a furnace of this size under the wear and tear of the high temperatures for hardening high-speed steels.

Interviews with furnace men were far from encouraging. They all derided the idea of getting one furnace that would handle our range of work, and ridiculed any suggestion about making a special furnace for the purpose. As it became evident that we could not buy a suitable furnace, the writer finally set out to build one to meet the requirements of the special work to be heat-treated. The furnace finally produced is shown in the accompanying illustration, from which it will be seen that there are two compartments separated by a partition 2 inches thick. When this partition is lowered there are two independent furnaces, one of which is 13 inches long and the other 25 inches long. The small compartment is provided with extra burners to give the high temperature required for hardening high-speed steel. There are also six burners—three on each side of the furnace—each of which has an independent valve so that each burner can be regulated irrespective of the other five. To obtain an even temperature all through the furnace, all of the valves are thrown wide open, and the regulating is done by the main gas and air valves. When the larger compartment is not in use, the four valves for heating this compartment are shut. The air and gas are mixed before entering the main pipe which leads to the burners, and in this way an even mixture can be obtained.

It will be seen that there is a door at each end of the furnace so that the two compartments may be used independently; this does away with the necessity for raising the partitions except when it is desired to move work from one compartment to the other or to handle work which requires the entire size of the furnace. The doors and partitions are raised and lowered by means of cables which connect with counterweights. This type of door has been criticised by some people because in the event of an explosion there is no outlet for the pressure. With a hinged door, the pressure resulting from an explosion will blow the door open, thus allowing the pressure to expend itself. In the present case, however, the correct mixture of gas and air is insured before the doors are lowered. So far, no trouble has been experienced, and it may be mentioned in favor of this type of door that it is found extremely useful when it is required to heat-treat the ends of pieces that are too long to go into the furnace. In such a case, the work is pushed into the furnace and the door lowered on it. This keeps free air away from the heated part of the work and does away with the danger of damage from oxidation.

A hinged iron leaf is provided at each end of the furnace which can be swung out of the way when it is not required. When the leaf is in position it comes flush with the top of the bed of the furnace. When removing the work from the furnace these leaves are found very helpful, particularly when heavy carbonizing boxes are being handled. The box can be dragged out of the furnace onto the leaf, where it is more convenient to obtain a good grip on it. Men who have experienced trouble in getting hold of work while it is still in the furnace will readily appreciate the value of this attachment. The bed of the furnace is made in three equal sections and we usually keep two or three extra sections in stock. The small compartment is used for work requiring extremely high temperatures, and this end is also used for a variety of odd jobs. As a natural result, the bed at this end of the furnace gives way before the opposite end is worn out. The worn bed can be easily taken out and replaced whenever necessary.



Combination Heat-treating Furnace for Carbonizing and Hardening Operations

The end view of the furnace shows the positions of the extra burners for heating the small compartment. The horizontal burner on each side is one of the six regular ones which heat the furnace. The inclined burners are the two extra ones which are used to raise the temperature of this compartment sufficiently for hardening high-speed steel. These extra burners throw their heat above the bed at such an angle that the flame does not strike the work, but strikes the top of the furnace, from which it is deflected in a way to give the best possible results. In handling the large high-speed steel cutters referred to in a previous paragraph, the work is laid in the large compartment and uniformly pre-heated to a temperature of about 1800 degrees F. The partition is then raised and the cutters drawn through to the small compartment, in which the temperature of the work is quickly raised to 2200 degrees F. The work is then taken out and plunged into an agitated oil bath. From the pre-heating to the final compartment, the work does not come in contact with the air, so that there is no possibility of damage from oxidation. For small work, it has been found very handy to use two sizes of boxes for carbonizing, one $9\frac{1}{2}$ inches round and the other 12 by 9 inches. For a small odd job, one of the boxes will go into the small end of the furnace. When there is enough small work to fill two boxes, the large end is used.

PATENTS—SOME ESSENTIAL FACTS FOR THE ENGINEER*†

INFRINGEMENT—PATENT OFFICE PRACTICE—VALUE OF PATENT—SCOPE OF PATENT

Most engineers, designers and mechanics will find it of great practical advantage to know something about patents and the elements of patent law. Such men are engaged in all sorts of industries and simply cannot afford not to know something about these subjects, because our factories are making patented articles on patented machines to a great extent, and the men working in or for those factories are trying to increase production or get more business, or at least to make sure to keep their own jobs and get better ones, perhaps.

Now, as a designer or experimenter, you may make something new, and the question will come up whether you or the company you work for ought to try to protect it by a patent. Or it may be found that a competitor has patents covering his articles, or makes the same thing you do more cheaply or better through the use of a patented process; and in either case it may be up to you to improve your own product or process to compete successfully. You will have to consider how to get around his patent and, if possible, make something better or at least different from his, with good talking points of its own to help the sales force. Maybe what you do will amount to invention and deserve patenting. You may be called on as the engineer or executive of a plant to determine the value of a patent which someone wishes to sell you, or give you a license under; or you may have to appraise the assets of a company, which are made up in part of good will, patent rights, and the like. Possibly you may have an opportunity to act as an expert witness in a patent infringement suit. In all of these relations you will probably have the aid of a patent lawyer, but nevertheless a clear general understanding of the subject should be of considerable value.

The making of inventions and the American patent system, which has encouraged inventing more than that of any other country, have been tremendous factors in our industrial success. Patented improvements are constantly making many things better and cheaper. For example, the price of sulphuric acid is about fifteen times less than it was in 1807, and about one-half of what it was in 1870. And there would not be many inventions if patents were not granted, since few people work hard on new things except when they are stimulated by the hope of substantial reward. Under our present system, Americans are always willing to try out new ideas, to see if they will work. That reminds me of the small boy who had the investigating spirit. He came home from Sunday school and went right upstairs, and presently his mother heard an awful splashing. So she went up, and there he was standing in the bath tub with all his clothes on, and water all over the floor. "For goodness sake, Willie, what are you doing?" she said. "Why, mother," he replied, "they told us in Sunday school about the Lord walking on the water, and take it from me, it's some stunt." Of course, he didn't mean to be sacrilegious.

What an Engineer Ought to Know about Patents

In considering what an engineer ought to know about patents, the subject opens up roughly, under these heads: (1) What a patent is, how it is obtained, and what it purports to give you; (2) how to determine the scope or value of a patent; (3) when it is worth while to make an invention and secure a patent on it; and (4) how in a general way to make use of a patent to get value out of it.

First, then, a patent is a grant in the nature of a contract between the United States and the inventor. The government gives the inventor the exclusive right, for seventeen years, to make, to use, and to sell, whatever it is that is covered by the patent. No one else can make it, or use it, or sell it, without his permission. If they do, they are infringing the patent, and he can bring suit to stop them, *i. e.*, get an injunction against the continuance of their infringing operations. He can also collect three-fold damages for what they have done, or the profits which they have made by the infringement. The inventor, in return for this monopoly, makes his invention public, by clearly describing it in his patent, so that the public are taught how to practice it; and at the end of seventeen years the patent runs out, and then every one is free to practice it. The inventor might have kept his discovery a secret. That is why the United States gives a monopoly for seventeen years in return for his disclosure of the invention to the world, by means of the patent.

In order to be patentable a thing must be novel and useful; and the exercise of the inventive faculties must be involved in the production of it, as distinguished from simple mechanical skill. No general rule can be laid down to define when the making of a new thing involves invention, although there are many rules as to when it is not invention. But the distinction from an older thing must be more than mere excellence in workmanship, or the improvement which would naturally occur to a skilled engineer or workman in that line. For instance, the patent which covered the first circular saw mill adapted to sawing logs was declared invalid by the supreme court, as not amounting to invention, since they found the patentee had merely made a larger machine like earlier ones which were adapted for sawing laths.

As to the form of a patent, it is made up of a specification, or a describing part; and at the end there is a claim, or usually a number of claims, which state in a very concise way exactly what it is that is protected by the patent. For example, a claim for a new chemical product: "As a composition of matter; a phenol-methylene condensation product containing a halogenated phenolic substance incorporated therewith, substantially as described." You will notice that this describes what the invention actually is, instead of enumerating its advantages, which are stated in the body of the specification.

Patents may be taken out for new inventive compositions of matter, like the above; for apparatus or machines; for articles of manufacture, such as a new kind of phonograph record having a different kind of record groove formed on it; and for new processes. Not all processes are patentable. For instance, the mere statement of a law of nature is not. In the patent of S. F. B. Morse for the telegraph, the eighth claim was held void by the supreme court, as being merely for the use of an electric current for marking intelligible signs at a distance. He did not discover the electric current, and claiming just one principle of nature, as he did in that claim, was held unpatentable. If his process, as claimed, had been for the use of several laws of nature, in an orderly manner, to produce a new result, it would have been patentable. The use of a series of steps involving chemistry, light, electricity, or other natural sciences; or of a series of steps, all working to the same end, and which may be performed by hand or by different mechanisms, may be patentable as processes. A case in point is the art of weaving, when it was new. Claims for a machine cover a number of parts which work together to produce a new result. It doesn't matter if all or some of the elements of the combination are old by themselves, so long as the combination of them is new, and makes a new result, which is not obvious. But if the elements of the claim do not cooperate together, the claim is an aggregation, and unpatentable. For instance, the man who first put a rubber on the end of a lead pencil had his patent knocked out, since the court said both the pencil and the eraser were old, separately, and they acted separately, whether they were joined together or not.

What Constitutes an Infringement

The claims show what is protected by the patent. It is infringed by any device which one of the claims describes. If the claim has some elements described which are left out of the other device, it is not infringed by it. For instance, a claim for a machine might include a part that had to be

* For additional information on the subject of patents and kindred matters see "Filing Your Own Patent," by Ford W. Harris, published in the February, 1914, number of MACHINERY, and other articles there referred to.
† Address by Dyer Smith presented to the students of Lehigh University, South Bethlehem, Pa., January 9, 1914.

moved periodically, and a spring for moving it. That would not be infringed by a machine that left out the spring, and depended on gravity. But it would be infringed if a weight was substituted for the spring, in most cases, as that would be the recognized equivalent of the spring. If the patent stated that it didn't matter whether the part was moved by a weight or a spring, or by the positive actuation of another part which was clearly described, and then the claim included broadly "means" for moving the part, it would be infringed by any of these devices.

To get a patent, the application is prepared and filed in the patent office together with a filing fee of $15. The application consists of a petition; an appointment of an attorney to represent the applicant, unless he wishes to prosecute the application himself, as he has the right to do; the specification, describing the invention clearly and fully in connection with drawings if it is such an invention as can be illustrated by drawings, and having at the end a number of claims, as previously described; and an oath. A patent is a highly technical instrument, and its value depends chiefly on the skill with which it is written and prosecuted before the patent office, and particularly on the way the claims are worded when the patent is finally allowed. Therefore, it usually does not pay to attempt to do without an attorney, or to employ an attorney of doubtful standing or ability.

The patent is to be applied for by the real inventor, alone, if he made the invention by himself; and by two or more persons, jointly, if they made the invention jointly. If one man makes the invention and another puts up the money, they must *not* apply for the patent jointly, since, if it can be proved later that it was not the joint invention of both of them, the patent will be invalidated. So, also, the application must not be made in the name of the employer or superior of the inventor. But the employer is the real inventor if he conceived the invention, gave it to the employe to work out, and told him what to do; and the employe, in putting it into practical form, did no more than any good mechanic or chemical worker would do under the circumstances, in employing common knowledge. In this case, the employe may exercise invention in improving on the conception of his chief; and then two applications might be filed: one, on the broad idea, in the name of the chief and the other, on the improvement, in the name of the employe.

Similarly, if the invention is really the joint effort of two or more persons, the patent should be applied for in the name of all, since if it can ever be shown that the patent was taken out by less than all the inventors who jointly made it, it is invalidated. An invention is made jointly by two or more people when its conception and working out is the result of their joint effort. One suggests some features and the other, other features; and these different features cooperate in the operation of the complete machine or invention, and both men work out these features together.

I may say here, in passing, that many large corporations employ regular staffs of experimenters and inventors; and most of these concerns have contracts with these employes, which provide that the latter are to assign to the company all inventions made by them in the regular course of their employment. If the employe makes an invention at home, or away from the company's plant and out of hours, or on something not connected with his regular employment with the company, it belongs to him, unless, perhaps, he has contracted absolutely to assign to them everything he invents for a certain period. If there is no contract at all and you make an invention in the line of your regular work, for a person or corporation, the title to the invention remains in you and you cannot be compelled to assign it to your employer. In this case, however, your employer has a shop-right to the invention, or a license to make, use or sell the invention without paying you royalty. On the other hand, if you have taken out a patent, he cannot prevent you from licensing other parties to make, use and sell the patented device, or from selling the patent outright, subject to your employer's license, or from making, using and selling the device yourself. Of course, if you were employed by some concerns, and did these things, you might lose your job, which is a point to be considered.

Another point to be noticed is that if you have no written contract to assign your inventions to the company, but you always have done so and it is expected of you, there may be an implied contract so that they could force you to do so.

The Practice of the Patent Office

To return to the matter of securing the patent, we will assume that the application papers and drawings, with the filing fee of $15, are filed in the patent office. There are forty-odd different examining divisions in the patent office, in each of which are examiners who examine only certain particular classes of invention, and your application goes to one of these. For instance, if your invention is in wireless telegraphy, it is placed on the desk of a man who spends all his time in acting on wireless telegraph applications. In a month or more, or maybe less, he reaches your case, reads it, notes certain objections or criticisms, and proceeds to study the claims. He compares these, separately, with his knowledge of what has been done before, and searches the files of patents relating to wireless to find an anticipation for the invention expressed in each claim. He has at his command all the wireless patents of both the United States and foreign countries, and all the technical magazine articles and books of the world, relating to wireless, all classified according to the different subdivisions of the subject.

After his search, the examiner writes a letter, in which he probably rejects some of the claims, in view of certain earlier patents. The inventor, then, through his attorney, studies this action and amends the application, canceling some of the claims, perhaps, changing others somewhat, adding new ones, and arguing that others are all right as they stand. In course of time the examiner answers this, either by allowing the case or by again rejecting certain claims; the attorney answers again, and this process is kept up until either the case is allowed or finally rejected. If this latter happens, the inventor has several appeals permitted him to the Board of Examiners in Chief, then to the Commissioner of Patents, and then to the Court of Appeals of the District of Columbia.

It may happen that the application which you have filed covers the same invention, in whole or part, as other applications of other inventors which are pending before the patent office at the same time. For example, Alexander Graham Bell filed his first application for a patent for a telephone in February of 1876, on the very day that Elisha Gray filed a caveat covering the same general idea.

When two or more patent applications are pending before the patent office at the same time, the office determines to which one the patent should be issued by means of a proceeding known as an interference. This is started by the examiner arranging for a claim or claims in the same language to be adopted in all the interfering applications. In due course of time, if the interference is contested, testimony will probably have to be taken to determine who is the real inventor. It is not simply a question of which man files his application first in the patent office because if the opposing inventor had, for example, actually built the machine and tested it, or otherwise practiced the invention at an earlier date, he would be likely to win. It may be quite a complicated matter, but the main dates involved are, first, when you conceived the invention in your mind; and second, when you reduced it to practice by actually making and testing it successfully or, what is counted as the same thing, by filing an application on it in the Patent Office.

If you file your application before the other man has conceived the invention or done anything, you win, of course, without more ado. But if he reduced it to practice by actually making and testing a specimen of the invention before you did, and before you filed your application, he wins. If, however, you can prove that you conceived it first and worked steadily and diligently on the idea, perfecting it and making it practical from before the time your rival entered the field until you reduced it to practice or filed your application, you win. This shows the great advantage of keeping accurate records of what you do in conceiving and perfecting an in-

vention, and signing and dating all your sketches and records and having them witnessed, preferably by someone you trust, who can understand the invention and to whom you describe it. It also shows that if you have something that seems valuable and you have not or cannot reduce it to practice, you should file an application as soon as possible, since your delay, if not excused, may cause you to lose an interference, if you should get into one.

The Protection that a Patent Affords

As to the question of what protection a patent purports to give you; it gives you the right to exclude everyone else from making, using, or selling the thing patented, without your permission. It does not, necessarily, give you the right to make, use and sell the thing yourself, although it is a very common mistake to think that it does. You may not be able to make, or use, or sell, your own invention—even though you have a perfectly good patent on it—because your invention may be an improvement on an earlier patented invention, and the use of yours may infringe the claims of the earlier patent. To illustrate: Alexander Graham Bell was granted the first patent in telephones, and this was of an all-embracing character. The courts held that Bell had discovered, and that his patent in 1876 pointed out, the great principle that electrical impulses, induced by the vibrations of a current produced by sound waves, correspond in form and character to the sound vibrations which they represent. This is embodied very broadly in a claim in his patent, as follows. "The method of and apparatus for transmitting vocal or other sounds telegraphically as herein described, by causing electrical undulations similar in form to the vibrations of the air accompanying the said vocal or other sounds, substantially as set forth."

In the course of time it developed that this claim was so broad as to dominate the whole telephone industry. Practically, no improvement in the telephone could be used without using Bell's invention and infringing his patent until the end of the seventeen-year life of the patent. It was what is called a pioneer patent. Bell's actual device was crude, of course, and later inventors improved on it and took out patents on their improvements. For instance, Edison invented and patented the carbon transmitter. This was a long step in advance, for Bell's first telephone, using a magneto instrument like the present receiver for both transmitter and receiver, was much too faint. Edison's patent was a pioneer patent so far as transmitters of the carbon, or variable resistance type go; but it was merely an improvement on the broad invention of Bell, and Edison's transmitter could not be used without infringing the broad claim of Bell's earlier patent, since using the carbon transmitter in any telephone system would cause electrical undulation similar in form to the vibrations of the air accompanying the vocal sounds of the person using the telephone, as claimed by Bell. Therefore, Edison could not use his invention without Bell's permission. Also, neither Bell nor any one else could use Edison's transmitter without his permission. And when later inventors improved on Edison's transmitter, they could not use their improvements without his permission, if using or making their improvements involved using or making the combination of elements claimed in the Edison patent; and at the same time, neither Edison nor anyone else could use their patented improvements on the Edison transmitter without permission.

All this shows that before you buy a patent, or build a plant to manufacture something under a patent, you should first make sure that you are free to use your own patented device or process. A good patent lawyer should be employed to make an infringement search, and report to you what your rights are. Maybe all of the earlier patents in your line having broad claims have run out. Or maybe, while some of the earlier patents have pretty broad claims, your invention reaches its result in an entirely different way and does not infringe any of the claims of the earlier patents. Or you may find that while some of the earlier patents have claims which you seem to infringe, they are, as a matter of fact, broader than they had any right to be because of what was already old at the time they were taken out. In this case, the earlier patents will have to have their claims narrowed by construing their language to mean only what the patentee really did invent, and in that case you may not infringe. Or your lawyer may tell you that you infringe some patent with the exact device you intended to make, but that if you make certain changes you will escape the patent. Or it may be that you cannot get around some broad earlier patent at all, and then, if you cannot show that the earlier patent is invalid for some reason, you will have to either sell out or take your chances of not being molested, or else just keep the patent for what it may be worth to you to prevent competitors from using your patented improvement.

The Scope of a Patent

The scope or value of a patent, as you will now readily understand, depends largely on the claims. The claims are broad when it is hard to get around them and narrow when it is easy to get around them. As a general rule, the more details that are set forth in a claim the narrower it is, because competitors can supply other details or leave some of them out, and so avoid infringing. The Bell telephone claim was very broad, because it covered the method and apparatus necessary for telephone communication in its essentials, without being limited to any details. If Dr. Bell and his attorney had not realized the true fundamental scope of his invention, and had claimed it only by its details, it could easily have been gotten around and the Bell companies would not have had the monopoly they did for the life of his first patent. For example, Bell might have claimed "Apparatus for transmitting vocal or other sounds telegraphically, consisting in an electrical circuit, connecting two distant points; a magnet situated at each of said points, the coils of which are included in said electrical circuit; a diaphragm of soft iron positioned to act as a vibrating armature for each magnet; and a mouthpiece in front of each diaphragm, whereby vocal or other sounds impinging on either diaphragm cause electrical undulations similar in form to the vibrations of the air accompanying the said sounds to pass over the line to the distant coil, substantially as set forth."

That would claim the invention only with respect to the particular means for carrying it out, which Bell had in mind when he filed his application—one main line circuit in which the magnetic transmitting and receiving instruments are placed, the electric impulses generated directly by the sound waves passing over the line. That would not have been infringed by Edison's invention, since his sending instruments are not in the main line circuit at all, as claimed in my hypothetical claim, but in local circuits with the batteries and primaries of the induction coils; and because Edison's transmitters do not include magnet coils, but are devices for varying the resistance in the closed local circuit with the battery.

So you see how Bell might have lost his monopoly by claiming his invention too narrowly—that is with too many details in the claim. But he could very well have had some narrower claims like the one I made up, in addition to his broad claim, and then if the courts had held that he wasn't entitled to the broad claim but was entitled to some of the narrower claims, he would have had a monopoly so far as the narrow claims went. Each claim is like a separate invention, and they all have to be considered separately, without reference to each other.

When it is Worth While to Take Out a Patent

The question of when it is worth while to make inventions and take out patents should be considered in a business-like way, and not gone into as a blind speculation. The farmer who passes the long winter evenings by inventing and patenting a non-refillable bottle probably loses his time and money, since he doesn't know what the practical conditions and needs of the bottling business are. But he does know something about plows, and if he sees how an improvement can be made which will cheapen the plow or make it do better work, he has something he can figure on. You, as engineers, are in a better position to realize on inventions than the farmer, for engineering problems are involved. Suppose, for instance, you are familiar with the coal business and get an idea that would seem to make the dumping of coal cars a much cheaper

and quicker proposition, and would simplify the construction of the cars. You calculate as an engineering proposition that it can be done practically and that there are no objectionable features about the scheme which would overcome the advantages. You look over the trade catalogues and decide that your scheme would really effect a considerable saving over any of the advertised devices, so much so that different concerns should be very glad to get it.

Then you go to any good patent lawyer and have him make or have made what is called a preliminary examination. This is inexpensive, and results in showing you the four or five earlier patents which are nearest to your scheme. Some of these may be so similar that it is evidently not worth while going to the expense of applying for a patent, in spite of the fact that you never heard of such a device being on the market. Or it may be that yours is quite different, or again that some of these patents are similar in a general way to yours, but lack some important details, which make yours a practical success, while they were practical failures. If your attorney tells you that the improvement is something that amounts to invention, as it probably does, the patent that you then apply for and get will be valuable in spite of being only for an improvement, since the improvement is needed to make the device a real practical success.

While I have emphasized the necessity of only trying to patent practical things, that does not necessarily mean that what you have invented must be in highly perfected form before you apply for your first patent. If you feel that you have the principle of something that will work, and that there will be a future demand for, it does not so much matter that your first device is crude. Bell's first telephone, Edison's first phonograph, and Selden's automobile were all crude; but their patents were gold mines because they described the big, fundamental ideas that, in the form of patent claims, gave them broad protection. The crude devices they described as particular embodiments of their inventions would work to some extent, and illustrated the principles which the inventor had discovered.

What to do with Your Patent

This brings us to the question of what to do with the patent when you get it. If you already have a manufacturing business in which your invention can be used it is simply a matter of stamping "Patented" with the date, on the thing you make—if the patent is on a product of your factory—and seeing to it that your rights are respected. When your competitors know that you operate under a good patent, they will be likely to keep off, or will stop upon your notifying them that they infringe. Sometimes it is necessary to actually bring suit, and the defendant may decide after you have started the suit that it is better and cheaper for him to give up rather than to fight the suit to a finish; and either pay you a royalty in future, or get out of that line altogether. If your competitor is big and rich, and unscrupulous, it will be a question whether the expense of fighting him through to a finish will be compensated for. This should be calculated in advance, so far as possible.

Once you have won one suit on your patent and had the patent declared valid by the court, you are in a much better position; and you can almost immediately get preliminary injunctions against other infringers, to have their operations stopped. You should understand that when you bring suit for the infringement of a patent, the defendant can—in most cases—allege and attempt to prove that your patent is invalid, as well as that he does not infringe it. It may be invalid, for example, because the claims are too broad in view of earlier patents. The court may either decide that your patent is valid and infringed, as to the particular claims you allege are infringed, or that some of them are; or that it is valid but not infringed in the particular case, decided, or that it is invalid. If the verdict is against you, and the matter is of sufficient importance, you may appeal from the United States District Court where the case was tried to the United States Circuit Court of Appeals for the circuit in which that particular district court is situated.

The result of having your patent sustained by a suit may be to cause all the infringers, or those who would like to use the invention, to pay you royalty for the life of the patent. Or you might decide to license a limited number, giving each one rights for a different part of the country on payment of royalty; or, of course, you could sell outright, or else give an exclusive license to one concern alone.

If you take out the patent as an individual, without any manufacturing connections, the first thing to decide will be whether to manufacture under it, sell the patent, or license one or more parties to use it on payment of royalty to you. To get the greatest advantage out of any of these courses requires the expenditure of thought, time and money. This is obvious as to the manufacturing. Perhaps you can sell out, if the patent is for something useful, without much trouble; but the patent will have much more value after it has been declared valid as the result of a suit brought for its infringement. A good scheme for an individual patentee who does not expect to manufacture, himself, is to form a small company to develop and exploit the invention, and thus get in some money as working capital. You will then be in good position to bargain with people whom you may hope to interest or to give licenses to, and to protect your rights in such fashion that it will be plain you are not to be trifled with. I know one man who recently took out some broad patents on automobile mechanism, started various suits against owners of automobiles who went back to their dealers for protection, and eventually signed a license agreement giving an important association of manufacturers rights on royalty, from which he is realizing a very considerable sum. Another inventor I have in mind—a chemist—has associated himself with another man as a sort of manager; and they are continually forming small companies to exploit his inventions, which they license manufacturers to use and thus make a good income.

Conclusion

In conclusion, patents have been a tremendous aid to the business and manufacturing of the country, and to the inventors themselves when they have been good business men or have associated themselves with good business men, and when they have applied good practical and engineering sense to their problems. The patent system may well be improved in some ways to make its operations cheaper and quicker, and something has lately been done in this direction, but legislation which has been proposed to cut down the inventor's reward, or that of a corporation to which he sells his patent should not be approved, and various engineering societies are on record as being opposed to such changes.

WESTINGHOUSE ELECTRIC VETERANS' ASSOCIATION

The employes of the Westinghouse Electric & Mfg. Co., East Pittsburg, Pa., who have been in its employ for a period of twenty years or more held a meeting and organized the Veteran Employes' Association of the Westinghouse Electric & Mfg. Co., Saturday evening, February 21. About 325 employes of the company are eligible to membership and approximately 315 of these were at the meeting. L. A. Osborne, vice-president of the company, was toastmaster at the dinner. E. M. Herr, president, Charles A. Terry, vice-president, and James J. Barrett, representing the shop, made speeches. Guy E. Tripp, chairman of the board of directors, was elected an honorary member of the association, as was also Mr. Herr, neither of whom have been connected with the company the required twenty years. A standing toast was drunk to George Westinghouse, who was unable to be present on account of illness.

* * *

It is stated in the *Railway Age Gazette* that a large increase in the capacity of passenger locomotives has been made possible by the use of alloy steel, properly heat-treated, for the reciprocating parts. This material effects a considerable reduction in the weight of the counterbalances, and thus allows an increased load to be applied to the driving-wheels. Hence, the boiler can be materially enlarged and the capacity of the locomotive as a whole increased without adding to the total weight.

COUNTERBALANCED AND INDEXING FIXTURES

VARIOUS TYPES OF SPECIAL FIXTURES ILLUSTRATING DIFFERENT METHODS OF COUNTERBALANCING AND INDEXING

BY ALBERT A. DOWD*

Work of irregular form having several holes to be machined, and castings or forgings in which a single hole is to be bored at one side of the piece, require special fixtures upon which they can be clamped for the machining operations. There are a number of conditions which affect fixtures of this kind; for instance, the work may be small and of light weight,

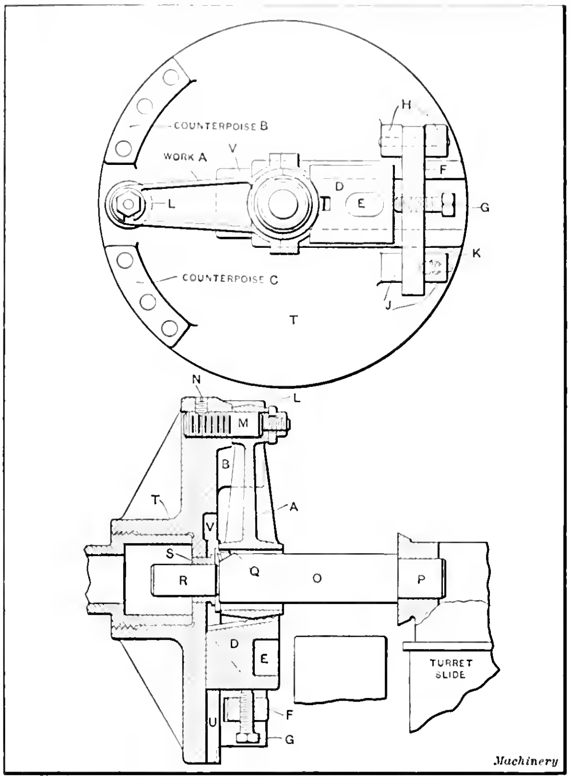

Fig. 1. Counterbalanced Fixture for Connecting-rod

or it may be large and very heavy; it may have several parallel holes, or they may be at various angles, sometimes even converging to a common center; the part may be very much one-sided; it may have been partially machined in some previous setting, or perhaps is a rough casting or forging. All these things affect the design of the fixture, as does the type of machines to which the fixture is to be applied.

Counterbalanced fixtures are used only on the class of machines where the work itself revolves, such as engine lathes, turret lathes, boring mills and cylindrical grinding machines. Indexing fixtures, however, can be used on all the foregoing, and also on many other machines, such as drill presses, milling machines, planers, shapers, slotters, etc. Very frequently indexing fixtures are supplied with some provision for counterbalancing, when used on the first-mentioned group of machines. Sometimes this counterbalance is so arranged that it can be moved to suit different conditions, and, in other cases, it is made solid with the fixture and is carefully balanced at the time the fixture is made. There are two things which must be carefully considered before any attempt is made to design a fixture, *viz.*, the machine most suited to the work in question, and the speed at which it will have to run in order to be thoroughly efficient. The latter is important if a counterbalance is to be used, because more care must be exercised in the balancing if the fixture is to be run at high speed. In addition to this, a high-speed fixture should be arranged with a suitable guard (if cutting lubricant is to be used) so that the operator will not have to wear a bathing suit. It is evident, therefore, that these things should be thought of before the design of the fixture is started. This is one of the cases where "an ounce of foresight is worth a pound of hindsight," for when a device of this kind is finished and ready to put on the machine, it is very annoying to be obliged to hold up the work a couple of days while a guard is being made and fitted. Incidentally, it does not redound to the designer's credit, for it should have been thought of in advance.

* Address: 84 Washington Terrace, Bridgeport, Conn.

A Few Points on Fixture Design

1. Rigidity. This is of prime importance in every kind of a fixture, and when the fixture is designed for use in a horizontal machine, the overhang from the end of the spindle should be made as short as possible in order to prevent vibration.

2. Positive location for the work and rapid-acting clamping devices of such a nature that it is not necessary to disturb them when indexing the fixture. In this connection it might be mentioned that the writer has seen indexing fixtures which were so designed that the clamps holding the work required loosening before indexing. Needless to say, this is very poor design.

3. Method of obtaining accurate indexing with provision for taking up wear at the locating points. Either taper pins or taper wedges are suggested.

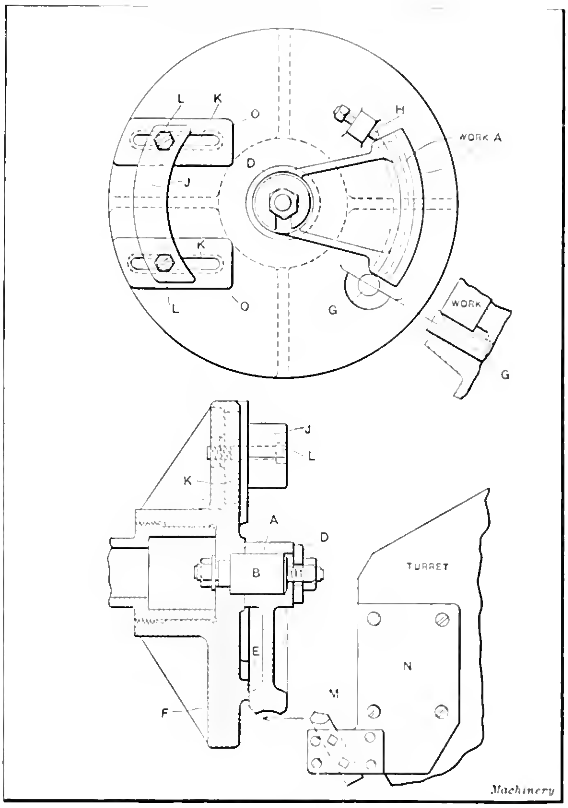

Fig. 2. Fixture with Adjustable Counterbalance

4. Adequate protection from dirt and chips so that errors in indexing will not be caused by imperfect contact at locating points. This point is of special importance on fixtures indexing in a horizontal plane, as for example, those used on a milling machine or a vertical boring mill.

5. The method of counterbalancing. If the counterbalance is to be a part of the fixture, the weight must be figured so that it will slightly exceed the portion which it balances in

order that it can be drilled out or chipped off when assembled with the work in position, to obtain a smoothly running fixture. A sliding counterpoise is a very good arrangement when several pieces of a similar kind are to be machined, for it can be so proportioned that it will take care of varying conditions.

6. Rapidity of handling, both in clamping the work and in the operation of the indexing mechanism. As these two points make considerable difference in the cost of the fixture,

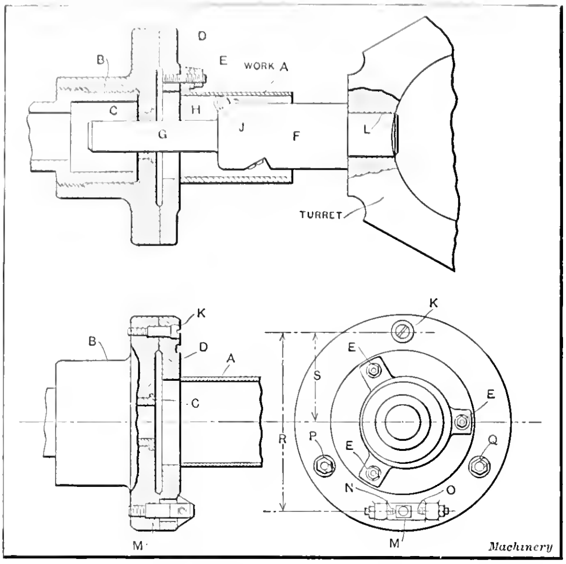

Fig. 3. Swinging Fixture for Eccentric Piston Ring

they should be proportional (to a certain extent) to the number of pieces which are to be machined. In fact, the entire fixture should be designed with this point continually in mind, so that its cost as a whole will not be too great.

Counterbalanced Fixture for a Connecting-rod

A very good example of a simple counterbalanced fixture is shown in Fig. 1. In this case the work *A* is a steel connecting-rod forging which has been faced on both sides and the wrist-pin hole in the small end has also been bored and reamed in previous operations. This fixture is used to bore and ream the large hole at a fixed distance from the wrist-pin hole and parallel thereto, the machine being a horizontal turret lathe. The body of the fixture *T* is of cast iron and is screwed to the spindle. The steel stud *M* is screwed into the body and is held in position by the pointed set-screw *N*. It is located at the correct distance from the center of the spindle and is turned down and threaded at one end to receive the U-washer *L* which is clamped down on the work by the hexagon nut shown. The sliding V-block *D* is dovetailed to fit the slide *U* in the body of the fixture. This centers the work from the outside of the forging and it should be noted that it also has a holding down action due to the angularity of the V-block. This is clearly shown in the lower view. The lugs *H* and *J* act as supports for the swinging latch *F*, and the detent pin *K* keeps the latch in position. The block *D* is clamped against the work by the square head set-screw *G*, located in the latch. The elliptical hole *E* is a finger hole by which the block is pulled back out of the way when removing and placing a new piece of work in position. The cored pocket *V* in the body of the fixture is provided so that the V-slide can be planed without difficulty, the pocket allowing a place for the tool to "run out."

The lugs *B* and *C* serve to counterbalance the weight of the latch and blocks on the opposite side and are at first proportioned so that they are somewhat heavier than necessary. After the work is put in place on the fixture it is carefully balanced by drilling into these lugs until sufficient stock has been removed to secure this result. Attention is called to the fact that the counterbalance is located as far from the center of the fixture as possible. This is done in order to make the weight more effective. A hardened and ground tool steel bushing *S* is located in the fixture body and acts as a guide for the boring-bar pilot *R*. The bar *O* is turned down at the rear end, as shown at *P*, so that it fits the turret hole. A recess in the fixture allows the boring tool *Q* to pass slightly beyond the work. A pilot bushing in the spindle might have been preferable, in that there would have been more space in front of the tool. If this had been done, however, the fixture would not have been self contained.

Adjustable Counterbalanced Fixture for a Worm-gear Sector

A condition which is somewhat out of the ordinary is illustrated in Fig. 2. The work shown at *A* is of two different sizes. The outside diameter is almost the same, but there is considerable difference in the weight of the two castings, one of them having a much wider rim than the other and also a heavier web section. Therefore it was necessary either to make the fixture in such a way that it would take care of both pieces, or else make two fixtures. As all other points in design would be the same, it was decided to make a movable counterpoise which could be adjusted to take care of the difference in weight.

The fixture body *F* is of cast iron, and is screwed onto the spindle as shown in the lower view. The locating stud *B* is shouldered and is held in place by a nut and washer on the inner end; the outer end is turned down and threaded to receive a hexagon nut which clamps the work through the U-washer *D*. The pointed set-screw *H* is set at a slight downward angle and forces the work over against the stud *G*. The partial section shows how the angular part of the stud tends to overcome any tendency to lift or strain the casting out of

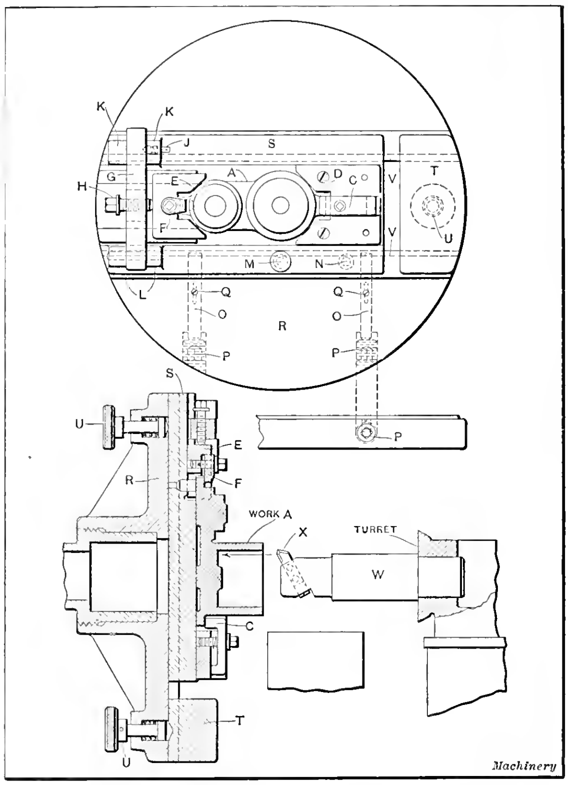

Fig. 4. Fixture with Adjustable Slide and Counterbalance

its correct position. The circular pad *E* forms a resting place for the work. The counterpoise *J* is a cast-iron segment resting on the two finished surfaces *O*. Two slots *K* permit the passage of the screws *L* which clamp the counterpoise in the desired place. An enlargement of the slots on the back of the body serves to prevent the hexagon nuts from turning when the weight is being adjusted. The lower part of the illustration shows the tool-holder *N* fastened to the face of the turret and ready to take a straight cut on the outside of the

sector with the tool M. This arrangement was very satisfactory in every respect. The two sectors were put in position and the counterweight adjusted for each piece, the pads being marked by a scratch line so that the counterweight could easily be placed in either position.

Swinging Fixture for an Eccentric Piston Ring

The work A shown in Fig. 3 is a cast-iron ring-pot from which eccentric packing rings are turned and cut off. Previous to the machining operation indicated, these pots are rough-ground on the back of the clamping lugs E, and are also

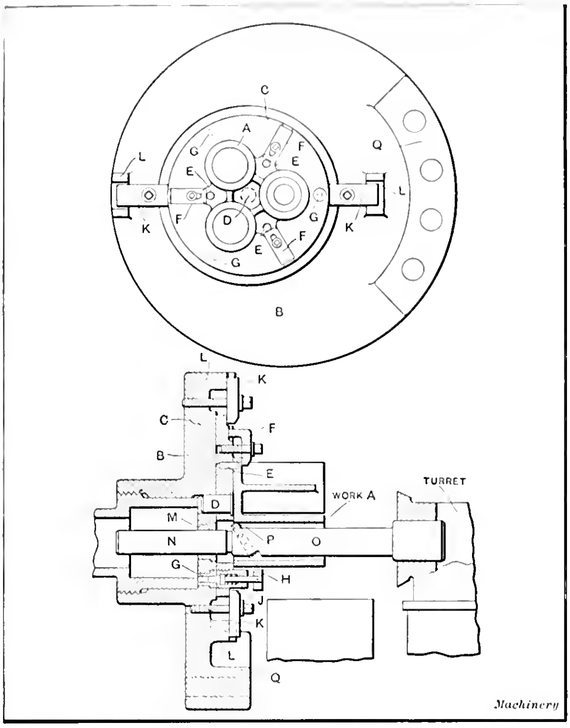

Fig. 5. Counterbalanced Indexing Fixture for Triple Cylinder

jig-drilled at these points. The customer for whom this fixture was designed did not wish to go to the expense of a special attachment for boring and turning eccentric at the same time. Therefore it was considered expedient to design the holding device so that it could be set over to produce the proper amount of eccentricity without re-setting the casting. The machine on which the work was done was a horizontal turret lathe of standard make.

The work A is located on the three studs E, and held fast by nuts and washers. The body of the fixture B is of cast iron and is screwed onto the end of the spindle. It is fitted with a bushing C which acts as a guide to the pilot end G of the boring-bar F. The swinging plate D is pivoted on the shouldered screw K, and it should be noted that this screw is set well down into the body of the fixture to give additional strength. An opening is provided in the plate D so that the square stud M in the body can extend out through it to act as a stop for the screws N and O in the swinging plate. These screws are provided with check-nuts so that they can be locked after being properly adjusted. In this particular case, the eccentricity of the ring was 1/16 inch and, as the distance R on the fixture was made exactly double the distance S, only 1/8 inch adjustment between screw O and stud M was required to obtain the correct setting. The studs and nuts P and Q are used for clamping the plate firmly to the body, the holes being slightly elongated to permit the necessary movement. In the operation of this device, the tool J in the boring-bar F was first used to bore the hole. The plate was then swung over against the stop and the turning tools machined the outside eccentric. Excellent results were obtained with this device.

Counterbalanced Indexing Fixture for a Carbureter Body

The work A in Fig. 4 is a brass carbureter body, and the fixture for it is considerably out of the ordinary in regard to the counterbalancing. The shifting of the slide from one side to the other makes it necessary to arrange the weight in such a way that it can be changed quickly from one side to the other, as occasion may require. The machine used with this fixture is a Pratt & Whitney turret lathe. Prior to this operation the casting is milled on one side on a vertical milling machine. It should be noted that a lug is left on the casting at each end for clamping purposes; this is cut off after the machining operations have been completed.

The body of the fixture R is cast iron and it is screwed onto the spindle. The slide S is fitted to the dovetail V in the body of the fixture, and the indexing locations are obtained by a taper pin in the bushings M and N. The clamping of the slide in each position is effected by the shoes O; these are beveled to the same angle as the dovetail and are prevented from turning by the set-screws Q which bear against the flat portion of the shoes. The hollow set-screws P act against the ends of the shoes and hold them firmly against the dovetailed portion of the slide. The work is located by the V-blocks D and E, which center the rough casting. The block D is screwed and doweled to the slide and contains the clamp C which bears against the lug on the casting. The block E at the other end is dovetailed on its lower side and fits the slide. The clamp F grips the lug and draws it up against the stud shown in the lower view. A latch G is pivoted on a pin in the lugs L and enters a slot in the opposite lugs K where it is retained by the detent pin J. The screw H forces the V-block against the casting. It will be noted that the latch is so hung that if the machine should be accidentally started while the latch is open, the latter would tend to close without damage to the fixture. This point in design is frequently overlooked and yet it is well worthy of attention.

The counterpoise T is of cast iron and is an easy sliding fit in the dovetail of the body, so that it can be removed without difficulty. It is countersunk on its lower side to receive

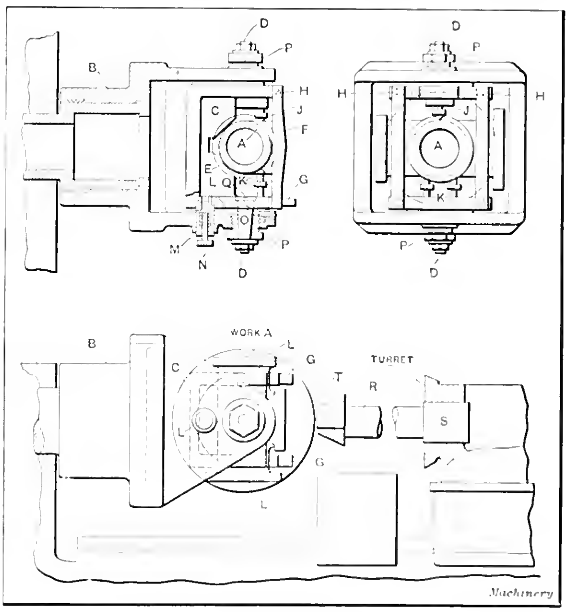

Fig. 6. Indexing Fixture for Cast-iron Valve Body

the spring detents U, which are located on opposite sides of the fixture. It is evident that this counterpoise must be transferred from side to side as the slide is indexed from one position to the other, so that the balance of the fixture can be preserved. The boring-bar W is shown in position in the turret; the tool X is used to rough out the pocket, as indicated by the arrow. This fixture was made up several years ago for an automobile factory in the eastern states, and it was used with good results for one season's production. It was

abandoned only on account of a change in the carbureter design and not because of any fault in the fixture itself.

Counterbalanced Indexing Fixture for a Triple Cylinder

The work *A* in Fig. 5 is a triple cylinder of cast iron with three bored and reamed holes equidistant about a common center *D*. The fixture was used on a horizontal turret lathe. The arrangement of swivel-plate, clamps and counterweight was made as symmetrical as possible so that very little change in the balance of the fixture would take place when indexing from one cylinder to another. The work was milled across the base and the holes *E* jig-drilled before the turret lathe operation took place. The body of the fixture is screwed onto the spindle and is made of cast iron. The swivel-plate which holds the work is also of cast iron and is pivoted on the hardened and ground steel stud *D* which enters the body. The three pins *E* act as locaters and drivers; they are in the plate and match the jig-drilled holes. Three clamps *F* are used to hold the piece, and they are bent over on the ends so that they enter a slot in the plate, which prevents them from turning while the screws are being tightened. They are also slotted so that they can be pulled back out of the way when putting the work in position.

A hardened and ground steel plunger *H* (shown in detail in the lower part of the illustration) is tapered to fit the

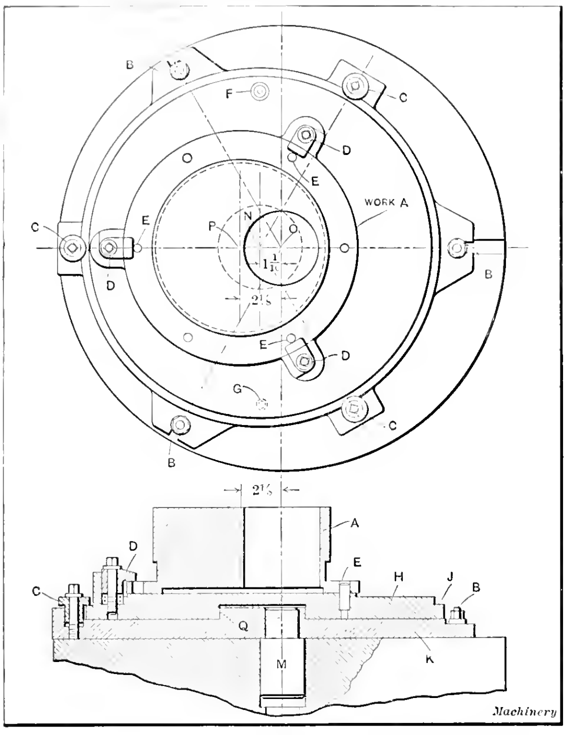

Fig. 7. Indexing Fixture for turning and boring Eccentric

bushings *G* which control the indexed locations as the plate is swiveled. The steel bushing *J* acts as a bearing for the pin and also forms a pocket for the spring. The clamps *K* are loosened when indexing the plate but are set up again before the machining is done, so that rigidity and freedom from chatter are insured. The counterpoise *Q*, in this instance, is a part of the body casting. At first it is somewhat heavier than the parts to be balanced; it is then brought to the required weight by drilling out the stock after the work is clamped in position. Attention is called to the fact that the body *B* contains a bushing *M* in which the piloted end *N* of the boring-bar *O* is guided. It will also be seen that considerable chip room is provided for the tool *P* when it passes through the work. The results obtained by the use of this fixture were perfectly satisfactory.

Indexing Fixture for a Cast-iron Valve Body

The work shown at *A* in Fig. 6 is a cast-iron valve body to be machined complete at one setting. It will be noted that the holes are at 90 degrees with each other, so that the fixture required indexing through an arc of 180 degrees during the process of machining. The casting is in the rough state when placed in this fixture. The cast-iron body *B* is screwed to the spindle, and its forward end is formed like the letter *U* to receive the swivel-bracket *C*, which holds the valve body. This swivel has a pair of V's which serve to

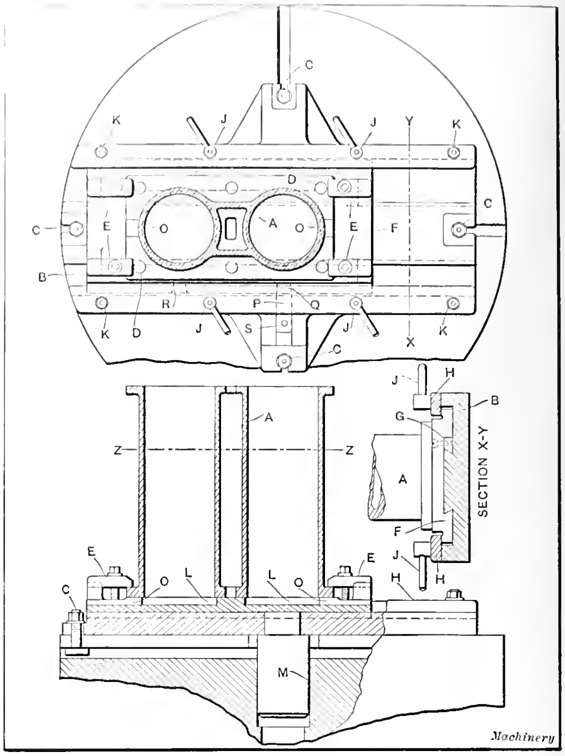

Fig. 8. Adjustable Fixture for Twin Cylinder

locate the casting centrally in one direction. The swinging clamps *F* are pivoted at one end on the shouldered screws *H*, and they are clamped against the casting by the action of the thumb-screws *G*. The work is centered in the other direction by the steel "bull-center" *T*, which is forced onto the shoulder of the bar *R*. This center is used in the rough cored hole before the clamps have been set up tightly, and while it is in

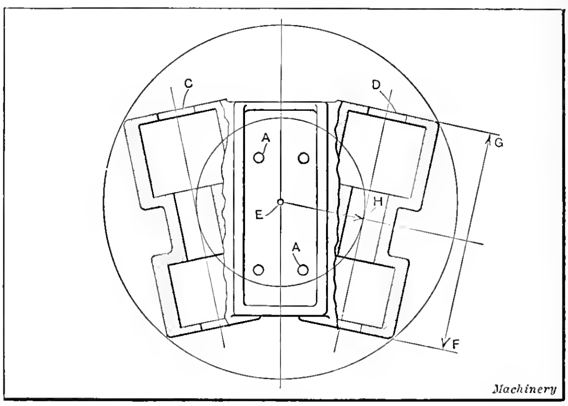

Fig. 9. Roller Bearing Bracket machined with Fixture shown in Fig. 10

position, all screws and clamps are tightened. The pointed set-screws *J* and *K* overcome any tendency of the casting to move during the machining operations. The bearings for the swivel are somewhat out of the ordinary as they are provided with a "take-up" for wear. The hardened and ground steel studs *D* are screwed into place in the swivel and are tapered on their outer ends to form the pivots. The threaded

bushings P are milled hexagon on the ends and are tapered on the inside to fit the pivots. Headless set-screws prevent the bushings from turning.

The indexing locations are determined by the bushings L, which are forced into the swivel at the three points shown. These bushings are tapered on the inside to fit the pin N, which is also encased in the bushing M. A coil spring assists in keeping the pin in position. This fixture was not satisfactory due to the overhang of the spindle and a certain tendency to chatter caused partly by the excessive overhang

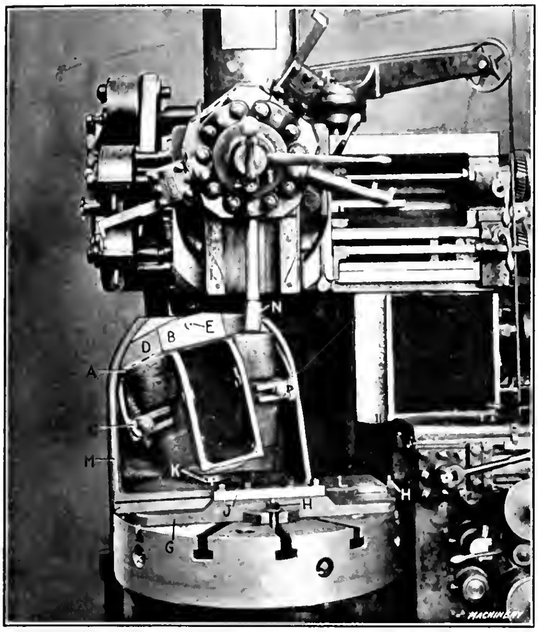

Fig. 10. Bullard Vertical Turret Lathe arranged for machining Roller Bearing Bracket

and partly by imperfect balance when in either of the positions not shown in the illustration. The writer has, however, applied a fixture of very similar construction to a vertical turret lathe with perfectly satisfactory results, showing that the greatest fault was in the excessive overhang when used on the horizontal type of machine. Some of the details of construction in this fixture may, however, be applied to advantage on other work, and it is of considerable value in showing "what not to do," for we really learn more by failures than we do by successes, although a failure may be somewhat expensive.

Indexing Fixtures for the Vertical Turret Lathe

Let us now take up the subject of fixtures which are designed for use on machines of the vertical spindle type. In the majority of cases, it is not necessary to provide counterbalances for this type of fixtures because of the construction of the table bearing which always tends to center itself on account of its conical form. The great weight of the table is also of assistance in overcoming trouble which might be caused by heavy castings of an eccentric or one-sided form. It might be possible to have a manufacturing proposition come up which called for a great number of very heavy eccentric castings of the same kind. In a case of this kind, a counterweight might be used in order to save the machine from excessive strains and unequal wear on the spindle and table bearings. It is not, however, the usual practice to make any provision for counterbalancing.

Indexing Fixture for an Eccentric

A rather peculiar fixture is shown in Fig. 7, this having been made for a vertical turret lathe. The work A is of cast iron and is an eccentric strap. In a previous operation this has been turned, faced, and recessed on the flange side, having been held by the solid portion of the body at this setting. The operation of drilling the flange holes in a jig also took place before the setting shown in the illustration. The work for which this fixture was designed is the boring of the eccentric hole, the facing of the top, and the turning of the outside portion. The casting is located by the three pins E in the swivel-plate H and is clamped down by the three hook-bolts D. It will be noted that these hook-bolts are well backed up by bosses on the swivel plate. The backing is cut away on one side so that the bolt can be swung around when placing a new casting in position. The coil springs underneath assist in releasing. This swivel plate has the point N (shown in the upper view) for its center and swings on the boss Q. As point N is equidistant from O and P, it follows that when the swivel-plate is swung around 180 degrees, it will be in the correct position for turning the outside diameter. The three buttons C are set in the base K and act as clamps on the annular shoulders J of the swivel plate. The base itself is held down to the table by the T-bolts B, which enter the table T-slots. It is centered on the table by the plug M. The indexing locations are determined by the bushings F and G in the base. These bushings are tapered to fit a taper spring-pin in the swivel-plate. It will be noted that this method of holding the work made it possible to perform all the turning operations in two settings.

Twin Cylinder Fixture for the Vertical Turret Lathe

The casting shown at A in Fig. 8 is a twin cylinder which has previously been machined across the bottom, and in which the flange holes have been jig-drilled. The casting is placed on the sliding plate F and is located by the two pins D which are diagonally opposite each other. The four clamps E are used on the flange to hold the work in position. It will be noticed that the two recesses at L permit the boring tools to pass completely through, and provision is made for cleaning out these pockets by sweeping the chips into the two grooves at O. Attention is also called to the fact that these pockets are not bored entirely through the slide, for if this were done trouble might be experienced with chips or dirt. The slide is dovetailed on its lower side, as shown in the section X—Y, and provision is made for take-up by the gib G.

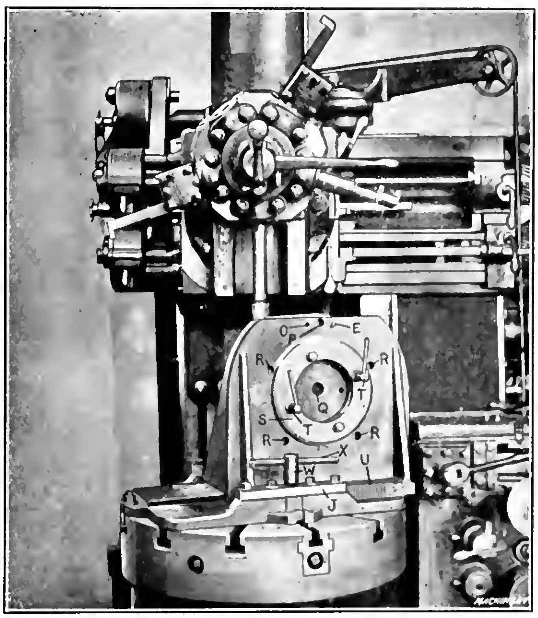

Fig. 11. Rear View of Fixture for Roller Bearing Bracket

The base of the fixture B is bolted to the table by the T-bolts C and is centered by the stud M. The steel strips H are so fitted that a sliding fit is insured when the binders J are loosened. The indexing is governed by the taper wedge shown at P in the upper view. This wedge enters the two slots Q and R which are tapered to receive it. The pin S is used to pull the wedge out of engagement. It will be noted that the view of the work shown in the upper illustration is a section taken on the line Z—Z, in order to make the construction more apparent.

Indexing Fixture for a Difficult Piece of Work

Fig. 9 shows a partial section of a steel casting which is of considerable size and weighs nearly 300 pounds. It is a tangential roller bearing bracket in which four large pockets are provided to receive the rollers. The center-lines of each pair of pockets *C* and *D* meet at a common center, which is so far outside of the casting proper that it is obviously out of the question to design any sort of fixture for it using this center as the pivot point. Therefore an arbitrary center *E* was used as a pivot for the work, this point being half way between *F* and *G* and on a line perpendicular to the axis of the bearings. It is apparent that the work can readily be swung on this center a sufficient amount to bring the center-lines parallel to the axis of rotation. The back of the casting has been milled off on two parallel pads (not shown in the illustration) and four small holes jig-drilled before the work is placed in the indexing fixture. The two holes *A*, which are engaged by pins on the fixture, are used for locating the casting.

Fig. 10 shows a front view of the vertical turret lathe having the fixture in position on the table. The work *A* is slipped onto the two pins mentioned and is drawn back against the finished surface *B* by the two clamps *C*, which are C-shaped to permit rapid handling. The swivel-plate *D* is of cast iron and has an 8-inch annular ring at the back on which it pivots. This ring is made of generous size in order to give greater rigidity, and also to provide a means of clamping when the work is indexed. The pin *E* is tapered and fits the tool-steel bushings which determine the swivel locations. The sliding portion *M* of the fixture is dovetailed to fit the base *G* and rigidity is secured by gibs *J* in addition to a dovetail gib not shown in the illustration. The screws *H* hold the base down at four points where they enter the table T-slots. Another taper pin shown at *K* is used in obtaining the longitudinal locations. A core drill *N* is shown in position in the turret, and other tools used in machining may also be noted in their respective positions.

Fig. 11 shows a rear view of the fixture; the protruding end of the taper locating pin may be noted at *E*. The other bushing *O* gives the correct location for the other hole in the casting. The two holes *P* and *Q* have nothing to do with the fixture itself, except that they were used by the toolmaker in order to fix his locations more conveniently. A steel clamping ring *S* draws up the swivel-plate tightly after indexing, by means of the two binders *T*. The four holes at *R* give access to hollow cup set-screws in the swivel-plate. These set-screws are brought up against the rough casting to give additional support. A clamping gib on this side of the fixture is provided with a hole through which the squared stem of a twelve pitch pinion protrudes. This pinion meshes with the rack *U* on the slide. The socket wrench *W* fits the squared head of the pinion, and it is provided with a sliding handle *X*. This sliding handle was a necessary feature as several revolutions of the pinion had to be made to obtain the required movement of the slide. As the sliding portion of the fixture with work attached weighed about 800 pounds, it will be seen that some method of traversing the slide was necessary, so that the operator would not be compelled to push it over by hand. This fixture was built for the Bullard vertical turret lathe and its action was very satisfactory.

THE SOCIETY OF AUTOMOBILE ENGINEERS AND STANDARDIZATION

Howard Marmon, secretary of the Nordyke & Marmon Co. and retiring president of the Society of Automobile Engineers, recently stated that the society is now one of the great engineering bodies of the world. It has a membership of nearly 2000 and is a most vigorous expression of the world's fourth industry. It is, in many ways, a unique organization, but it is not merely an organization—it is a working agency of high efficiency. Every day the work of this society leaves its mark on the American automobile industry. The problems that this body has had to solve were much the same problems, diverse and complex, that faced the railroads and their allied industries in their days of rapid growth. The automobile business brought with it almost innumerable engineering, manufacturing and industrial questions that demanded, and that still demand, quick and skillful consideration.

The modern car has reached its present stage only after a great amount of experimentation. During the past few years the Society of Automobile Engineers has directed this work. What, then, has the society accomplished? Among other things, it has raised the standard of design and effected the standardization of parts. This may not mean much to the average user, but the engineer and the producer know very well how large an undertaking it has been. To standardize an apparently unimportant part often means an amount of labor incomprehensible to the non-mechanical mind. Past construction must be borne in mind, and yet the advance to a new standard of merit must be made. The varying views of engineers must be considered and commercial demands must be regarded, for after all automobiles are made to be sold. Where motor-car companies used to pay eight to ten cents a pound for "double extra special" crankshaft steel they now buy "S. A. E. Specification 10-40" at two or three cents a pound—the same quality in every respect. The engineers of the steel division of the standard committee got together, and using common sense as a text, obtained from the steel makers a commercial price for their wares.

Before the standard committee had formulated its specifications there were 1100 sizes of seamless steel tubing, differing by a few thousandths inch—just enough to make life miserable for the manufacturer. Now the "Data Book" which is rapidly becoming the automobile engineer's bible specifies 160 sizes only. These made up in large quantities come cheaper and delivery is quicker. The result is that the prices of the motor car are less. The owner may now try various carbureters without having his car entirely rebuilt. Gasoline pipe sizes and threads have been made standard, as have the lever connections and the flanges which are joined to the engine or the intake pipe. No longer is a car owner unable to shift from one magneto to another. Again the reason is that magneto bases and connections are now made the same. Wheels for motor trucks have been standardized. They used to vary by small dimensions, and the manufacturer ought to keep in stock four sets of wheels for each truck to meet the varying sizes of tires produced. Now all the tire manufacturers make their tires to conform to S. A. E. standards. Tires are interchangeable on the same wheels. It is estimated that this reform alone has saved $300,000 within the past year.

INFLUENCE OF VARIOUS METALS ON THE CORRODIBILITY OF IRON

Silicon in iron increases greatly its tendency to corrode; 0.3 per cent of silicon will make iron rust 20 per cent more rapidly than would ordinary iron free from silicon. On the other hand, alloying steel with nickel or copper gives it increased resistance to corrosion; 0.20 per cent of copper in steel produces a material which is attacked by acids at one-tenth the rate of ordinary iron. The corrosion in the atmosphere is only one-third that of iron free from copper. An increase of copper above 0.20 per cent does not add to the corrosion resisting qualities of the iron. These results have been obtained not merely by laboratory experiments, but in practice. Roofs have been covered in and around Pittsburg with ordinary sheet steel and also with a sheet steel containing 0.20 per cent of copper. The copper alloy roofs were in good condition when the ordinary sheet iron roofs were completely corroded. The results of these experiments also showed that the metals are less attacked in rural districts than in cities, this being due probably to the carbon and acid fumes present in the city atmosphere.

During 1913, 302 people were killed by automobiles in New York City alone. The controlling mechanism of automobiles may have been developed to perfection, but the reckless driver seems beyond control.

ADJUSTABLE CAM-SHAFT AND TIMER DRIVE

BY JOHN L. ALDEN*

The cams and timer contacts of a gasoline engine must bear a precise relationship to the throws of the crankshaft. This means that the error in timing and cam-shaft gear setting must be very slight, and that any angular adjustment, to be of value, must be very close. On motors built in quantities, it is customary to mark the meshing teeth on the crankshaft, cam-shaft, and magneto or timer gears. In this case, no provision is made for changing the timing of the valves and ignition closer than the variation obtained by shifting the meshing gears one tooth either way. When this scheme is used the gears are either keyed to the shaft or bolted fast to a flange.

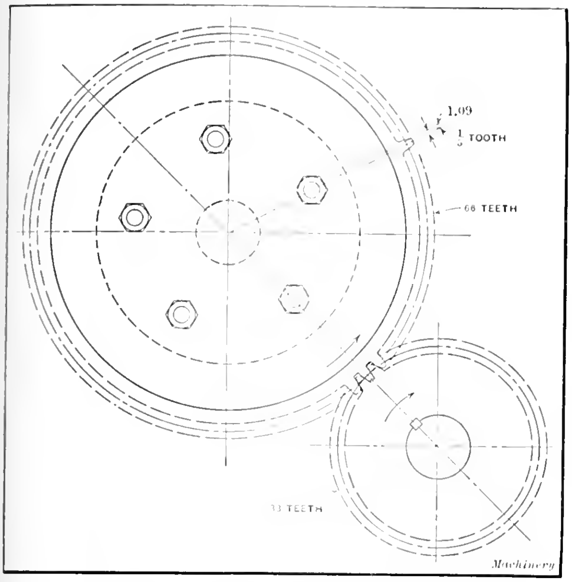

Fig. 1. Diagram illustrating Method of adjusting Cam-shaft Gear with Five Bolt Holes

However, it is frequently desirable to provide means for making finer adjustments than are possible by the method just noted. In fact, this is absolutely necessary in the case of experimental motors, racing motors, and other special machines of this kind. In such installations, means should be provided for shifting the gears with respect to the shaft in steps not greater than 2 degrees each. The most common method in use in this country consists of a gear bolted to a flanged shaft, one member having a greater number of bolt holes than the other. Thus, if two bolts are used, and there are twenty holes in the flange and eighteen in the gear, the closest angular adjustment possible is:

$$a = \frac{360}{18} - \frac{360}{20} = 2 \text{ degrees.}$$

Hence, to be of much value, at least eighteen holes must be used in each member. This makes a rather expensive installation, and is somewhat unsatisfactory in that it does not permit a high degree of precision in gear setting. There are a number of other contrivances in use, most of them, however, employing the slotted hole principle in one form or another. A bolt hole of this kind must be close to size, and, owing to its form, is expensive to machine. Therefore, it is readily seen that none of the devices in common use today are wholly satisfactory, there being some decided drawback in each case.

It is the intention of this article to present an improved adjustment which is not, to the writer's knowledge, common property in the American automobile and machinery field. This design is being employed with considerable success abroad, and it is hoped that the idea may be of service to designers on this side of the Atlantic. Like the methods previously described, this design requires a flanged shaft, drilled with a number of bolt holes exactly in register with corresponding holes in the gear. The holes in the latter must, of course, be located accurately with respect to certain teeth. The adjustment of the gear depends entirely upon the fact that the number of bolt holes is not an even divisor of the number of teeth. The relation between the number of teeth and the number of holes is most simply expressed by the formula:

$$N = kn + r.$$

$$\frac{N}{n} = k + \frac{r}{n} \qquad (1)$$

where N = number of teeth in gear;
n = number of bolt holes;
k = integral part of quotient obtained by dividing N by n;
$\frac{r}{n}$ = fractional part of quotient obtained by dividing N by n.

The angular adjustment, expressed in degrees, is represented by:

$$a = \frac{360\,r}{N\,n} \qquad (2)$$

The method of making this adjustment is very simple. When the setting has been made to within one tooth of the desired point, the operator should ascertain whether the valves have lag or lead. For the sake of illustration, assume that the valves have a slight lead. The gear is then removed from the flange and turned backward against the direction of rotation, one or more holes, the shaft being held stationary. After remeshing the teeth, the cam-shaft gear is again fastened to the flange thereby completing the operation. In case the valves lag, the gear should, of course, be turned ahead. To make the matter clearer, let us consider a numerical example taken in connection with Fig. 1.

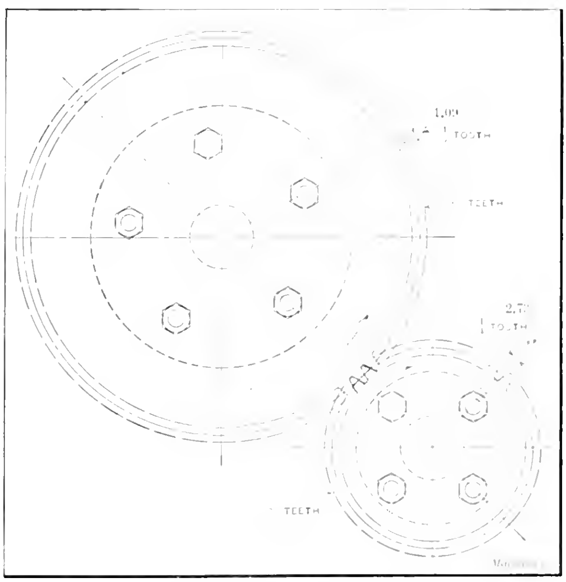

Fig. 2. Bolt Holes in both Cam-shaft and Crankshaft Gears to provide for Finer Adjustment than can be made with Arrangement shown in Fig. 1

It is required to find the finest angular adjustment which can be given to a cam-shaft whose gear has sixty-six teeth and five bolt holes. From Equation (1):

$$\frac{66}{5} = 13 + \frac{1}{5}.$$

Hence $k = 13$ and $\frac{r}{n} = \frac{1}{5}$.

From Equation (2) the angular adjustment is:

$$a = \frac{360}{66} \times \frac{1}{5} = 1.09 \text{ degree.}$$

In case even closer regulation is required, the driving gear

* Address: 701 Green Ave., Champaign, Ill.

— in this instance the crankshaft gear may be provided with precisely the same type of adjusting device. If this is done, the angular adjustment becomes:

$$a = \frac{1}{2} \times \left(\frac{360\, r_1}{N_1 n_1} - \frac{360\, r}{N\, n} \right) \qquad (3)$$

where N_1, n_1, and r_1 are the corresponding values of N, n and r for the driving gear on the crankshaft. Thus for the example shown in Fig. 2 the possible adjustment is:

$$\frac{1}{2} \times \left(\frac{360 \times 1}{33 \times 4} - \frac{360 \times 1}{66 \times 5} \right) = 0.275 \text{ degree.}$$

This provides an adjustment which is delicate enough for any ordinary purpose, and has the additional advantage of being relatively inexpensive. It will, of course, be understood that it is only the fractional part of a tooth, $\frac{r}{n}$, that affects the adjustment, as the movement of a whole number of teeth k does not affect the relative positions of the shafts when the gears are remeshed after making the adjustment.

CHARACTER OF PAPERS TO BE READ AT THE ENGINEERING CONGRESS

In the December number of MACHINERY mention was made of the International Engineering Congress which will be held September 20 to 25, 1915, in connection with the Panama-Pacific Exposition in San Francisco. This congress is conducted under the auspices of the great national engineering societies in the United States. The character of the papers that will be read will be of especial interest. As a general rule, it is intended that each paper shall treat its assigned topic in a broad and comprehensive manner and with special reference to the important lines of progress during the past decade, the present most approved practices, and the lines of present and future development. It is intended, furthermore, that all such papers shall be accompanied with a reasonably full bibliography of the subject, giving reference to the important original papers and sources of information relating to the special topic of the paper. In this manner the reader will be furnished with a rapid and comprehensive review of the recent important work relating to such topic, together with references to individual papers and sources of information for more complete and minor details. Papers of this type, rather than those which deal with individual constructions or special and individual problems or investigations, will generally serve the purpose of an engineering congress better. Papers of the latter type will naturally find their place in the proceedings of the regular sessions of the various engineering societies, while the occasion of a great engineering congress furnishes a more appropriate opportunity for papers of the broad survey or encyclopedic type.

An important exception to this general plan, however, will be found in a series of papers relating to the Panama Canal, of which it is intended to make a special feature of the congress. These papers will deal with the engineering of the Panama Canal in all its branches, with the influence of the canal on world commerce, commercial trade routes and general transportation problems. Colonel Goethals has promised his aid in securing this series of papers, which will thus form a definite and authoritative discussion of the engineering problems involved in this great undertaking.

In other special fields it may be found desirable to depart somewhat from the character of the papers outlined above, but, in general, and aside from those relating to the Panama Canal, the papers will be of the character indicated. In order to realize these various purposes with regard to the papers and especially to avoid either the overlapping of two or more, or the omission of some important topic, the Committee on Papers is now preparing a carefully considered list of topics to be treated in the various branches of engineering, together with a general syllabus or outline of the specific ground to be covered by each paper, and to which each contributor will be asked to adhere as closely as practicable.

PROPERTY RIGHTS IN ENGINEERING DRAWINGS AND DATA

In an address before the student branch of the American Society of Mechanical Engineers, at Cornell University, Prof. Frederick R. Hutton touched upon the subject of the relations of the draftsman and engineer as regards his proprietary right in the designs which he creates. This question is closely allied with that of ownership of patents which originate during the work carried out by the draftsman. The subject was divided into four principal questions, as follows:

1. May a draftsman make blueprints from his own drawings embodying his own computations, and take these home with him or away with him when he leaves his job? May he do this with the drawings of his fellow workers? These will enhance his value to any subsequent employer. Are they *his?*

2. Suppose he bought his own paper, and did his printing at home on Sundays and holidays, so that his records were not made at his employer's expense? Does this change anything?

3. Suppose that this same information, tables of sizes and proportions, design data and standards, are in note-books, may the draftsmen copy these, and carry such priceless information gathered through years of wage-paying and experiment with him to his next place, and perhaps to a competitive concern?

4. Can an improvement in a process, or a new process or an improved design, or a new mechanical movement be patented by the draftsman for himself, while he is working for an employer on a similar problem, and be used to hold up his employer until the parties can agree as to the terms of use or sale?

The accepted answer, emphasized by decisions of Court, and embodied in codes and standards of professional ethics, is that drawings and data belong to the employer, and the engineer or draftsman may not take them away with him. The reasons back of this practice include: 1. The shop furnished the plant—rent, heat, light, tools, etc.—where these ideas were conceived. 2. The shop presented the problem—without this the invention or the design would never have been created. 3. The shop furnished antecedent knowledge and acquired experience, which molded the creation, and prevented mistakes and waste. 4. The shop furnished experimentation, actual or precedent, which gave the creation its practical or commercial shape. 5. For many creations, the shop furnished or will furnish the manufacturing facilities which the inventor would otherwise have to struggle to find or pay for heavily elsewhere. 6. For many creations, the shop furnishes the selling or marketing facilities of its commercial organization.

Again, the draftsman or engineer may contract by a signed instrument to give shop or manufacturing rights to the employing shop, while retaining the right to sell or license to outside parties. Or, again, this principle may be made applicable to patents which relate to the employer's business, while patents in no way related thereto may be expressly excluded, and the employer stands as an outsider would, in relation to purchase or license.

Closely interwoven with this matter is the "trade-secret" problem. Here the employer confides to his engineer or draftsman or other employe knowledge of immense commercial importance to him, and which for many practical reasons he cannot protect by the procedure of the patent. The European practice has some vogue where the engineer and draftsman agree by signed instrument not to enter another concern in the same line of production for five years after leaving his confidential relation. Five years will render much of his inside knowledge obsolete; and the first concern will not suffer from a breathless and panting chase of another five years behind it. Many of these contracts have, however, been declared void by the Courts in the United States.

Fine spun theoretical knowledge, unless mated with horse sense, breeds frills and gewgaws in design and causes waste of effort and money.—*Journal Worcester Polytechnic Institute.*

HEAVY-DUTY SHAFTS WITH TWO AND THREE BEARINGS

AN INVESTIGATION OF SHAFT DESIGN WITH TWO AND THREE POINTS OF SUPPORT

BY W. G. DUNKLEY*

Many cases arise in machine tool design in which one or more gears have to be placed near the middle of a shaft owing to the location of other gears. In such cases, the shaft may either be designed to carry the load when it is supported in two end bearings or a third bearing may be provided at the middle. The latter method of procedure is coming into very general use. The purpose of this article is to investigate the design of a shaft under both these conditions and discuss the various points which arise when three bearings are used instead of two.

Fig. 1 illustrates the conditions which have been assumed for the purpose of discussion. In this illustration, W_1 is the driven wheel and W_2 the following driver, the shaft between these wheels transmitting the torque. The calculations are based on the assumption that the wheels are capable of transmitting the full horsepower of the motor when running at their lowest speed. The tangential tooth loads are 5 tons on wheel W_1 and 7.5 tons on wheel W_2; the torque on the shaft is $5 \times 19 = 95$ inch-tons. The bending moment on the shaft will approximate its maximum value when the shaft centers lie in a straight line as shown in Fig. 2, *i. e.*, when the lines of action of the tangential tooth loads are parallel. The dotted arrows in Fig. 2 show the actual directions in which the tooth loads act if the obliquity of action is taken into account. Strictly speaking, it will be seen that the greatest possible bending moment on the shaft S_2 will be produced when the lines of centers S_1 and S_2 and S_2 and S_3 are each inclined at an angle of 14½ degrees to the horizontal. With lines of

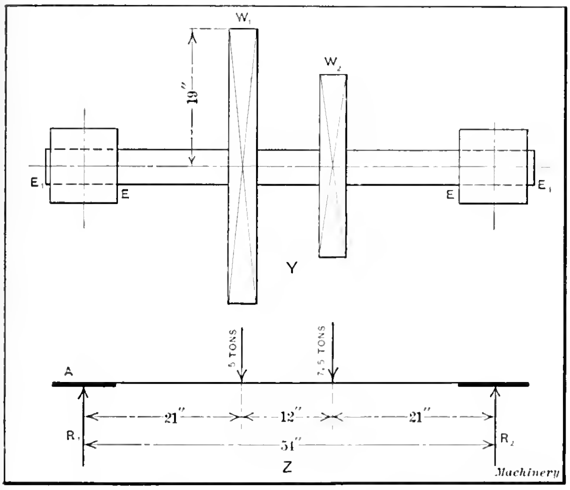

Fig. 1. Diagrams illustrating Conditions assumed for Discussion of Shaft supported by Two Bearings

contact inclined in this way the dotted arrows representing the actual direction of the pressure on the teeth would be parallel.

Shaft Carried in Two Bearings

To obtain the maximum bending moment it is assumed that the shaft is simply supported at the middle of each end bearing as shown at Z in Fig. 1. For this to be the case, it would mean that the reactions at the bearings are evenly distributed over the entire bearing surface. This point will be referred to in detail in a later paragraph. By taking moments about A, we have:

$$54\,R_2 = 5 \times 21 + 7.5 \times 33$$

$$R_2 = \frac{352.5}{54} = 6.5 \text{ tons}$$

$$R_1 = 12.5 - 6.5 = 6 \text{ tons}$$

The maximum bending moment M will occur under the 7.5-ton load.

$$M = 6.5 \times 21 = 136.5 \text{ inch-tons}$$

$$T = 95 \text{ inch-tons}$$

The diameter of the shaft that is required for carrying this combined bending and twisting load can be quickly obtained from the charts which were published in connection with an

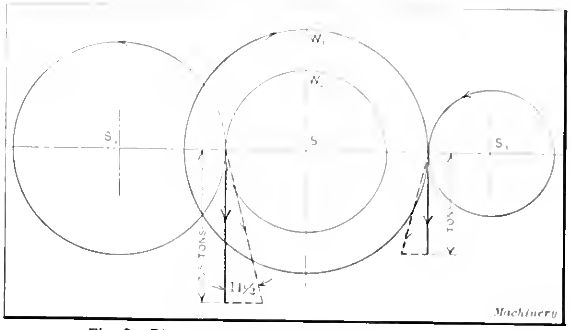

Fig. 2. Diagram showing Direction of Lines of Action of Pressures on Gear Teeth

article by the present writer that appeared in the August, 1913, number of MACHINERY. Using the chart, the value of the shaft diameter is found to be 7.5 inches. If the charts are not available, the result may easily be obtained by calculation. Denote the twisting moment that is equivalent to the combined bending and twisting moments acting on the shaft by T_1.

$$T_1 = M + \sqrt{M^2 + T^2} = 136.5 + \sqrt{136.5^2 + 95^2} = 302 \text{ inch-tons.}$$

The required diameter D of the shaft is obtained from the following equation:

$$D^3 = \frac{16\,T_1}{\pi f}$$

where

f = safe fiber stress = 3.5 tons per square inch;

$$D^3 = \frac{16 \times 302}{3.1416 \times 3.5} = 439;$$

$D = 7.5$ inches (approximately).

The next point is to make sure that the deflection of the shaft due to the load is not excessive. For the given arrangement of the loading the most convenient method of obtaining the deflection would be by graphical analysis. This amount of work is hardly necessary in the present case, however, as a sufficiently accurate idea of the deflection can be obtained by regarding the loads as concentrated at the middle of the shaft. For this condition, the deflection d is given by the following equation:

$$d = \frac{WL^3}{48\,EI}$$

where

I = moment of inertia $= \dfrac{\pi D^4}{64} = 156$;

W = load on shaft = 12.5 tons;

L = length of shaft = 54 inches;

E = modulus of elasticity = 13,000 tons.

Then

$$d = \frac{12.5 \times 54^3}{48 \times 13{,}000 \times 156} = 0.0202 \text{ inch.}$$

The actual deflection will be slightly less than the preceding value because the loads are not actually concentrated at the center of the shaft in the way that was assumed to facilitate calculation. Consequently, a shaft rather smaller than 7.5 inches in diameter might be used with safety.

If, instead of acting in parallel directions, the loads on the shaft are inclined in the directions of the arrows indicated at X in Fig. 3, the maximum bending moment is obtained as follows: The inclined load W_2 is resolved into components $W_2 \sin \theta$ acting vertically and W_2 cosin θ acting horizontally.

* Address: 25 Rothwell St., Salford, Manchester, England.

At Y is shown the arrangement of the vertical load W_1 and the vertical component of the load W_2; at Z, the arrangement of the horizontal component of W_2 is shown. Call F and F_1 the reactions due to the vertical loads shown at Y, and P and P_1 the reactions due to the horizontal load shown at Z. Then there will be one bending moment $M_1 = F_1 \times 21$ which acts under the load W_2 and also a second bending moment $M_2 = P_1 \times 21$ acting under the load W_2 at right angles to the first bending moment. The resulting bending moment M under the load W_2 is then obtained by the following equation:

$$M = \sqrt{M_1^2 + M_2^2} \quad (1)$$

Similarly there are two bending moments acting at right angles to each other under the load W_1 which have values given by the following:

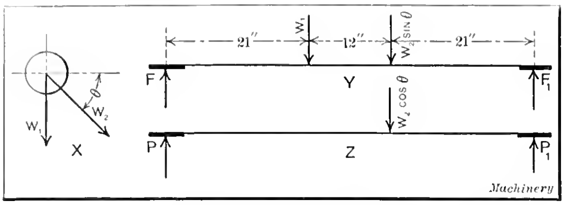

Fig. 3. Diagrams showing Condition of Shaft carrying One Vertical and One Inclined Load

$$M_3 = F \times 21 \quad \text{and} \quad M_4 = P \times 21$$

The resultant of these bending moments is given by the following:

$$M = \sqrt{M_3^2 + M_4^2} \quad (2)$$

The maximum bending moment M is obtained from either Equation (1) or (2), the bending moment being the result of the equation which gives the greatest value. This result is then used with the twisting moment in order to obtain the required diameter of the shaft by the method of calculation previously explained.

To return to the question of the pressures being evenly distributed over the bearings of the shaft shown in Fig. 1: When the loads are first applied on the shaft the resulting deflection will tend to lift the ends E_1 off the bearing, thus concentrating the full bearing load at a point nearer the inner ends E of the bearings. As a result, the bearings will wear at the points where the load is greatest and this wear will tend to continue until it reaches a point where the pressure is evenly distributed. When this condition is reached, any wear which develops in the bearings will be uniformly distributed. If, however, the deflection of the shaft is of considerable magnitude, the condition indicated in Fig. 4 may be produced, *i. e.*, the ends E_1 of the shaft may be raised sufficiently to induce downward pressures L_1 and L_2. The total downward pressure will then be the loads on the shaft plus these induced loads L_1 and L_2, and this pressure will be concentrated at the points E. This condition will obviously tend

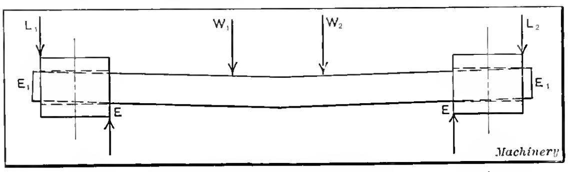

Fig. 4. Diagram illustrating Possible Result of Excessive Deflection of Shaft

to cause trouble in the bearings and such trouble may be experienced by having the shaft too weak, even though the load is not excessive or the design of the bearings defective in any way. Considering the large diameter that was found to be necessary from the preceding calculations, it is not surprising that it is becoming a general practice to support such a shaft on three bearings as shown at X in Fig. 5.

Shaft Carried in Three Bearings

In order to investigate the conditions of a shaft supported by three bearings, it will be necessary to not only obtain the required diameter of the shaft but also to investigate the distribution of the total load over the three bearings. The latter will be found to constitute an extremely important factor. The first step is to obtain the maximum bending moment on the shaft. Regarding the spans AC and CB as simple beams supported at the ends and loaded with 5 and 7½ tons, respectively, the negative bending moment diagrams are as illustrated at Y in Fig. 5. For the simple beam AC let R_a equal the reaction at A.

Then

$$R_a \times 27 = 5 \times 6$$

$$R_a = \frac{30}{27}$$

The maximum bending moment M is given by the following:

$$M = R_a \times 21 = \frac{30}{27} \times 21 = 23.3 \text{ inch-tons}$$

The ordinate DD_1 in the negative bending moment diagram is therefore made to represent 23.3 inch-tons. By a similar method of procedure it will be found that the maximum bending moment on the beam CB is 35 inch-tons and the ordinate EE_1 is laid off to represent this value.

The positive bending moment diagram is next superimposed upon the negative bending moment diagram. For the present, the value of the positive bending moment at the middle sup-

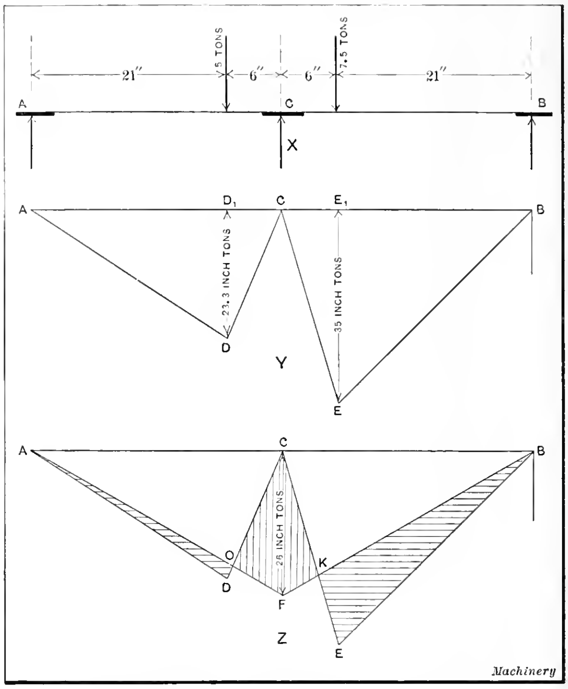

Fig. 5. Diagram showing Shaft supported by Three Bearings and Bending Moment Diagrams

port is unknown. The positive bending moment is obtained from the equation deduced from the theorem of three moments given by the following:

$$\frac{6\,Z}{L_1} + \frac{6\,Z_1}{L_2} = M_a\,L_1 + 2\,M_c\,(L_1 + L_2) + M_b\,L_2$$

where

Z = moment about A of the negative bending moment diagram for the span AC, *i. e.*, the moment of the triangle ADC about A;

Z_1 = moment of triangle CEB about end B;

M_a = positive bending moment at support A; the value of this moment is zero in the present case since the ends are simply supported.

M_b = positive bending moment at B = zero for the present case;

M_c = positive bending moment at C = ordinate CF;

L_1 = length of span AC = 27 inches;

L_2 = length of span CB = 27 inches.

For the present case the equation derived from the theorem of three moments reduces to:

$$6(Z + Z_1) = 4 \times 27^2 \times M_c \quad (3)$$

Sinco

$L_1 = L_2 = 27$ and $M_a = M_b = 0$

$$Z = \frac{23.3 \times 21}{2} \times \frac{2}{3} \times 21 + \frac{23.3 \times 6}{2} \left(21 + \frac{6}{3}\right) = \text{mo-}$$

ment of ADD_1 + moment of D_1DC about the end A.

$Z = 23.3 \times 147 + 23.3 \times 69 = 23.3 \times 216 = 5032.$

Similarly $Z_1 = 35 \times 216 = 7560.$

Substituting the preceding values of Z and Z_1 in Equation (3) gives

$$6\,(5032 + 7560) = 4 \times 27^2 \times M_c$$

$$M_c = \frac{6 \times 12{,}592}{4 \times 27^2} = 26 \text{ inch-tons}$$

Making the ordinate $CF = 26$ inch-tons, the triangle AFB, shown at Z in Fig. 5, represents the positive bending moment diagram which is to be superimposed on the diagrams of negative bending moments shown at Y. The shaded portions of the diagram show the resultant bending moment diagrams. The triangles ODA and KEB are the negative bending moment diagrams and the area $OCKF$ is the positive bending moment diagram. Consequently the maximum bending moment M occurs at the point C and has a value of 26 inch-tons. The twisting moment T has a value of 95 inch-tons, as previously determined. For this combined twisting and bending load the required shaft diameter is obtained from the chart or by means of the formula previously given, and is found to be 5.75 inches. This figure is based upon an allowable fiber stress of 3.5 tons per square inch.

Distribution of the Load on the Bearings

Let R_a represent the reaction at the bearing A (Fig. 5). Taking moments about the point C of all loads to the left of C gives $5 \times 6 - R_a \times 27$ = positive bending moment at $C = 26$ inch-tons.

$$R_a = \frac{4}{27} = 0.148 \text{ ton.}$$

Taking moments about the point C for all loads to the right of C gives $7.5 \times 6 - R_b \times 27 = 26$ inch-tons.

$$R_b = \frac{19}{27} = 0.7 \text{ ton}$$

From the preceding we obtain

$$R_c = 12.5 - R_a - R_b = 11.6 \text{ tons.}$$

It will, of course, be evident that the reaction of R_c represents the load on the middle bearing, from which it will be seen that by far the greater portion of the load is carried at this point and it is extremely important for this fact to be remembered when determining the dimensions of the middle bearing. In the case of the shaft carried by two end bearings, the most important factor was the deflection, and as it is obvious that the provision of a central bearing will materially reduce this deflection, the necessity for providing a large central bearing may easily be overlooked. If this mistake is made, the provision of the central bearing may actually do more harm than good. Although the end bearings A and B in Fig. 5 take only a small part of the load for the conditions shown in the illustration, it must not be forgotten that the maximum loads on the end bearings probably occur when other gears on the shaft are carrying the load. The fact that the load is distributed over the middle bearing will make the shaft slightly stronger than it was found to be by the preceding calculations.

Finally, it is desirable to examine the torsional stiffness of the shaft, particularly for cases where the gears have to slide on keys. For the case under consideration, where the twisting moment $T = 95$ inch-tons, let

L = the length in inches of shaft carrying the torque;

N = modulus of rigidity = 5000 tons;

θ = angle of twist in degrees.

Then

$$\theta = \frac{583\,LT}{ND^4}$$

Assuming that under certain circumstances the whole length of the shaft is under torque, *i.e.*, $L = 54$ inches

$$\theta = \frac{583 \times 54 \times 95}{5000 \times 5.75^4} = 0.55 \text{ degree, approximately}$$

The value obtained by the preceding equation is, of course, an extreme case which would seldom arise in actual practice, but calculating on this basis insures having a shaft of ample strength.

PIECE-WORK AND PROGRESS

BY J. CROW TAYLOR*

Perhaps the strongest point that can be raised by manufacturers and shop superintendents against piece-work is that it often proves a handicap to progress. Piece-work primarily makes for higher efficiency with the equipment and the men at hand. It encourages effort and makes its return in proportion to the amount of effective effort put forth.

The trouble comes when new improvements are offered in the way of machines and equipment to reduce cost. Here the piece-work system stands as a bar that sometimes may be let down easily and sometimes may not. There is always more hesitancy about installing labor-saving machines and devices where the piece-work system is in vogue than where day-work prevails, because, if for no other reason, it calls for a readjustment of piece-work prices. This is always a difficult and trying problem—one that too often results in dissatisfaction and labor troubles.

An illustrative instance of this kind was given by a factory owner recently in connection with their molding department. As any one familiar with molding knows cutting the sand is one of the unliked and tiresome jobs connected with the work. This man said that there was brought to him a proposition in the shape of a mechanical device that would do the work of cutting the sand for the molders in his place for less than half what it was costing him. Most of them were shirking this task themselves by letting it out to others on a contract basis. The man with the mechanical device would not offer to sell his device outright, but wanted to operate it on a contract basis. This involved more complications than would have been met with had the proposition been for the owner to buy the equipment and readjust his molding scale accordingly. The proposition involved giving the molders the benefit of the saving effected, yet a share of it must needs go to the factory owner, too, because some power was required to drive it and the power would have to be supplied by the factory. He said that he had been trying for some time to figure out a scheme by which they could use it because it could easily effect a saving for them and at the same time help the molders to make more money.

He will perhaps find a way somehow, some day, but the incident serves to illustrate how piece-work is often a handicap to progress, not necessarily because the piece-workers are opposed to innovations and labor-saving devices, but because any new thing of this kind calls for an entire reorganization of the system. This is troublesome and results in grumbling and dissatisfaction, and the upshot of it all is that many factory owners operating on the piece-work basis let opportunities to improve their plant in efficiency go by because of the handicap of piece-work.

Perhaps in a general readjustment of industrial affairs between employers and employes there will be devised some scheme for a satisfactory day wage regulation supplemented with a profit-sharing proposition that will be satisfactory all around. Then progress in the way of efficiency through new machines and appliances and methods will be made easy and freed from some of the handicaps that seriously retard it today.

* * *

Iridium was once cheaper than platinum, but at present its value is about twice that of the latter metal. Up to a few years ago, there was no other use for it except for the points of gold pens, but since then it has found extensive use as a hardener for platinum. Very little pure platinum is now being used and nearly all of the commercial metal going under this name is the so-called "hard" platinum which is an alloy of platinum and iridium.

THE ACCURATE HEAT-TREATMENT OF ROLLER BEARING PARTS*

EQUIPMENTS AND METHODS WHICH FACILITATE RAPIDITY IN HANDLING AND UNIFORMITY OF WORK

BY E. F. LAKE†

The manufacture of bearings of either the ball or roller type has grown into a good sized industry in the past few years. The automobile industry is responsible for a large part of this growth, as it would have been difficult, if not impossible, to make the automobile a success without these anti-friction bearings. This is especially true of roller bearings, which are used on nearly all automobile wheels and are a special benefit. They must be made as small and light as possible and, at the same time, strong enough to carry the load of the car, combined with that of the passengers or other weight that the car may carry.

The first essential of either type of bearing is a steel that possesses the qualities that will enable it to withstand the strains to which the bearings may be subjected. The second essential is correct machining operations, as the parts must be made within a fraction of a thousandth of an inch of the correct size. The third essential—and perhaps the most important one—is the heat-treatment that these parts receive. This must be of such a nature as to make the steel resist the crushing, vibrational, frictional, or other strains to which all bearings are submitted. The reason this is considered the most important factor in the process of manufacture is that the strength, wearing qualities, resistance to fatigue, etc., can be greatly increased or decreased by accurate or inaccurate heat-treatment. It is an easy matter to accurately heat-treat ordinary carbon steels and make them excel the highest grades of alloy steels which are not correctly heat-treated. At the same time, it is possible to give such alloy steels double the elastic limit and reduction of area of the ordinary carbon steels when both are correctly heat-treated. Likewise, the resistance to fatigue, or vibrational strains, of the alloy steels can be made more than quadruple that of the carbon steels.

After the steel parts of bearings have been machined to their correct size and shape, it is essential that they be thoroughly annealed before they are carbonized, hardened and tempered, or subjected to both these treatments. This relieves any internal strains, making the physical properties the same in all parts of a piece and the strength uniform in all directions from any given point. For this reason the annealing of all other steel parts is just as essential, and particularly those parts that have to resist strains of any kind. It should always be remembered that a steel piece is greatly weakened when more of the cohesive force, which binds the molecules together, is concentrated at one place than at another. When steel leaves the rolling mill it is full of these unequal strains.

Fig. 1. Casehardening Pots and Special Heating Furnaces used by the Timken Roller Bearing Co.

All steels that are used in the manufacture of ball and roller bearings are first poured into ingots that may be anywhere from 6 to 18 inches square. These ingots are usually hammered to a size that will make them small enough for the rolling or forging operations. The grain of the cast ingots is very crystalline and, hence, very weak in comparison with the same steel after it has been hammered, rolled, forged, etc. The mechanical working crushes the crystals together and gives the metal a more fine and dense structure. It increases the elastic limit and other static properties of the metal, as well as its dynamic properties.

While doing this, however, it sets up unequal internal strains in the steel which should be removed before attempting to give it its final heat-treatment. Therefore, the various parts that enter into the construction of the complete

* For other articles on the heat-treatment of steel published in MACHINERY, see "The Heat-treatment of Gears at the Boston Gear Works" by George L. Colburn, published in MACHINERY, June, 1913, and other articles there referred to.

† Address: 1453 Waterloo St., Detroit, Mich.

bearings of the best grades are always thoroughly annealed just before they are carbonized, or hardened and tempered. Sometimes steel is annealed before any machine work is performed. This first annealing is usually done at the steel mill before the steel is shipped, but it will not take the place of the annealing that should be done after the steel is manu-

Fig. 2. Use of Truck in placing a Pot in the Furnace

factured into the different pieces. This is because the machining operations are likely to set up other internal strains.

In heating steel, the temperature will reach a point at which there occurs a change in the grain, or a new grain structure is born. With this rearrangement of the grain structure any unequal strains will disappear. Annealing consists of raising the temperature of the steel high enough to be assured that the metal has had time to thoroughly complete this change of structure. The steel is then allowed to gradually cool to the temperature of the atmosphere. The slower this cooling takes place the more thorough will be the annealing and the obliteration of any internal strains. If cooled too quickly, a hardening of the metal takes place and other strains are likely to be set up; this is especially true if it cools unevenly or more quickly in some sections than in others. If the steel is heated too high above the transforma-

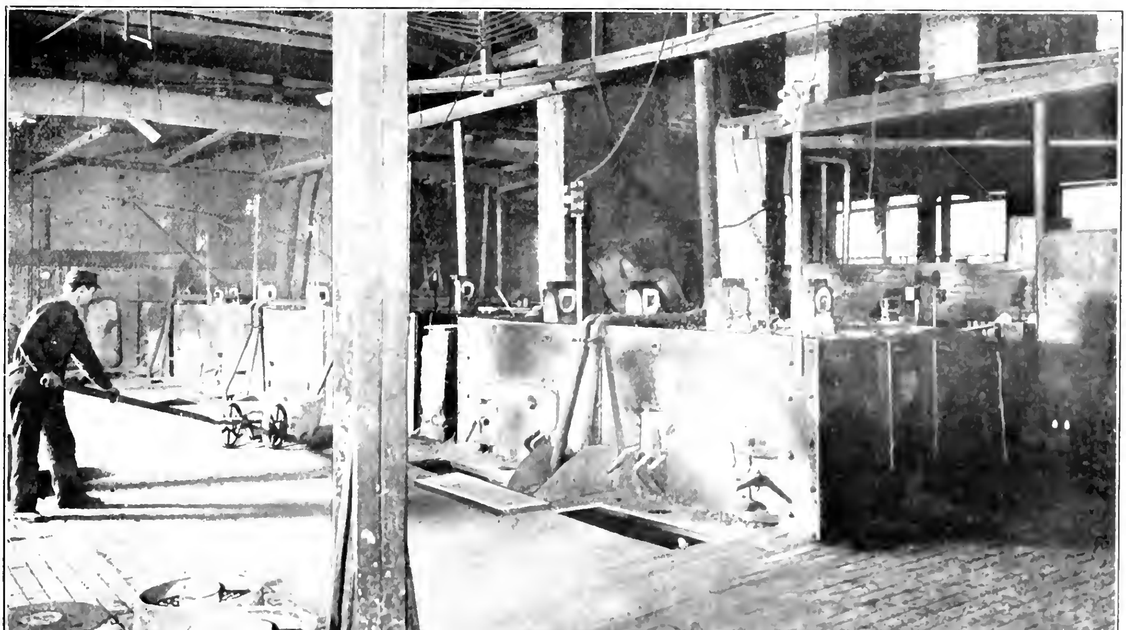

Fig. 3. Furnace with Floor-plate removed to show Burner

tion point the grain will become coarsened, as each degree of temperature above this point adds to the coarseness of the grain structure.

This information is the basis of three rules that it is well to follow when annealing all steels. First, heat the metal to a temperature above the highest transformation point but not far enough above to coarsen the grain; second, hold the temperature at this point long enough to allow the transformation to be completed but do not prolong it beyond that; third, make sure that the rate of cooling is sufficiently slow to prevent even a superficial hardening.

To insure a uniform heating in a neutral atmosphere and a slow cooling, small parts should be packed in some non-carbonizing material held in metal pots, the covers of which are sealed on with clay before the pots are put into the furnace to be heated up to the annealing temperature. The Timken Roller Bearing Co., of Canton, Ohio, probably handles this work as economically as it is possible to and still obtain the accuracy that is required. The method of procedure is shown in Fig. 1. Round cast-iron pots with hollow centers are used,

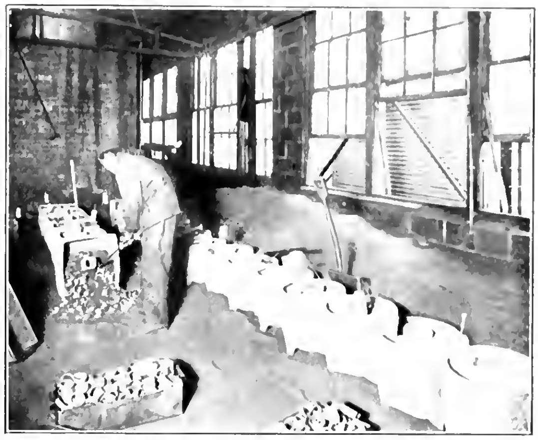

Fig. 4. Dumping and sorting Work that has been carbonized

in which the work is packed in the non-carbonizing material. When the pots are filled, they are lifted by the two-wheeled truck shown to the right and wheeled into the furnace, as shown in Fig. 2. Then the pot is dropped on its four legs, the truck pulled out and the door closed.

The oven of each furnace has been lowered so that its bottom is level with the shop floor, and thus a great deal of time and labor is saved in charging the work into the furnaces. In front of each furnace there is a pit covered with floor plates. The burners, piping and valves that convey and regulate the fuel and blast which supplies the furnaces with

heat are located in these pits, the combustion chambers of the furnaces being below the floor level. The burner in the first furnace is clearly shown in Fig. 3, by the white spot under the door of the heating chamber, the floor plate having been removed for this purpose. These furnaces were built by the company from their own special designs, with a view of obtaining accuracy and uniformity of temperature in the heating chambers. They are built in pairs.

Before adopting this method the pots were gripped with long tongs by one man, and two other men, one on each side of the furnace door, lifted each pot into the furnace or took it out, the furnaces being set on top of the floor, as is the usual custom. By lowering the combustion chamber below the floor level and thus bringing the floor of the heating chamber on a level with the shop floor, one man with the truck shown in Figs. 1 and 2 is able to handle larger and heavier pots in less time than that formerly taken by the three men. Thus, the saving in labor has more than paid for the lowering of the furnaces.

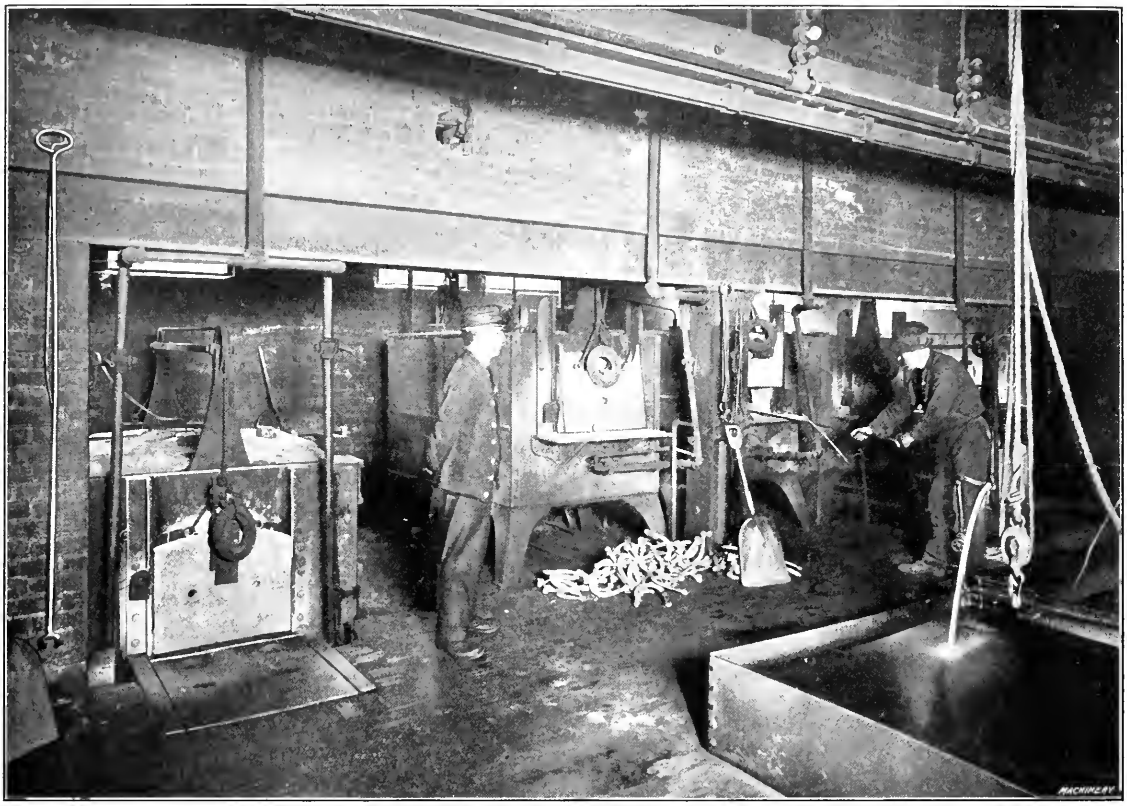

Fig. 5. Arrangement of Hardening Furnaces and Quenching Tanks

To be assured that the furnace temperatures are correct, a pyrometer system has been installed. Thermo-couples have been inserted in each furnace and the indicating meter is located in a separate room. Only one indicating meter is required to show the temperature in some twenty-four furnaces. One man has charge of this room and his only duty consists of operating the pyrometer to ascertain the temperature of each furnace at intervals of a few minutes, and to see that the furnaces are kept at the temperature desired. By means of electric lights, he gives the furnace operator a signal when the temperature of any furnace is too high or too low; and then he insists that the man at the furnace adjust the valves to bring it back to the correct temperature.

The signals consist of three incandescent lamps that are shown on a steel bar above the door of each furnace. The central light is clear glass, while the upper one is red and the lower blue. When the temperature of the furnace is correct the central light is the only one that shows. This is best illustrated in Figs. 2 and 3, where all the furnaces show the white light burning. If the temperature goes too high, this central light is turned off and the red one above it is lighted. Then the furnace operator must lower the fuel oil and blast that is going through the burners and thus reduce the size of the flame. When the temperature is too low, the blue light is turned on and the others are switched off. Then it becomes necessary to increase the column of the flame entering the furnace.

Fuel oil and dry steam are used for heating the furnaces. This oil is located in large tanks underneath the floor of the shop and quite a distance away from the furnaces. As pressure on the oil is needed, a pump drives the oil from this tank through the burners at a pressure of about 15 pounds per square inch. The steam passes through the burners at a pressure of about 60 pounds per square inch and this gives the proper combustion.

Some parts of bearings withstand the strain much better if made from low carbon steel and carbonized. This gives the outer surfaces of such parts a high carbon content that can be made hard to resist frictional wear or any tendency to crush or deform, while the low carbon center, or core, will remain soft and ductile, and thus make it difficult to break the piece with any of the severe shocks or strains it receives when in use. This carbonizing is done after the piece has been machined to the proper size and shape. Grinding is the only kind of work that is practical after the steel has been carbonized.

In performing the carbonizing operation, the work is packed in iron pots and heated in furnaces in just the same manner as shown for the annealing operations. The material in which the work is packed differs, however, as it must be a carbonaceous instead of non-carbonizing material. Bone, charcoal, charred leather and numerous other materials have been used for this purpose, both alone and in various combinations. Figs. 1 and 3 illustrate the methods of packing the work. Fig. 1 shows the bank of furnaces used for carbonizing. The first of these is a Frankfort furnace, which was installed by the Strong, Carlisle & Hammond Co., while

the others were built by the Brown & Sharpe Mfg. Co. The special annealing furnaces built by the company for their own use are shown in Fig. 3.

In the lower left-hand corner of Fig. 3 will be seen part of a pot that has been sealed up ready to insert in the furnace with the two-wheeled truck that is being handled by the man at the left of the picture. Beside it are two pots that are only partly filled. These show the way the work is laid in the carbonizing material. Each steel piece is kept at least one inch away from all other pieces. Then the carbon can penetrate all parts of the outer surface when the pot and its contents are heated to a temperature that is high enough to make the steel so hot that it will absorb carbon.

The amount of carbon that is thus injected into the outer surfaces of the steel and the depth to which it penetrates are governed by the composition of the steel; the nature of the carbonizing material; the temperature of the furnace; the larger will be the amount of carbon that it will absorb in a given time; and the greater the depth to which it is possible to make the carbon penetrate. Owing to the grain of the steel becoming gradually coarsened by each degree that the temperature is raised above the transformation point, there is a limit to the heat that can be successfully used when carbonizing steels. When heated too far above the transformation point the grain begins to crystallize, and at still higher heats the crystals begin to separate from one another. When these small cracks appear between the crystals the usefulness of the metal has been destroyed and it can only be restored by remelting and rerolling or reforging. Before the crystals begin to separate, the original fineness of grain can be restored by allowing the steel to cool and afterward heating it to a little above the transformation point and then suddenly cooling it by quenching in oil or water. This is the hardening operation and if properly done it will

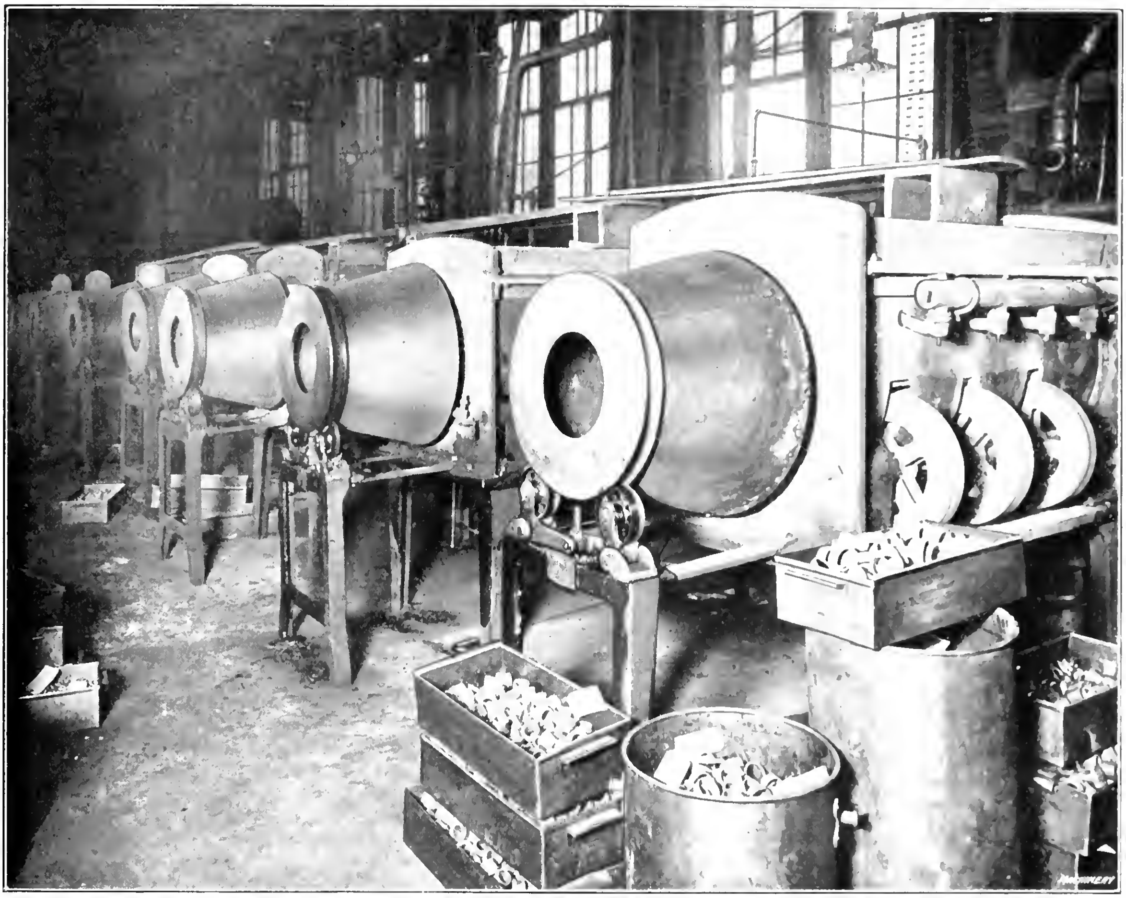

Fig. 6. Rotary Furnaces used for drawing the Temper of Roller Bearing Parts

and the time the work is held at this temperature. The outer shell of the steel piece is usually made to absorb enough to give it 1.00 per cent of carbon. This percentage of carbon gradually diminishes toward the center of the piece until the low carbon content of the original metal is reached. This will vary from 0.10 to 0.20 per cent of carbon, as it is such grades of steel that are used for parts that are to be carbonized. Many of the high-grade alloy steels, as well as the ordinary carbon steels, are carbonized to various depths and with various percentages of carbon. These alloys give much better results in bearings than any of the carbon steels, and are nearly always used for the parts of bearings that have to withstand great strains. They are more expensive, however, and hence some of the cheaper bearings are made from the carbon steels.

The higher the temperature to which the steel is raised, the more quickly will it absorb carbon to a given depth; put the steel in as good a condition as though the grain had not been coarsened by overheating.

Therefore, carbon steels with a transformation point of 1500 degrees F. or below can be held at a temperature of 1650 degrees for several hours, when carbonizing them, and the coarsened grain can then be brought back to its greatest degree of fineness by the subsequent hardening operation. Some of the alloy steels with a transformation point of 1650 degrees F. can be heated to 1750 degrees for the carbonizing operation. These temperatures will give a rapid penetration of carbon; they also give as high a percentage in the outer shell as is required for practical work and to the necessary depth. Under ordinary conditions, a temperature of 1650 degrees F. maintained for one hour will cause the carbon to penetrate to a depth of 1/64 inch; three hours will give a depth of case of 1/32 inch; nine hours a depth of 1/16 inch; and twenty-four hours will give a depth of 1/8

inch. It is very seldom that the high carbon content is required for a depth of more than 1/16 inch and thus each lot of steel parts can usually be carbonized in a day's run.

After deciding what is the best temperature for the carbonizing heat, the best results can only be obtained by keeping the furnace uniformly at that temperature during all the time the work is in the furnace. Hence the same pyrometer is installed on these furnaces that is used on the annealing furnaces and on all other furnaces used in the heat-treating department. Then the time will decide the depth of penetration, and when the desired depth has been obtained the pot should be taken out of the furnace and allowed to cool slowly to below 600 degrees F. After that, the work can be taken out of the pot and allowed to cool quickly. Then it is ready for any hardening and tempering that is required. In Fig. 4 is shown the way the work is removed from the pot and sorted. The square pots are used for carbonizing work and the round ones for annealing. Thus there is no excuse for getting the work mixed in these two operations. Some take the pot out of the furnace and dump the work directly into the quenching bath for the hardening operation. The carbonizing temperature is usually too far above the transformation point, however, to give the steel the finest grain that it is capable of assuming. Thus it is far better to allow the work to cool down from the carbonizing temperature and then re-heat it for the hardening operation.

In hardening carbonized bearing parts, the best results are obtained by giving them a double heating and quenching to get the proper degree of hardness in both the hard outer shell and the soft core. This is due to the fact that the transformation points of high and low carbon steels occur at different temperatures, which are often 200 degrees apart. The steel should first be quenched from the high transformation point of the low carbon steel in the core and then reheated to the lower transformation point of the high carbon steel of the outer shell and again quenched. This produces bearings that it is almost impossible to break or crush under the load that they are designed to carry. It also gives them a wearing surface that will last a long time, as its grain is very fine and dense.

Some parts of the bearings are made from steel that contains the desired amount of carbon. These parts are hardened and tempered without being subjected to the carbonizing process. Such work is inserted in furnaces and heated to the hardening temperature without being packed in iron pots. When it has reached the correct heat for hardening, it is quenched in tanks of oil or water. If the hardening temperature has been just right, *i. e.*, just above the transformation point, the steel will then be in the hardest state to which it can be brought. It will be what is termed "glass hard," and hence brittle, and must be heated again to a high enough temperature to draw out enough hardness to obtain the desired degree of toughness.

The hardening temperature is the most important one and will not allow of as much variation as the annealing and carbonizing temperatures, if the best results are to be secured. If the steel is not heated up to the transformation point before it is quenched, the change in grain structure will not take place and the steel will be no harder than when it leaves the rolling or forging operations. If heated above the transformation point the grain coarsens in proportion to the number of degrees of temperature above this point. As it coarsens, the physical properties of the steel deteriorate. Each rise of 50 degrees F. above the transformation point will lower the elastic limit of carbon steels something like 5000 pounds per square inch, and other physical properties in like proportion. Thus the greatest strength that can be given the steel can only be obtained at a certain temperature. Any variation from this means weaker metal. Its capacity to resist fatigue also loses somewhat over 15 per cent with each 50 degrees rise above the transformation point.

In hardening the various parts of Timken roller bearings, furnaces similar to those shown in Fig. 5 are used. These are the Strong, Carlisle & Hammond Co.'s furnaces. When the correct temperature has been obtained, the work is thrown into one of the tanks shown at the right, so it will suddenly cool. The hot steel would naturally raise the temperature of this bath, and when raised too high the steel would not be cooled quickly enough to produce the greatest degree of hardness. To overcome this difficulty, the liquid is kept constantly in circulation by allowing the hot fluid to overflow at the top of the tank and run into a larger tank which is located below the level of the floor at a considerable distance away. This allows the liquid to cool by radiation, and it is then pumped back into the tank. The stream that can be seen steadily flowing into the tank is the cool liquid coming from this pump. A wire basket lies in the bottom of the tank and covers nearly the entire bottom. When the hot steel is thrown in the bath it is caught in this basket. The block and tackle shown is used to raise the basket out of the tank when it becomes filled with work which has had time to cool. The basket is merely raised above the level of the tank and the work dumped into cars or trucks that convey it to the other parts of the shop where it is to be used. Thus large quantities of work can be handled during a regular work day at a very small cost.

The accuracy of the drawing temperatures is also very important. When too much of the hardness is drawn out, the bearing parts will be too soft and will compress when under load. When too little of the hardness is drawn out, they will be too hard and brittle and thus likely to crush or break. To get the greatest accuracy in the drawing temperatures, the furnaces shown in Fig. 6 are used. The heating chambers of these furnaces are revolving retorts through which the work slowly travels until it has absorbed the highest temperature of the furnace. It then drops out at the far end into receptacles which are removed when they are full. The retort has a spiral web on the inside and this, in connection with the speed at which the retort is revolving, controls the time that is consumed for the work to travel through. The work is dumped into the round hole shown at the near end of the furnace. Thus the tempering is done automatically and the furnace operator can devote most of his time to adjusting the burners, so the furnace will be maintained at the correct drawing temperature. These furnaces can also be used for automatically heating bearing parts to the hardening temperature and then dropping them into a quenching bath at the far end of the furnaces. The retort would then have to travel slower to allow the work more time in which to reach this higher temperature.

* * *

THE FIRST STEAM ENGINES

The first steam engines are said to have been built for use in pumping water out of mines. They were connected to vertical reciprocating pumps and were built with vertical cylinders. As it was not considered practical to place the engine directly over the mine-shaft, the heavy parts were placed at one side and a beam was used to reach over the shaft and make connection with the pump rod. At a later date the same style of engine was applied to drive mill machinery, the pump rod being connected with the crank which drove the shafting. This type of engine was used for several generations before a man came along who saw that the beam was unnecessary where there was no pit's edge to reach over. This is but an indication of the value of experience in power transmission and other engineering problems, and it is the accumulation of knowledge in this way that enables present-day designers to work out a transmission system to meet existing conditions. Various types of transmissions are used to meet the complex requirements of modern manufacturing plants. The development of these drives is the result of experience, and in order to get the most satisfactory results from a given installation it must be of the type best suited for the work; the equipment must also be correctly installed and properly cared for after installation in order to obtain the maximum efficiency.

* * *

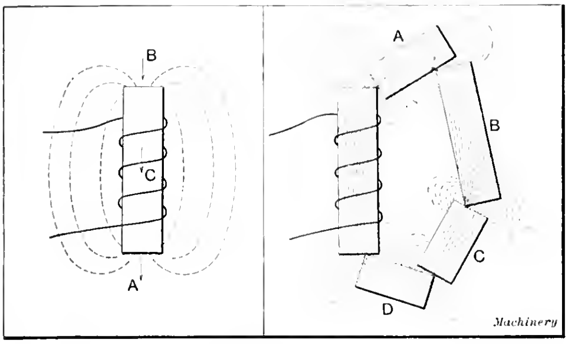
If iron is present in sufficient amount in brass castings, they will be hard and difficult to machine. The iron content should not exceed 0.5 per cent, in order to make good yellow brass castings that can be easily turned.

THE INSIDE OF THE MAGNETIC CHUCK—1

CHUCKS FOR VARIOUS PURPOSES AND PRINCIPLES OF DESIGN

BY HERBERT L. THOMPSON*

From the average mechanic who is not familiar with their various uses, magnetic and electrical appliances for shop use still receive a certain amount of distrustful indifference. This is undoubtedly the reason why they are not in more general use, and it is reasonable to believe that a better knowledge of the simplicity of their construction and operation would greatly add to their prevalence in all modern shops, both for tool work and manufacturing. Prejudice is often responsible for discrimination against magnetic chucks,



Figs. 1 and 2. Diagrams illustrating the Flow of the Magnetic Current

but if the tool designer would only realize how extremely simple they are, and how efficient for certain classes of work, we would see a great many more of them in use.

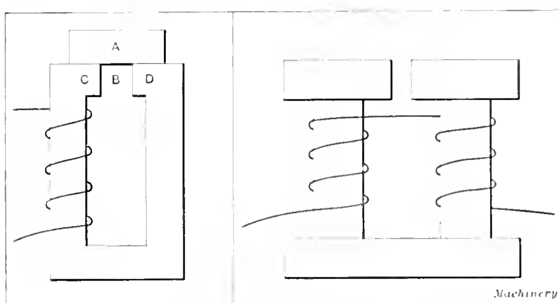
It is not difficult for anyone with an elementary knowledge of the principles involved to make good serviceable magnetic chucks; chucks that will hold any kind of iron or steel work and will operate on any direct-current lighting circuit of the voltage for which the coils are wound. The amount of machine work required in making them is generally slight and of the simplest kind, and when the low cost of the material and the operating current is considered, it is positively an expense to be without them, if any quantity of surface grinding, planing or milling is being done.

Every tool designer and tool-room foreman should be able to produce magnetic chucks for any work to which they are adapted. It is not a problem to which only an electrical engineer can aspire; on the contrary, the ordinary possessor of common sense and a little ingenuity can originate chucks of suitable sizes and shapes for a great variety of purposes, if he but knows approximately how to provide a proper magnetic circuit, energizing coils of proportionate size, and can use Ohm's law to determine the size of wire to employ in the coils to accommodate the voltage upon which the chuck is to be used. By computing the absolute resistance of the magnetic circuit and using a technically correct coil, a chuck could be made that might operate on a few cents worth less of current per week than one designed by the layman, but it is extremely doubtful if the possible economy would repay one for the extra effort. At any rate electrical formulas of this kind are very unsatisfactory, owing chiefly to the fact that the magnetic resistance of iron varies greatly, even in different parts of the same piece.

Comparatively few magnetic fixtures are employed for other than plain flat work on the surface grinder, the many obvious advantages obtained by the use of even an indifferent chuck in this connection having won them a place of some prominence. For milling, planing or turning, however, they have never been taken as seriously, and the reason is simply a deplorable lack of confidence in the holding power of a magnet for work of this character. While it is true that the ordinary surface grinder chuck is not intense enough to hold some of the heavier work, it is a simple matter to design chucks of enormous holding power for almost any shape of work. Of course, it is necessary to provide stops to take up the tool thrust on most heavy work, but as this in no way detracts from the value of the chucks as operation savers, it cannot be urged as an argument against them. Even non-magnetic metals such as brass or aluminum can be held on specially designed magnetic fixtures. To be sure, they cannot be held directly by the magnetism, as iron or steel could, but iron or steel clamping levers can be provided which are so disposed that the magnetic force will draw them against the work to be held. Perhaps this would not constitute a magnetic chuck, strictly speaking; but it is one of the variations that can be resorted to, and it will give instantaneous clamping and unclamping of the work which is the main consideration. Sometimes it is necessary to hold even iron or steel pieces in this way if they are very small or thin, as it is unhappily a fact that a piece of work must have a certain amount of cross-sectional area in order to be strongly held by any magnet.

Elementary Principles of Magnetic Chuck Design

The range of work that can be done with magnetic chucks is so enormous and of such diversified character that a description of a few of the different forms would avail little toward imparting useful knowledge to one who wishes to design them for special work, unless some attention was given to the elementary principles governing the production of an efficient electro-magnet. In other words, while the common type of chuck for flat work is very useful in the tool-room and at times in the manufacturing departments, it is the ability to adapt the magnetic circuit to any special work of varied shapes and sizes that is particularly valuable, for often work is held in a clamping fixture which consumes from 20 to 80 per cent of the operation cost in the clamping and unclamping, though it could be held with a magnet and gripped or released by simply throwing a switch. While it is not necessary to have more than a rudimentary knowledge of electricity in general to construct a good serviceable magnetic chuck, there are a few simple facts that must be borne in mind if the greatest success is to be obtained. The formulas given in the textbooks are suitable for dynamo design, in which a fraction of one per cent in efficiency is important; they are quite intricate, and as such accuracy is



Figs. 3 and 4. Diagrams showing the Function of the Air Gap and the Method of winding the Coils

unnecessary for magnetic chuck purposes, it would be a waste of time to master them. In fact, it is possible to explain all that is necessary by the use of a few simple diagrams.

A bar of iron upon which a coil of insulated wire is wound in one direction becomes a magnet when a direct current of electricity is passed through the coil. The greater the amperage (quantity) of the current, the stronger the magnet will be, up to a maximum point, which is called the "point of saturation." If the number of turns of wire about the bar is increased, the magnetism will increase in direct proportion, provided the amperage of the electric current is maintained and the magnetism does not approach too closely to the point of saturation.

The magnetic force caused by the passage of the electric

* Address: 287 Commonwealth Ave., Elgin, Ill.

current around the bar exists in the form of a magnetic current which enters one end and leaves at the other, as shown by the dotted lines in Fig. 1. It is apparent that the current that leaves at *A* is the same as that entering at *B*, and that there is a circuit up through the iron bar and back to the starting point through the surrounding air outside of the coil. Iron is an excellent conductor of magnetism, and for that reason the current travels easily through the bar; but in its effort to return outside of the coil it is greatly spread out, because it requires as much more air for its path as air is a poorer conductor than iron. To be more explicit, a conductor for either a magnetic or electric current must present a path of a cross-section increasing directly as the resistance of the material used. This is of paramount importance, as any increase in resistance results in a corresponding decrease of current, and if the material composing the circuit is of poor conducting quality, there must be enough of it to carry the current, as the resistance of any conductor varies directly as its cross-sectional area.

A bar magnet such as shown in Fig. 1 is not fit for any but explanatory purposes, as it really constitutes only a part of a magnet. That is to say, a complete magnet would be one in which the whole magnetic circuit was provided with a path of good conducting material, both inside and outside of the coil, so that there would be no loss through the resistance of an air gap. An approximation of this condition can be seen in Fig. 2, in which the poles of a bar magnet like Fig. 1 are roughly connected by the pieces of iron *A*, *B*, *C*

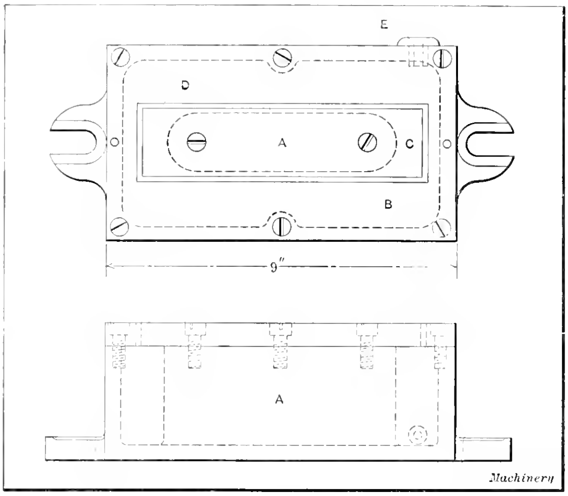


Fig. 5. Three-piece Gray Iron Chuck for grinding, planing or milling Work

and *D*. The dotted lines show how the magnetic current flows through them, and how it is no longer necessary for it to use the air except at the joints between the pieces, which offer too small a cross-section of iron for the conduction of all of the current without some help from the surrounding air.

A magnet will attract outside iron or steel only when the piece attracted constitutes a part of the path of the magnetic current, and the more its presence lowers the resistance of the circuit, the more forcibly it is attracted. Thus, at *C*, the magnet shown in Fig. 1 is not attractive, because a good conducting path is here already established, but at the poles *A* and *B* a strong attraction is felt, which is greatly increased by helping the outside part of the circuit with the pieces *A*, *B*, *C*, and *D*, Fig. 2. The magnet shown in Fig. 2 is feebly attractive only at the junction of the various pieces, as these are the only places where an improvement could be made in the conducting path; but any one of the pieces would resist being separated from its neighbors, and if, for instance, the piece *B* was removed, pieces *A* and *C* would become poles with the entire magnetic current spreading through the air between. They would strongly attract each other or any piece of iron brought within range of the greatly widened current between them. In fact, the entire energy of the magnet would be concentrated toward closing the gap between the pieces *A* and *C*.

The Function of the Air Gap

If the various pieces composing the system shown in Fig. 2 were welded into one continuous link, it would become a perfectly closed magnetic circuit, as there would be no gap for the current to cross through the air. If this was the case, however, the link would be useless as a magnet, as the whole of it would be as inactive as the magnet shown in Fig. 1 is at *C*, and for the same reason. As this is the case, it is highly essential in order to obtain the best results that a magnet should have a continuous conducting path of ample cross-section, except for one gap across which the work is to be held. Fig. 3 shows an example of a magnet of this kind and *A* represents the work in place across the gap *B* from pole *C* to pole *D*. It should be noted that the work *A* has sufficient area of contact with both the poles *C* and *D* to carry all of the magnetism, and that as the work *A* has approximately the same cross-section as either side of the link, it will form a path for the current without appreciably increasing the resistance of the whole circuit; therefore, the entire energy of the magnet will be expended upon holding the work *A* in place.

It is not strictly true that the iron path of any magnetic circuit will carry all of the current. It is necessary for all of the current to pass through the coil, but as the resistance of the iron is increased as the amount of current it carries increases, it is a fact that there will always be some small part of the current that will follow back through the air; for while air is greatly less conductive than iron per unit of cross-section, still there is always so much more air than iron available that it offers some inducement to the current. To receive the greatest possible efficiency from any magnet, it is necessary to have the polar gap adjacent to the coil, so that the piece to be held will bridge the most intense part of the circuit. With this object in view, it is desirable at times to use magnets of the form shown in Fig. 4, in which there are two coils with each pole piece as close as possible to the place where all of the magnetic current concentrates to enter or leave the coils. It is necessary to wind the coils of the magnet illustrated in Fig. 4 in directions as shown, as the direction in which the magnetic current travels is dependent upon the direction in which the energizing electric current flows; and if both magnetic currents moved in the same direction in each core (conductor inside of coil) they would oppose each other and result in no magnetism if they were of equal strength.

It is always desirable to have any magnet as nearly integral as possible, as a joint between two pieces of iron composing a magnet will always impose some resistance upon the current, however well they may fit. At least three pieces, however, are necessary to compose most magnets, as it would be very difficult if not impossible to apply the coils to the cores if the enlarged pole pieces were not removable. The objection to these joints is overcome by giving them as much area as possible and making them very smooth and close fitting. Careful workmanship at these points will make it possible to use more than three pieces in one circuit, when necessary, without unduly impairing the pulling power of the magnet.

Materials for Electro-magnets

Strictly speaking, iron is the only material that will make a satisfactory electro-magnet, but certain kinds of iron give better results than others, owing to their lower magnetic resistance. From the standpoint of efficiency, well annealed Swedish iron is not surpassed for magnetic chuck work, but as it is necessary to forge it into shape and do a great amount of machine work on it afterward, gray iron generally proves to be more practical, especially for chucks of the larger sizes. A magnet composed of soft Swedish iron would possibly hold with as much as 30 per cent more than one of similar design made of gray iron; but it would cost so much more than the cast-iron chuck that, except in case extremely small work was to be held, it would prove an unnecessarily expensive refinement. However, small rotary chucks are often advantageously made of Swedish iron forgings, as it is necessary to

machine them all over to insure good running poise. Whatever iron is used, it must be soft. Forgings should be well annealed after hammering, and if the gray iron castings should be somewhat chilled on the corners, it would pay to discard them and get new ones.

Forms of Magnetic Chucks

The simplest form of magnetic chuck is one having but two poles. There may be any number of coils, but if there is only one gap in the magnetic circuit it constitutes a "bipolar" chuck, and where the work to be done will permit its use, this form of chuck is the simplest and by far the cheapest one to make. Figs. 5, 6 and 7 are examples of bipolar chucks for various purposes. Fig. 5 is a three piece gray iron chuck having only one coil. It will hold any kind of flat work very nicely for surface grinding, and will also hold pieces that are of fair size and have a good contact surface for milling or planing, if suitable stops are provided so that the cutter thrust cannot slide the work off the chuck surface. This is probably the simplest kind of a chuck and is a very good one for the milder kinds of work. The coil is entirely enclosed with the iron frame, making it dirt and moisture proof. It is almost as easily made as an iron box, and while the drawing shows only a gap of plain rectangular outline, it could be made very intricate, if the nature of the work to be done required it.

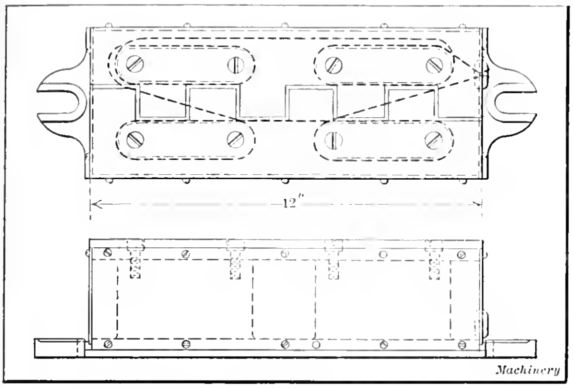

Fig. 6. A Four-coil Electro-magnetic Chuck

The core *A* of this chuck is cast integral with the base and sides. The top is composed of two separate pieces *B* and *C*, and a filler *D* which prevents magnetic contact between the pieces *B* and *C*. The form wound coil is dropped over the core *A*, and the supply wires enter and leave through the fiber bushing *E* in the side of the chuck. When an electric current flows in the wire composing the coil, a magnetic current is generated in the core *A* which circulates from end to end of the core *A* through the base, sides and top of the chuck, jumping the gap through the filler *D* and the air above and below the top plate. The filler *D* is an alloy composed of nine parts lead, two parts antimony and one part bismuth. It has the peculiar property of expanding upon cooling from the molten state. This greatly simplifies the making of the top of this chuck, which is accomplished in the following manner: The parts *B* and *C* are separate rough castings, each having been snagged fairly smooth on one side. They are laid with this smooth side down upon a flat surface, with the piece *C* carefully centered in the hole in the piece *B*. The molten filler alloy is poured between them until it overflows on the top, and when it cools its expansion holds the pieces *B* and *C* in position with absolute rigidity, though they are magnetically separated. The entire rough top plate can now be planed on both sides and the edges, exactly as if it was one piece, it being only necessary while planing the edges to maintain the position of the piece *C* so that when screwed to the base of the chuck it will center fairly well upon the core *A*, as of course, *C* acts as the pole piece of core *A*, while the piece *B* conducts the magnetic current from the sides and becomes the other pole when close to the gap. The piece *C* could be made almost any shape that would facilitate holding the work, but should be made as short in outline as possible, as the magnetic leak through the filler and air across the gap will depend upon the amount of pole area and the distance across the gap, which should never be less than 1/4 inch.

After the top plate is planed, drilled and counterbored for the screws and dowels, it only remains to plane the bottom and top of the base, and drill and tap the holes for the screws, dowels and the fiber bushing *E*, which completes the machine work on this chuck. If the work to be done warrants it, more than one top plate could be made for the base, each having a form of gap to accommodate a certain piece of work; it is such a simple matter to change them that it would probably prove an economy. Stop-pin holes can be drilled into any of the top plates to completely outline the work, if necessary, so that work requiring close location can be handled rapidly. Compared to any form of clamping jig, this little chuck should make an excellent showing both as regards adaptability and cost for any work within its scope.

Perhaps the chief objection to this form of chuck is the fact that one of the poles is too far from the coil, resulting in some loss of holding power; but for light work the simplicity and general compactness make it ideal. Such a chuck should not be made much larger than the dimensions on the illustration; in fact, no single coil chuck should be made much larger unless for holding single very large pieces; and even then a number of small coils would concentrate the force more and make a much more satisfactory chuck.

A Four-coil Magnetic Chuck

For holding work for severe planing and milling operations a chuck like the one shown in Fig. 6 is to be recommended. It will hold considerably more than the design illustrated in Fig. 5, because it has four coils and each pole is adjacent to the coils for its whole length. It is almost as simple as the chuck shown in Fig. 5, as it comprises only three iron parts. However, as it cannot be enclosed by integral iron sides without short-circuiting the polar gap, it is necessary to enclose the sides and ends with some non-magnetic material, so sheet brass is used. Of course, this does not make it water-tight, but as magnetic fixtures are seldom used with water or oil this does not detract much from the value of this shape. The top plate for this chuck is made in the same manner as the one in Fig. 5, but as neither pole piece in this instance embraces the other to any extent, it is doubtful if the expansion of the filler alloy would bind the two halves together firmly enough unless anchor holes were drilled or milled in the pole surfaces to insure a good grip. This can be done very easily though, by drilling quarter-inch holes at varying angles along the edge of the rough plate. The shape of the gap line can differ from the one shown, but it must not approach too

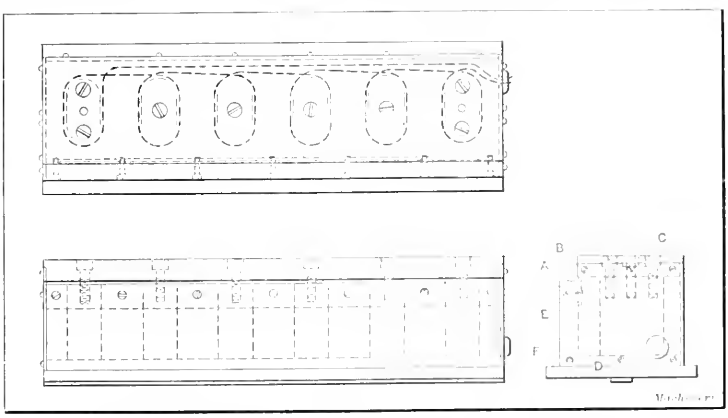

Fig. 7. A Magnetic Chuck adapted for Planing and Milling Operations

close to the junction of the cores with the top plate, as this would result in a partial short-circuit that would ruin the holding power of the chuck.

Very long pieces of work can be held with a chuck of this kind, as there is no limit to the length of gap line that can be made active if enough coils are used. The dimensions on the illustration show good proportions, and approximately the same number of coils should be used per unit of length, on any longer chuck. That is, if a chuck were to be made one-half again as long as the one shown, it should have six coils instead of four. In placing the coils on this chuck, great care should be used to see that they are connected as the drawing shows. Both coils on one side have the same polarity, and in order to accomplish this the electric current must pass around them in the same direction. The coils on the other side must both have opposite polarity to those on the first side, and any deviation from this order will result in partly or wholly neutralizing the chuck.

A Useful Chuck for the Planer or Milling Machine

When work is to be planed or milled parallel and at some definite angle with sides already established, a chuck of the form shown in Fig. 7 is certainly the most inexpensive and accurate fixture imaginable. The work is held by the poles *A* and *B*, and as the force is applied in both the vertical and horizontal planes, perfect location upon the chuck is the result. There are only two pieces of iron used in this chuck, the top plate *C*, the edge of which serves as pole *B*; and the base *D* which is integral with the six cores and the pole piece *A*. The filler in this case is a piece of one-eighth inch brass plate screwed to the pole *A*. It is shown on the drawing at *E*. One side and both ends of this chuck are enclosed by sheet brass, but the front is covered by the pole piece *A* and the filler *E*. No coils are supplied for the pole *A*, but their absence is compensated for by the shape and position of the poles, which present only their corners for magnetic leakage across the gap. As this chuck will often be made in very long lengths, the ledges *F* are provided for clamping it to the platen of the machine on which it is to be used. When in use, the current always warms the chuck to some extent, and if a long chuck were simply clamped at both ends to a cold platen, it would tend to bow up in the center to relieve the strain due to its linear expansion. For this reason it is preferable to place most of the clamping straps near the center of its length, and it is poor practice to draw them up very tight.

The poles *A* and *B* on this chuck are shown as they would be made for holding rectangular or cylindrical work, but they can be made to fit any shape of stock that would be necessary. Among other rather difficult operations that can be accomplished to advantage by the use of this chuck is the cutting of a perfectly accurate spline, or a flat side on a long piece of small round rod, the milling of absolutely parallel dovetail slides, or a number of parallel shoulders or slots in any long pliable work. This kind of work can even be done with the greatest accuracy when one or more rechuckings are necessary, as, for instance, in reversing to cut opposite sides of a dovetail slide or the vees of a straight ball race. Long work of this kind is seldom straight, owing to slightly unequal strains throughout the material; and this adds to the difficulty of holding it in any kind of a clamping fixture, as it will almost invariably bow up between the clamps. For this reason, a magnet is the only logical method of chucking, and it is also by far the most economical. The perfectly uniform attraction draws the kinky rod down to intimate contact with the chuck poles, and even though it is necessary to rechuck several times and the work springs a different amount after every cut is made, still each cut is parallel with its neighbor, regardless of how badly the whole piece may be bent. Of course, if the long pieces to be milled are castings, it will be necessary to give the first locating sides a fair average surface by hand or with the disk grinder, to prevent straining the crooked work straight for the first cut.

Light milling operations can be performed on this chuck without the use of stops of any kind, and if a stop is provided, the heaviest kind of back-gear milling cuts can be taken without fear of lifting or slipping the work. When a large number of duplicate parts of certain shapes require hand filing operations, no better bench vise could be wished; no manipulation is needed, and the pieces locate themselves if simply dropped near the poles. A magnet of this shape is also useful for locating work within its scope for jig-drilling; it is absolutely accurate, can be operated with one hand and in less time than any clamp. This is indeed a very useful form of chuck.

* * *

LIFE OF ELECTRIC POWER PLANTS

In a paper presented by C. M. Ripley before the annual meeting of the American Society of Heating and Ventilating Engineers, some statements were made regarding the long life of private electric power plants. It is an interesting fact that the oldest plant for generating electricity in a building in New York City was installed and put into operation less than four years after Thomas A. Edison announced the discovery of the incandescent electric light in October, 1879. George B. Post let the contract for a private electric plant in the Mills Bldg., opposite the Stock Exchange on Broad St., New York City, in 1883. This plant is still in daily operation. The fifteenth and nineteenth dynamos made by Edison have run every day for over thirty-one years and are still in perfect condition. Not only are the same dynamos in operation, but the original steam engines installed at the time by the New York Safety Steam Engine Co., now long out of business, are the sole means of driving the dynamos. H. J. Hardenbergh installed a private electric plant in the Dakota Apartments, New York City, in 1885 and some of the same apparatus is still in operation every day. The Evelyn apartment house has a twenty-five year old plant, consisting of one engine and dynamo, which is running every day. The Bank of New York has an outfit twenty-five years old which is held as a reserve but is run once a week to keep it in good condition. The Union Trust Co. for twenty-five years has had its same engines and dynamos running and at the present time they operate from eight in the morning to ten in the evening. The Tower Bldg., the first of a modern skyscraper type recently razed, had a power plant twenty-four years old. Many more examples of plants a long time in operation are quoted by the author. It has been the custom of many engineers and architects to assume a five per cent depreciation as the proper annual charge off on such installations, but this evidently is too high. Taking into consideration private electric plants installed as early as 1900, the results of the investigation show that twenty-four plants show less than five per cent depreciation, twenty-nine plants show less than four and a half per cent depreciation, seventeen plants show less than four per cent, sixteen plants show less than three and a half per cent depreciation and four plants show less than three per cent depreciation.

AN UNUSUAL MODEL SHOP

We usually think of a shop where miniature models of machinery are being made as occupying one or two rooms in an out-of-the-way corner, and employing but a few men. In view of this, it is interesting to note that the Peter Koch Model Works, at Koln-Nippes (near Cologne), Germany, devoted entirely to the making of models of machinery, steamships, etc., employ 200 men on this work. Models are made for experimental and demonstration purposes, engineering education and for exhibitions, museums, etc. As an example of what is accomplished in this line of work may be mentioned a model of a universal rolling mill for I-beams having a capacity for beams up to 40 inches high. This model was made on a scale of from 1 to 20, and when completed was about 8 feet long, 3 feet wide and 20 inches high. The model was so perfect that machine steel billets could be rolled in it into I-beams 3/4 inch in height. Steamboat models with all the external fittings almost perfect are also made, as well as miniature models of bridges and other structures and buildings. One of the particular uses for miniature models is for expositions, as it is often impossible to exhibit large machinery, and further, the model permits a much better perspective view of the whole mechanical arrangement.

COMMERCIALIZING A PRODUCT BY THE USE OF PRESS-WORK

PRESS-WORKING METHODS IN THE ECONOMICAL MANUFACTURE OF A PATENTED AUTOMOBILE WINDOW REGULATOR

BY CHESTER L. LUCAS*

Many a creditable device falls flat commercially because it cannot be marketed at the price which the cost of production demands. In this article will be described an ingenious device for the operation of the windows of an enclosed motor car, and the methods by which the product was gotten out at a price which would permit of its being marketable, still maintaining the highest possible quality. Figs. 1 and 2 show both sides of this device which is called the "perfect window regulator." It was designed and the details of production were worked out by A. K. Ternstedt, general manager of the Perfect Window Regulator Co., New York City. Its purpose is to raise or lower the window of a motor car, leaving it locked in any desired position; a side movement is also given to the window to throw it into its final position at the upper end of its travel. The "Perfect" window regulator is produced by press-work. Over twenty punched pieces, not including the chain, are employed in making, and no other machining operations, with the exception of the turning of a ball groove and the drilling of two or three holes, are resorted to. The remarkable part of the manufacture of this device is that it is almost entirely a product of punch and drawing presses. The die work is so perfect that the pieces are assembled without any fitting whatever, and the final operation of the mechanism is better than it would be if the pieces were produced by the more expensive machining operations often used on other products. The only parts of the regulator which are not made by press-work are two studs, three springs and a few screws, in addition to the balls in the bearings.

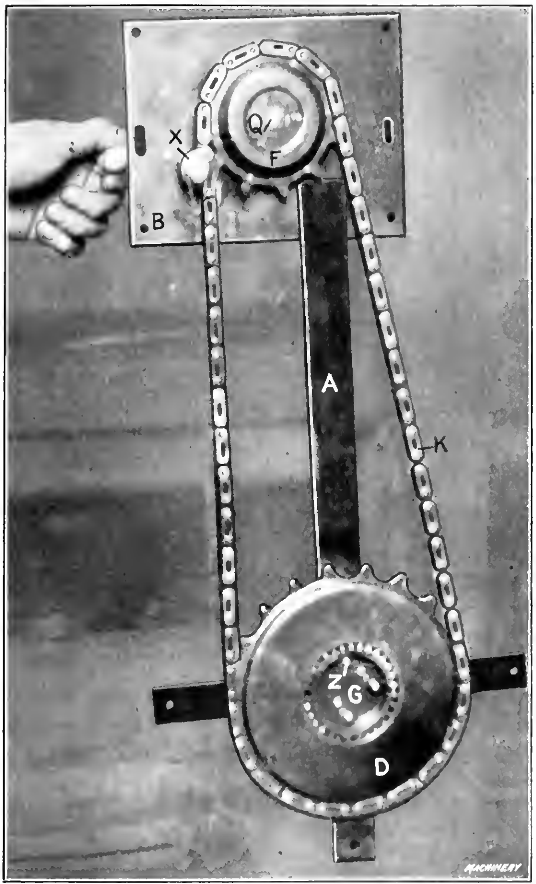

Fig. 1. The "Perfect" Window Regulator in Place on Rough Frame of an Automobile

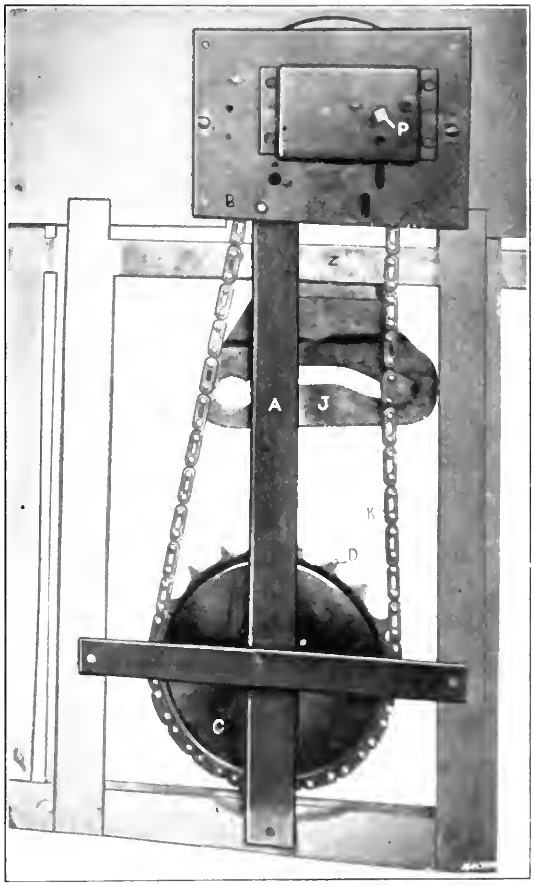

Fig. 2. Opposite Side of "Perfect" Window Regulator shown in Fig. 1

By referring to the various illustrations, some idea of the amount of press-work necessary may be obtained. Fig. 1 shows the assembled device from the rear; in Fig. 2 it is shown in place in the automobile before the inside finish has been applied to conceal it; in Fig. 3 are the various parts laid out for inspection, while Figs. 4 and 5 are sectional views through the sprocket mechanisms. The principal parts are the spacing bar *A*; the back-plate *B*; the cover *C* which fits over the lower sprocket; the lower sprocket *D*; the two halves *E* and *F* of the upper sprocket; the lower sprocket ball-race *G* and the upper sprocket ball-race *H*. The gear-box may be seen at *I*, the cam-plate at *J*, and the operating chain at *K*. These parts are the principal ones that are visible in the assembled device, but in the mechanism there are also smaller parts which can best be seen by referring to the sectional drawings, Figs. 4 and 5, showing the upper and lower sprockets, respectively. The mechanism in the upper sprocket is composed of the clutch shown at *L*, the clutch-cam *M* and the small torsion spring *N*. The pinion *O*, mounted on the stud *P*, is within the gear-box and meshes with a thirty-five-tooth gear on the spindle for the upper sprocket *Q*. The three parts which comprise the thirty-five-tooth gear are shown at *R*. A coil spring *S* is used for compensating the weight of the window frame and glass. This spring works within the sprocket cover *C* and cover *D*, one end of the spring being looped around the lug that has been bent up out of the sprocket, and the other looped around the stud on the spacing bar that projects through a hole in the sprocket cover.

The chain is built up of punched links *T* and studs.

* Associate Editor of MACHINERY

Mounted on the chain are two hooks V, on which is supported a spiral spring W that takes up the slack of the chain. A roller stud fastener X is applied to the chain to support the stud and roller which operates in the cam-plate attached to the window sash. The spring Y that is mounted on the roller stud to prevent rattle at the cam-plate and the clip Z for closing the ball bearing filling slot in the lower sprocket, the miscellaneous screws and the steel balls complete the parts of the device. The thirty-five-tooth gear is composed of three punchings and the small pinion, while not made completely by press-work, has its teeth formed by a punch-press broaching operation, as will be explained later.

In order to understand the functions of the different parts, it will be best to first explain the operation. This can best be done by referring to Fig. 2, which shows the device installed in the framework of the limousine, for after it is in place the only visible part is a handle which fits upon the squared section P of the pinion shaft. This handle is not shown in the illustration. The window regulator is supported in the framework of the car by screws in the ends of the spacing-bar and cover plate. The glass window of the car is represented by Z in this illustration; the lower edge of the window, being mounted in a metal channel, forms the base that supports the cam-plate. Fig. 2 shows the window in its lower position; by turning pinion-shaft P with the handle which is provided the chain travels upward over the sprocket, carrying the stud that is mounted on the chain which, in turn, causes the cam-plate and window to be raised. As soon as the cam-plate, which fits around the stud, reaches the level of the upper sprocket's top edge, the stud slides along the slot in the cam-plate. The cam-plate is bent so that its surface lies in two different planes as is shown at J, Fig. 3. Therefore when the stud passes the bent section of the cam-plate, the cam-plate, and consequently the window, is thrown over sideways for the necessary distance to fit the window over the ledge which supports it when closed.

Taking up the parts of the device separately, the spacing-bar is made of two sections of strip stock which are sheared, the holes punched in the ends, offset and riveted at the center. In the back plate, which is made of sheet steel 5/64 inch thick, there are twenty-nine punched holes. No drilling or counterboring is done on this plate. It comes from the punch press direct to the assembling bench. The lower sprocket cover C is a plain cutting and drawing operation, but the lower sprocket, itself, shown at D, is a more complicated piece of press-work. This is made from sheet steel 0.080 inch thick, and to leave it in its finished shape requires nine operations. These are as follows: rough-blanking and drawing, first redrawing, second redrawing, annealing, drawing edge down and setting up the center, swelling out for the ball-race, closing in the edge of the ball-race, trimming the piece and shearing in the spring lugs. A section of this sprocket appears in the line-drawing, Fig. 5, and the most unusual part of the work is the forming of the ball-race in the stock at the center, for it should be remembered that the ball-race is not finished by grinding or turning. When it leaves the dies it is done. The economy of producing this part alone by press-work will be readily appreciated because the stock required and the machining operations that would be necessary to make the piece from solid stock or from a casting would be considerable in themselves.

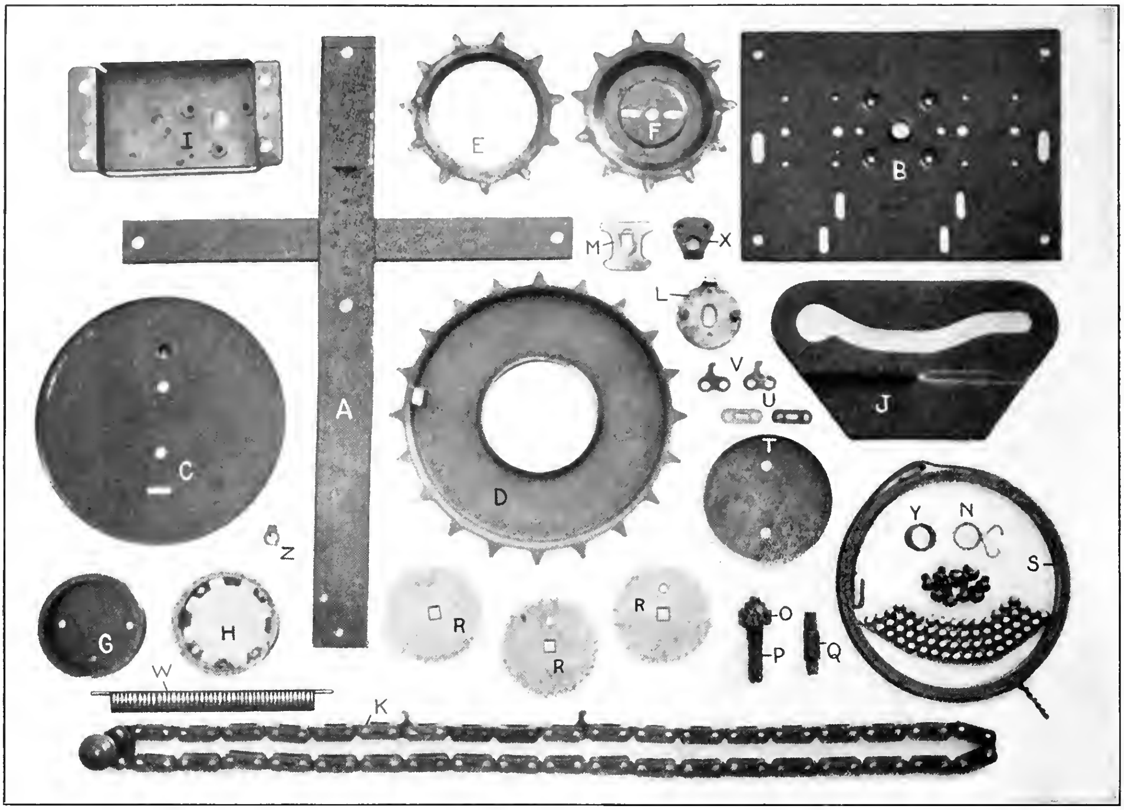

Fig. 3. The Various Parts of the Device—Nearly All Products of Press-work

The halves E and F of the upper sprocket are made in the same die. The first operations are comparatively simple, comprising the blanking and drawing of the piece, the trimming of the piece and the piercing of the hole. The top half of this sprocket is made by simply punching out the center of the bottom half stamping. The ball-race sections for the top and bottom sprockets are also both made in the same die. These two pieces are shown in Fig. 3 at G and H, G being the ball-race for the lower sprocket and H the ball-race for the upper sprocket. These are formed from steel 5/32 inch thick. On account of the drawing operation, the sides of the cup that comprise this part are much thicker than the bottom—the edge being thickened as the result of the drawing operation. The thick edge, of course, forms the section in which the ball-race is turned. The lower sprocket ball-race has three holes punched in it and also a filling slot punched

in the edge. This filling slot, after the balls have been put in place, is closed by the small spring clip that may be seen at Z, Fig. 3, and thus the balls are prevented from coming out of the groove while in action. The upper sprocket ball-race is formed from the same cup as the lower ball-race by punching out the center. In punching out this center, the stock is removed so as to leave the edge in the form of clutch teeth. By referring to the line illustration Fig. 4, the purpose of these clutch teeth will be seen. The clutch is shown at L, Fig. 3, and is a plain punching with a lug that is afterward bent up. Two pins are forced into holes that have been punched and an oblong slot in the center provides for a plain in-and-out motion of the clutch that acts in conjunction with the clutch teeth in the ball-race.

The purpose of this mechanism is to provide for the raising or lowering of the sash to any desired point, with the

Broaching the Teeth on the Pinion

The pinion blank and pinion spindle shown at O and P in Fig. 3 are, of course, produced on the screw machine, but the forming of the teeth on the pinion blank, leaving it in the condition shown in the illustration, is a press operation, and one that is worthy of description. These gear teeth, ten in number, are formed on the 3/4-inch diameter section of the pinion blank by a broaching operation, the piece being finished to the entire depth at one pass of the broach. The fact that the pinion face is one-half inch wide makes this operation of decided interest.

The die used for this broaching operation is shown in section in Fig. 6, and Fig. 7 shows it in place in the press. This illustration is intended to give only a general idea of the tools for broaching these gear teeth, but from it will be seen that the press has an extra long stroke. The punch is fluted

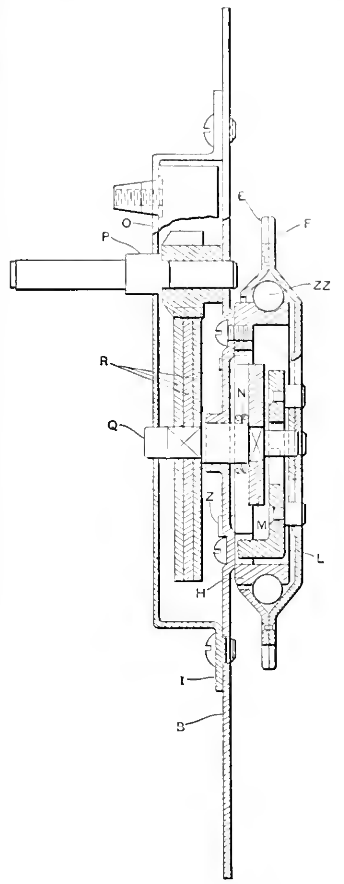

Fig. 4. Sectional View through Upper Sprocket and Gear-box

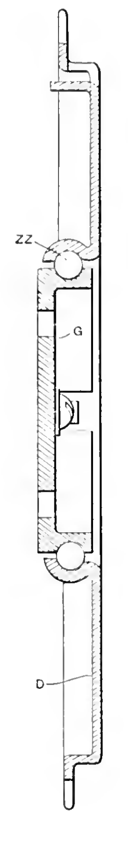

Fig. 5. Sectional View through Lower Sprocket

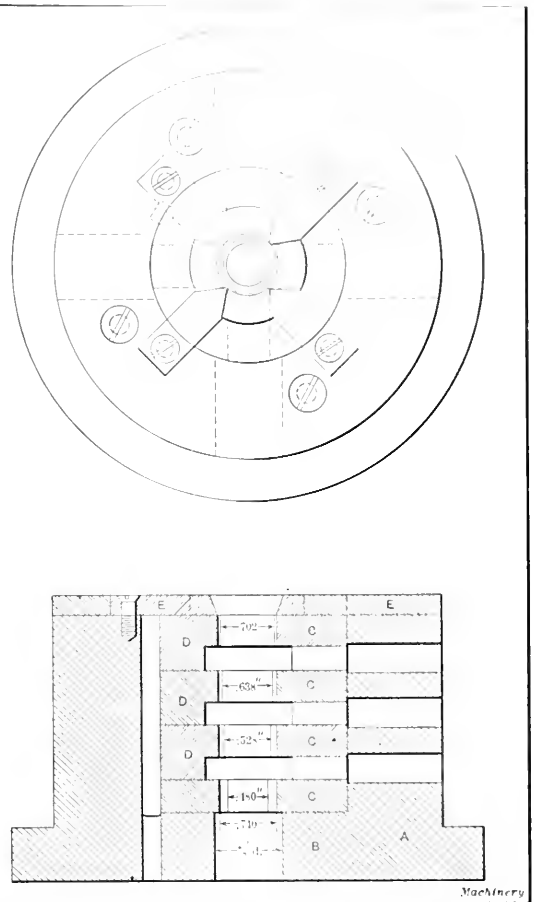

Fig. 6. Sectional View of Broaching Die for cutting Teeth on Steel Pinions

surety that it cannot be pushed open by an outsider or jar out of position. When the handle on shaft P is turned, the pinion O and gear R cause shaft Q to turn. As the clutch-cam M is anchored to this shaft, it also turns, of course, causing its sides to act on the two pins in the clutch, and giving the clutch a longitudinal movement to disengage the teeth. Continued turning raises or lowers the sash, as the case may be, and when pressure is released from the handle, spring N throws the clutch-cam in mesh again.

The spring-case, cam-plate and gear cover are all good examples of press-work, but there is nothing extraordinary in the production methods that are employed. The three gear-blank punchings shown at R in Fig. 3 are lined up when assembled on the square section of the sprocket spindle so that the three gears form a composite or sectional gear as shown at R, Fig. 4.

for its entire length with grooves corresponding to the gear teeth so that there will be no interference when pushing the gear blank through the die. The die is fitted with a lubricant pipe for supplying oil to the broaching sections of the die. Now, by referring to the line illustration which shows the die in section, it will be seen that it is built up within the heavy casing A. A base-block B is fitted at the bottom of this casing and four sets of broaching dies C are used for cutting the teeth. These broaching dies are separated with spacing blocks D at intervals of 5/16 inch; thus the first broaching die measures 0.702 inch at the bottom of the teeth. As the blank is 0.750 inch in diameter, it will be seen that the first die section removes 0.048 inch. The second die section measures 0.638 inch internal diameter, thus removing 0.064 inch additional from the gear teeth. The third section which is 0.528 inch diameter reduces the teeth in diameter

to this size, removing 0.110 inch of metal. The fourth and last section measures 0.180 inch in diameter, reducing the blank by 0.018 inch only; thus the last cut is more of a finishing operation than a metal removing process. A pilot on the punch serves as a locating point for starting the gear blank, and as the sides of the gage strips *E* are slightly beveled, the blank is made to enter the broaching dies straight. This broaching operation is very successful, and the teeth are cut much more rapidly and accurately than could be done by ordinary gear-cutting methods.

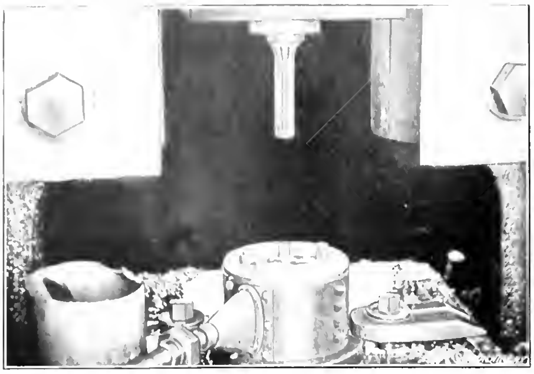

Fig. 7. Gear-teeth Broaching Punch and Die in the Press

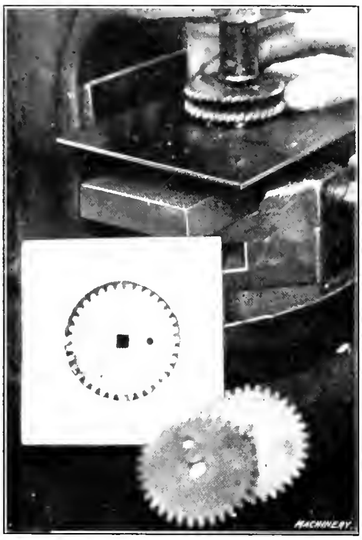

Fig. 9. Assembling the Sections of the Thirty-five-tooth Gear

Assembling the Regulator

The assembling operations are shown in Figs. 8, 9, 10, 11 and 12. Fig. 8 shows the assembling of the chain. This is done in a foot press, inserting the rivets through the links and upsetting them sufficiently to keep the parts in place until they can be riveted on a power riveter. In each chain must be correctly located two of the hook links for supporting the spring that takes up the slack and correctly tensions the chain, and also a stud supporter for carrying the stud-roller which works in the cam-plate and acts on the window frame, as has been previously described.

Fig. 11. "Running-in" the Clutch Mechanism

Fig. 9 shows the building up of the thirty-five-tooth gear, using the three punched sections that were shown at *R*, Fig. 3. These are assembled on the square section of the spindle by using a hollow punch in a foot-press. The ring shown before the press has aligning teeth to engage the three punchings and is used for locating the sections when being forced into position so that the teeth will match up correctly.

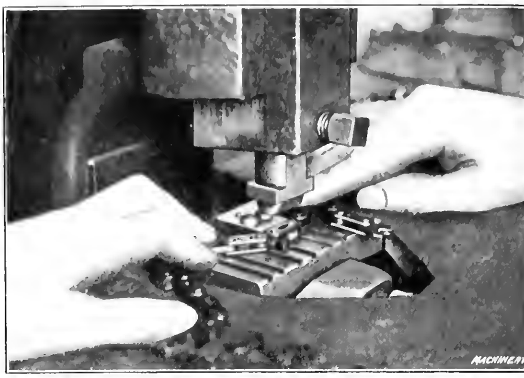

Fig. 8. "Building" the Chain

In Fig. 10 may be seen the assembling operation on a back-plate. The screws are driven into place with an Errington stud-setter, using a screw-driver for this particular job. By this means the screws are all driven to the same tension a great deal faster than they could be by hand. Fig. 11 shows the "running in" of the upper sprocket. In order to insure that this part of the device works successfully, it must be run in so that it is free from all jumpy action or sticking. Here again an Errington stud-setter is employed having a square socket to take the place of the handle. This is used on the end of a horizontal shaft and any excessive friction causes the stud-setter to slip, thus showing that the part in question is defective.

Fig. 10. Errington Stud-setter used as a Screw-driver

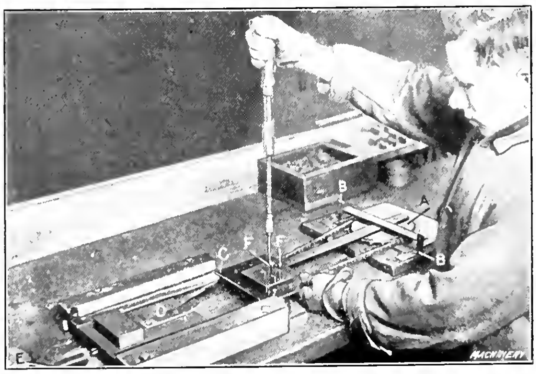

Fig. 12. Adjusting the Tension of the Chain

Fig. 12 shows the final assembling operation; *viz.*, the tensioning of the device. At this time the device has been as-

sembled in two sections: the spacing bar with the lower sprocket, and the back-plate and upper sprocket. It now remains to locate the back-plate and upper sprocket on the spacing bar at the correct distance from the lower sprocket so the chain will operate freely under load. This is tentatively done by two screws in the spacing bar that pass through slots in the back-plate. These slots are about one-half inch long, which gives considerable latitude. The tensioning device is shown in Fig. 12. The spacing bar and lower sprocket, shown at *A*, are held against the brackets *B*. The chain is passed around the sprockets and the back-plate by means of two corner holes located on the slide *D* that is drawn back by the tensioning spring *E*. The spring used is sufficiently strong to give tension enough to counterbalance the weight of the automobile sash and window that the device is to be used in connection with. As soon as the spring has drawn the back-plate to its position, the operator sets up screws *F*, after which he drills and rivets the back-plate to its permanent position on the spacing bar.

This operation completes the regulator and it can now be appreciated that the entire device has been built to the "tune" of a punch-press—no castings, forging or other machined parts being used. It will also be noted that all the way through, as far as possible, simple dies have been used and whenever it was found possible to produce more than one part from the same die by a little change in design, this was done. The simplified design and the elimination of all operations except that of press-working has made it possible to produce this device at a marketable price, and it has been very successful.

FILING YOUR OWN PATENT—A REPLY

BY A. P. CONNOR*

In the February number of MACHINERY there was an article entitled "Filing Your Own Patent"; there are many inaccuracies in this article. In order to correct the wrong impressions which its publication may have created, the present writer will analyze it, so that the reader may not only be warned of the pitfalls which lack of knowledge may lead him into, but be equipped with that information which will serve to assist his judgment in determining the proper course to take in such matters.

The title itself, "Filing Your Own Patent," is subject to criticism. The writer did not refer to the *filing*, but the *prosecution* of a patent *application*. Hence, the article should have been entitled, "Prosecuting Your own Application for Patent."

[On page 167 of the *World Almanac*, 1914, in a statement revised by the Patent Office, the following appears: "If an inventor wishes to file an application for patent * * *" This would indicate that the expression "filing" is not entirely incorrect in this connection.—EDITOR.]

In the first paragraph of the article in question, it would seem that the previous writer intended to keep on both sides of the matter, first by pretending to discourage the inventor against applying for his own patent, and then advising him to do so, through insinuations that his path would not be so difficult, if he really wanted to try it. The writer evidently thought that some excuse for his article was necessary, as he assigns the ground that "stern necessity may compel the inventor to prosecute his own application for patent." This reason is worth analyzing. When does this "stern necessity" compel an inventor to take the course suggested? The most practical reason which may appeal to many readers is the financial one. It may be suggested that the inventor is penniless, which, however, is seldom a fact, because invention is dependent on industry, and industry keeps a person with some loose change. Secondly, if his invention is valuable and worthy of a patent, can he not get someone to pay the costs of the fees for the patent application, in exchange for an interest in the invention? If not, the case is a very rare one in our present age, when the value of patents is appreciated.

The writer is frequently requested, by persons he knows personally, for opportunities to get an interest in good inventions. Almost anyone would risk the moderate cost necessary in patent matters for a chance to make a substantial fortune out of it. Then, again, an attorney will usually be reasonable in pressing financial matters on his clients, so the inventor will not be unduly embarrassed. Can any one of intelligence imagine a case where it would be advisable for an average inventor, or even a person of exceptional ability, who is inexperienced in patent matters and practice, to prosecute his own application, and expect to be as amply protected as his invention merits?

We are further informed that "it is a notorious fact that there are a great many incompetent patent attorneys." The statement is so serious that it seems hardly possible to believe that it could be made with such *sang froid*, and the late writer should either prove it or withdraw it. A copy of any proofs in the matter should also be submitted to the Commissioner of Patents for appropriate action.

[On page 167 of the *World Almanac*, 1914, in a statement revised by the Patent Office, the following appears: "The Patent Office cannot recommend any particular attorney or firm, but advises applicants to avoid doing business with those who advertise the possession of unusual facilities for obtaining patents."—EDITOR.]

The present writer may incidentally say that the registration of patent attorneys is a very strict matter at the present time, and the requirements are severely enforced. Assume, for an argument, that the statement is true that we have incompetent attorneys. The inventor is advised to prosecute his application even though he does not know what he is doing, but he is warned to keep away from incompetent attorneys. It would seem that an application for patent would be safer in the hands of the most incompetent attorney, because he must know *something* about what he is doing, rather than in the hands of an inventor who knows absolutely *nothing*.

We are further informed "that most patents are valueless because they have no real invention behind them." Surely the country would like to have the authorities and proofs supporting the statement. However, the courts sustain the patent practice, all inventors of ability and consequence patronize the Patent Office, and the examiners have to pass the strictest examination in the whole civil service and are in addition usually trained as lawyers. All corporations, capitalists and other persons interested in patents will not consider inventions without patents protecting them. Have all these been fooled? Has all our industrial progress, and the fortunes made on patents been the outcome from inventions with no real invention in them? If the original writer has the key to the identification of valuable invention, which has been overlooked by everyone except himself, now is his opportunity to enlighten the world.

[In 1909, the *American Machinist* investigated the matter of how many patents paid back their own cost and found that only twenty-three patents out of a hundred paid their own cost. Note that this does not imply a profit, so that while it is not known how many of these twenty-three were actually profitable, it was certain that in the hundreds of cases covered, seventy-seven out of one hundred did not pay their own cost. This investigation carefully carried out under reliable auspices seems to give some strength to the statement of the former writer that most patents are valueless.—EDITOR.]

As to the suggestions for selecting an attorney: We are told that attorneys should "have built up a reputation over a long period of years, and be known to prominent attorneys, bankers and business men." Evidently the question of ability, technical training, energy and actual results are not worth consideration, nor would a young struggling conscientious attorney be considered. Yet, if the advice was made use of and it was found that the prominent attorney had turned the case over to an employe, and that the former in fact never saw the invention at all, what would the prior writer say, even if the original attorney has all the qualifications given? The writer has known of several instances where it proved more dangerous to make use of attorneys with reputation than the more mediocre ones, because of the fact that the former gave very few of the cases their personal attention. Therefore, the suggestions are by no means adequate, but rather misleading, especially to the inventor with more ability than money.

* Consulting electrical and mechanical engineer and patent attorney, 121 Carroll St., S. E., Washington, D. C.

MAKING FORMED CUTTERS*

MACHINING THE FORMER AND MASTERS, FORMING THE BLANK, AND CUTTING AND RELIEVING THE TEETH

BY F. H. JACOBS†

Milling cutters of irregular shape that can be sharpened without altering their contour, an example of which is shown in Fig. 1, are generally called formed cutters. They are used for milling irregular surfaces on gun and sewing machine parts and on other work of like nature. Perhaps the first formed cutters to be commonly used were the gear-cutters known to every mechanic. Satisfactory formed cutters can be procured from any cutter manufacturer at a moderate cost, but as several weeks often elapse before special cutters are delivered many shops are equipped to make their own cutters.

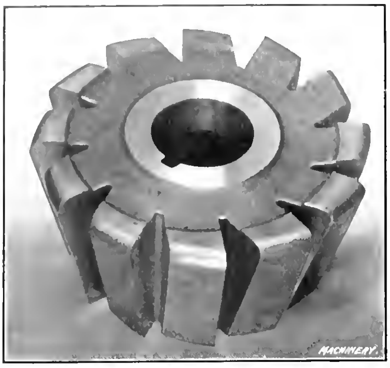

Fig. 1. A Typical Formed Cutter

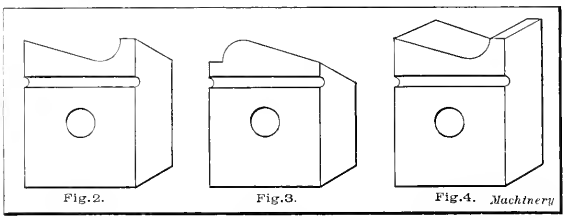
In explaining the various steps in the making of a formed cutter we can use the tool illustrated in Fig. 1 as an example. As this is a male cutter it is formed and backed off with the female former shown in Fig. 2. As this former has to have a clearance of at least 15 degrees, with the original lay-out accurately preserved, it is necessary to form it at an angle by means of the master shown in Fig. 3. As this master has a convex surface that would be difficult to work out accurately by hand, a second or female master is made. This is shown in Fig. 4, and it is an exact counterpart of the shape we wish to mill worked out in a block of steel without any clearance. This piece is hardened and drawn to a medium straw color.



Figs. 2 to 4. Former and Male and Female Masters for producing Formed Cutters

To make the masters and former without distorting the contour, and at the same time give the former the necessary clearance, the angle block and tool shown in Fig. 5 are used. The angle block is strapped to the platen of the shaper and the female master is fastened to the angle tool. First, however, the outline is worked to shape as near as possible with regular tools, the female master being used only for finishing. As the illustration shows, it works with a drag cut which necessarily means slow procedure. It will also be seen that the faces of the two masters are parallel; this is why the proper contour can be maintained, notwithstanding the fact that clearance is imparted to the male master. This master is now hardened and drawn and the same process gone through with in making the female former.

The masters and former are sharpened by grinding their tops or faces. The slight groove shown is for the corner of the wheel to run into. They should be sharpened on the surface grinder, as their faces must remain flat; otherwise the contour will be changed. In finishing the master and former on the angle block, it is necessary to use a very slow cutting speed to avoid chattering. As a very smooth surface is desired, good lard oil should be used as a cutting medium.

Formed cutters can be made of bar stock chucked out and turned up in the usual way. About 0.003 inch should be left in the hole for finishing by grinding after hardening, and it is a good plan to relieve the sides as shown in Fig. 1, as this eliminates a certain amount of unnecessary grinding. The hole should be chambered and provided with a keyway. The form is turned on the cutter with the former previously made. This is done in the lathe, the former being fastened to the tool shown in Fig. 6. It is seen that both this and the angle tool are made on the goose-neck principle to obviate chattering.

The cutter is now ready for cutting or scoring. This is generally done with a 30-degree angular cutter rounded at the point. Before cutting, it is a good plan to drill holes as shown in Fig. 7. This leaves a slight clearance for the corner of the wheel to run into during the grinding operation. After this operation is finished, the cutter is ready for relieving, or as it is more commonly called, backing off. There are several appliances for this purpose in the form of attachments for the lathe and milling machine. The device shown in Fig. 8 is simple to construct, easy to set up and it gives very good results. Briefly described, it consists of a sliding base mounted in a bed that is strapped to the milling machine platen. A strong spring thrusts the base toward the spindle and cam. The cam is mounted on a cast-iron holder that screws onto the nose of the spindle, while the cutter is mounted on a stub arbor. The former, shown in Fig. 2, is fastened to a sliding head that is actuated by a screw. This regulates the depth of cut in backing off the cutter. The details are shown in Fig. 9, which illustrates an end elevation and longitudinal section. As each cam has a fixed number of teeth, three are generally provided for cutters with ten, twelve, and fourteen teeth, respectively. It is very necessary that these cams be accurately made; otherwise faulty cutters will result. The method employed in laying out and machining will be explained later.

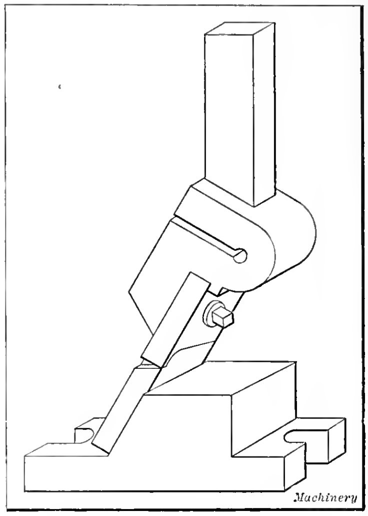


Fig. 5. Angle Block and Tool used for making the Former and Master

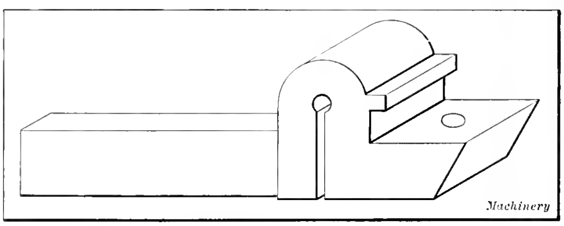

Fig. 6. Gooseneck Tool-holder on which Former is mounted for machining Formed Cutters

In setting up for the backing-off operation, it is necessary that the cutter be set so that the teeth are in the correct re-

* For additional articles on formed cutters and allied subjects, see "Importance of Grinding Gear Cutter Teeth Radially" published in MACHINERY, July, 1907; "A Formed Tool Problem," January, 1910; and "Milling Radial Teeth in Cutter Blanks," November and December, 1911, and other articles there referred to.

† Address: 1040 North Illinois St., Indianapolis, Ind.

lation with the corresponding cam rises. To this end, an arbor without a tang is used. A line is scribed on the cam meeting the high points of two rises that are opposite. The arbor is placed loosely in position, the cam set central by means of the scribed lines and a surface gage, and the arbor adjusted so that the cutter tooth does not meet the former within 1/16 inch. The arbor is now driven solidly into position. The object of the 1/16-inch leeway is to make sure that the former is moving toward the cutter before the tooth is reached.

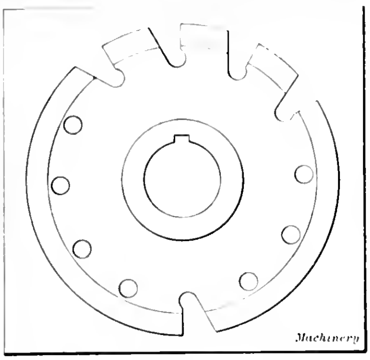

Fig. 7. Holes drilled in Blank before cutting Teeth

In backing off, a very slow speed should be used and the work should be lubricated with lard oil. Light cuts should be taken, as heavy cuts are likely to leave scores which result in unsatisfactory work on the part of the finished cutter. After the teeth have been backed off, the former should be reground and the top whetted on an India oil-stone wet with gasoline. It should be examined under a glass to make sure that it has a clean sharp edge without scores. It is then placed in position again and a light finishing cut taken. It is necessary that the top of the former be set central with the cutter, for if it is above or below, an incorrect contour will be formed.

The cutter is now hardened and drawn in the usual way. After hardening, the sides should first be ground. A Heald piston-ring grinder is an excellent machine to utilize for this purpose, but if one is not available the universal grinder can be used. After grinding the sides, the cutter is strapped to the faceplate of the grinding machine, the hole trued up with an indicator and ground to the desired size. The next operation is to grind the faces of the teeth. While this is a simple operation, care should be exercised to see that the teeth are equally spaced, for while they probably were equally spaced after cutting, the hardening process may have distorted them slightly. This grinding operation was fully described in MACHINERY, February, 1912.

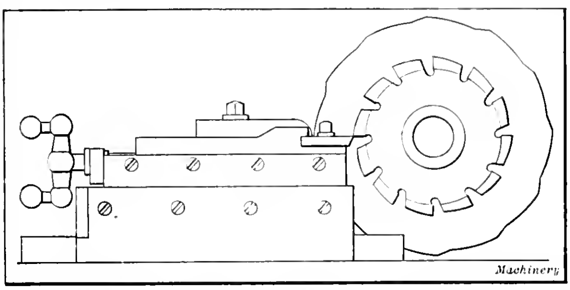

Fig. 8. Milling Machine Relieving Attachment for backing off the Teeth

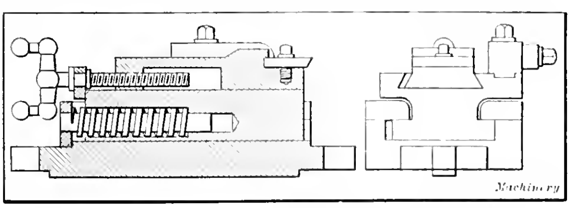

Fig. 9. End Elevation and Sectional View of Relieving Attachment shown in Fig. 8

As previously stated, the cams for relieving the teeth should be accurately made, and the most simple and efficient way is as follows: The cam plate is first chucked out to fit the mandrel *A* shown in Fig. 10 and the sides and periphery turned in the usual way. The hole is then plugged up, as this space has to be utilized in laying out. This lay-out is illustrated in Fig. 11. First one actual sized cutter tooth is drawn or rather scribed, as shown, the object being to determine the pitch of the clearance. It is necessary to have enough clearance to allow the cutter to take hold of the work; and at the same time, if too much is allowed, short-lived cutters having a tendency to chatter will result.

A good practical way to determine the correct amount of clearance is to use as a guide a formed cutter made by a reliable cutter manufacturer. Set this cutter central on the cam blank and carefully scribe the clearance line. This line is nothing more nor less than an arc set off center. With a pair of dividers, find the center and mark it with a center-punch mark. This center is shown at *B*, and the line of clearance at *C*. From the center *B* the arc *D* is scribed, which gives the same relation between the points *E* and *F*. The 30 degrees in the arc *G* represent one tooth. To make sure that the former will not start to return until the complete tooth has been gone over, and also that it will be ready to start cutting as soon as the next tooth strikes it, the time of return is confined between the lines *H*. Next the circle *J* is laid off. It is seen that this connects the lowest point of the stroke with the beginning of the next stroke. The center of this circle is carefully center-punched.

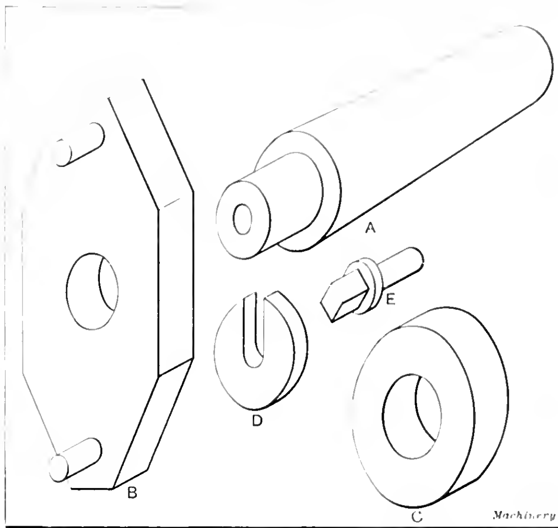

Fig. 10. Tools used in machining the Relieving Cams

The two holes *K* and *L* are next laid off, and the centers punched. There are twenty-four holes altogether, two for each tooth. These are used for locating the cam while machining the rises. Before doing this, it is necessary to be provided with the tools shown in Fig. 10, where *A* is a mandrel to fit the milling machine dividing head, and *B* is the locating piece, the hole in this locating piece being a driving fit over the mandrel. Before using this piece, however, it is necessary to finish the twenty-four small holes, also the twelve large ones in the cam blank. This is done in the milling machine, the dividing head being used for spacing the holes. The head is set at right angles with the platen, its center being on a plane with the milling machine spindle.

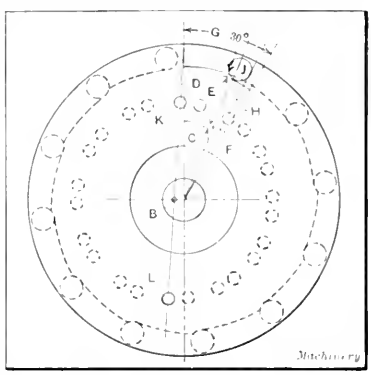

Fig. 11. Layout of One of the Relieving Cams

The cam blank is placed in position on the special mandrel with the collar *C* back of it. This collar is used simply to

fill up the space that is later occupied by the piece *B*. The screw and washer *E* and *D* are used in clamping the cam blank. The punch mark for the hole *K* is carefully centered, after which the hole is drilled, trued up with a boring chip and then reamed. The dividing head having previously been set for twelve divisions, the remainder of the holes corresponding to *K* are finished. Next the center for the hole *L* is located and all the holes in this circle finished. These holes are shown by the small dotted circles in Fig. 11. It is evident that these holes finished in the manner described will serve as an accurate means for locating the blank while machining the rises. Next the hole *J* is located, drilled, bored and reamed. As this is comparatively heavy drilling to do in the manner described, the superfluous stock can be drilled on the upright drill. The piece is then replaced in position on the milling machine and the holes bored and reamed. The center hole is now indicated and bored in the lathe to the correct size to fit the cam back.

By referring to the piece *B*, Fig. 10, it is seen that it has two holes in a line with the center. These holes are supplied with dowels. It is evident that when the holes *K* and *L* in the cam blank are slipped over these dowels, the arc *D* is thrown in a position where it can be machined as part of a circle. This is done in the shaper, the dividing head being used for the purpose, the cam blank and the piece *B* being held on the special mandrel. After planing one rise as shown by the dotted lines, the piece is moved into position for the next rise, and so on until all are gone over.

In the final finishing, all the rises are gone over one after the other with a very light chip, the set of the tool not being disturbed. It is very necessary for all the rises to be alike; otherwise, cutters with uneven teeth would be the final result. For this reason, after the final finishing chip has been started it should be continued, for if the shaper should be allowed to remain idle for a time—say over noon hour, or what would be worse, over night—some rises would surely be higher than others. Three of the holes can be used for dowels in locating the cam on its back, while three more can be countersunk and used for screw holes. The cam should be made of tool steel and it should be hardened in cyanide and oil, as any other hardening process might distort it.

A NEW FIELD FOR THE OXY-ACETYLENE CUTTING TORCH*

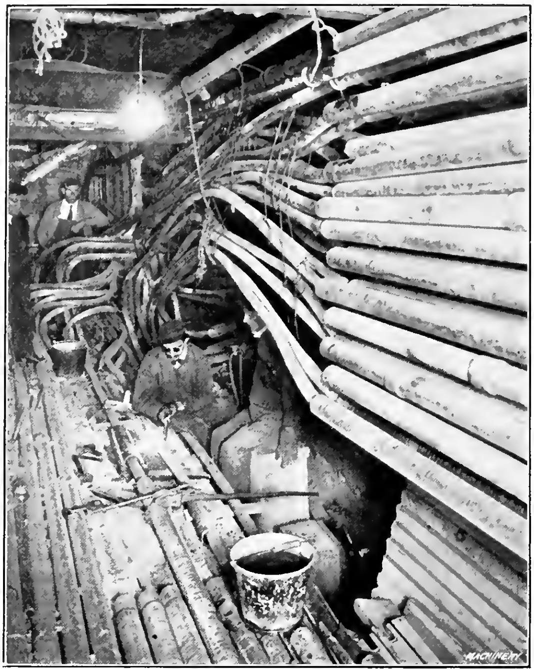
BY GEORGE G. PORTER†

A new field for the oxy-acetylene cutting torch is shown by the accompanying illustration which was taken in the basement of the Warren Telephone Exchange at Syracuse, N. Y. The underground lead cables carrying all of the wires from the city 'phones into the exchange, entered from the street first into a manhole which extended underneath the sidewalk to the wall of the building, and from there to the exchange room the cables were encased in three-inch iron pipes. After the consolidation of the two telephone companies in Syracuse, and the consequent increase in the number of cables coming into this exchange, the manhole soon became very much congested, which made an enlargement necessary. This was effected by removing a portion of the wall of the building and extending the manhole back into the basement a distance of about fifteen feet.

After the wall was removed it was necessary to also remove the iron casings from the lead cables so that they could be bent and re-arranged to make room for the new ones. This looked like an almost insurmountable task, as there were about eighty casings in the two tiers, over half of them containing cables, and to remove them by cutting off with hammer and chisel would have been an almost endless job, and practically impossible, as the pipes were so close together that swinging a hammer would be very difficult, and then too the noise would be transmitted through the pipes to the entire building—a most objectionable feature. It was suggested that a special machine be built which would mill slots in the sides of the casings, and then saw them around so that they could be removed, but this was also abandoned on account of the lack of room in which to operate it.

Finally the Porter-Cable Machine Co. of Syracuse was consulted about the job, and after looking it over a decision was made that it might be possible to cut off the iron casings with the oxy-acetylene cutting torch without damaging the lead cable underneath. This too seemed like an impossible thing to do, as the melting point of lead is about 600 degrees, while that of wrought iron is about 2300; and the oxy-acetylene flame has a temperature of over 6000 degrees. However, a piece of the cable and casing was obtained to experiment on in the shop. The first experiments were failures, as the lead was melted almost instantly, but a plan was finally developed, and special appliances were made, consisting of guides for the torch and semicircular copper shields to slip in between the cable and the casing. After a few trials this plan seemed to be so successful that the Porter-Cable Machine Co. was awarded the job of removing the casings. The job was handled as follows:

A copper shield about two feet long was slipped in between the cable and casing, then the casing was cut around with the



Oxy-acetylene Torch being used for cutting away Iron Armor of Lead covered Telephone Cables

torch for a short distance and at a safe distance from the inner end of the shield, so as not to allow the flame to come too near to the lead cable; the casing was then rolled over a small amount, the shield re-adjusted and another cut taken. This was continued until the casing was cut all the way around; it was then slid back on the cable and split in two lengthwise, allowing the pieces to be removed. The reason for making the shields of copper, was that the oxygen cutting jet will only cut wrought iron and steel, and does not have any cutting effect on copper.

At the time the photograph was taken, about half the casings had been removed, those on the floor tier still remaining to be done. As it was necessary to make two cuts lengthwise to allow the short pieces to be removed after being cut off, and as the circumference of the casings was about eleven inches, the total length of the cuts made by the torch was about 1500 feet.

The cables were practically uninjured, there being two small holes melted in them during the entire job. This was at the commencement before the operator had become thoroughly familiar with the requirements. This is believed to be the first time this kind of job was ever attempted.

* For articles on oxy-acetylene welding and cutting previously published, see "Machine for Making Welded Seamless Tubing," October, 1913; "Preheating Metals to be Welded by Oxy-acetylene Process," October, 1912; and other articles referred to.

We pay only for articles published exclusively in MACHINERY

FEED CHUTE FOR DRAWING PRESS

Figs. 1 and 2 illustrate the application of an interesting form of feed chute that is used to prevent the breakage of drawing punches. The press on which this device is used is employed in performing a drawing operation on the cups shown in the illustration. These cups enter the chute *A* from a hopper and pass down at high velocity; when the bottom of the cup strikes the pin *B* the cup rebounds and drops into the feed-pipe *C*, which leads to the feed fingers of the press.

It is necessary to have the cups feed into the press with the closed end down, as shown in Fig. 1. It sometimes happens, however, that a cup enters the chute *A* in an inverted position, as shown in Fig. 2. If the cup reached the die in this position, it would result in breaking the drawing punch. Fig. 2 shows how this is avoided. The cup enters the chute *A* and slides down until it catches on the pin *B*. Thus it cannot rebound, but swings on the pin *B* and drops into the feed-pipe *C* with the closed end down in the manner illustrated. This device is carried by a bracket which is attached to a stationary part of the press.

LAWRENCE FAY

BOOK AGENTS AND APPRENTICE BOYS

There are men calling themselves book agents who travel through the country visiting shops and factories. In reality, these men are nothing but "leeches" who prey upon the ignorance of the average shop hand or apprentice. I have had a good deal of experience with these so-called publisher's agents, and find that in most cases they pick apprentice boys for their victims and sell them several massive volumes full of old wood cuts and manufacturers' engravings. To do this they "hand out a line of talk" that throws the dust in the boys' eyes, with the result that they buy costly set of books that are probably never opened after a cursory inspection of the pictures is made. In most cases the books consist of from two to four volumes, costing \$15 to \$25 for the set. The binding is attractive, but the books are altogether too heavy for a shop man to carry in his tool chest to refer to when in need of information. There are few shops where shelves are available to keep such books and in most cases there would be a row if an employe was seen opening a book weighing from ten to twenty pounds during working hours.

The main objection that I have to the book agent is the method that he uses in making a sale. He usually starts in by telling his victim that Mr. Bank of Blank & Co. bought a set of these books when he was only making \$12 a week and that he is now earning \$5000 a year and owes it all to the information he obtained from his set of books. Mr. Blank is further quoted as having stated that he would not be without a set of these books at any price. This usually is the means of making a sale. In a certain case that came to the writer's attention, an apprentice boy happened to mention that his grandfather had bought a set of the first edition of a certain work. This was the agent's cue. He asked the grandfather's name and immediately said that he remembered having sold him the books in question but that the first edition was now entirely out of date and the apprentice should have books giving information concerning the most modern practice. This boy bought the books in question for \$25 and offered to sell them three weeks later for \$10. He was a boy of average intelligence, and if he had been given time to look into the matter he would have seen that he was paying an exorbitant price for something from which he would get little benefit. He was simply carried away by the agent's arguments and that is the way in which most valueless books are sold.

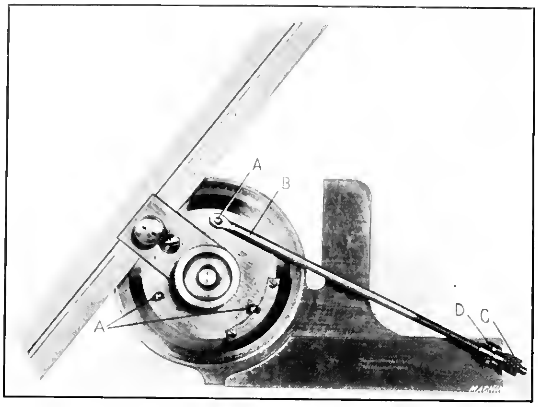
I think that a satisfactory remedy for this state of affairs would be to have the superintendent of a factory or some other man of sound judgment take a little more interest in the employes' welfare. If book agents were refused admission to a shop without first leaving copies of the books they wish to sell at the office to be looked over with the view of determining the value of the information contained in them and the fairness of the price, a lot of this trouble would be eliminated. It is generally quite easy for an agent to deceive an inexperienced apprentice boy, but it would be another matter if he had to convince an older man of the merit of the books he was selling. If such a course of action were followed, an agent could be granted admission to the shop after his book had been O. K'd. The foregoing must not be

regarded in the light of a criticism of shop agents of reputable publishers, as the books and magazines issued by such firms are certainly of the greatest value to every shop man.

Newark, N. J. G. W. Jager

BEVEL PROTRACTOR ADJUSTING BAR

The following describes an adjusting bar for use on the B. & S. bevel protractor. This bar can be easily made by any toolmaker to suit the protractor which he uses, and will be found of value in making accurate adjustments. When not in use, the adjusting bar can be taken off. Referring to the illustration it will be seen that three pins *A* are driven into the movable disk 120 degrees from each other. These pins are made of drill rod 3/32 inch in diameter and are located



Bevel Protractor fitted with Adjusting Bar for making Accurate Settings

¾ inch from the center of the disk. The adjusting bar *B* is also made of 3/32 drill rod, which is flattened at one end and drilled to receive one of the pins *A*. The opposite end of the adjusting bar is threaded to receive the adjusting nut *C*. A swivel-bracket *D* is attached to bar *B* by means of two lugs which are bent over the nut. This bracket can also be readily removed when the adjusting bar is not required.

Chicago, Ill. H. E. Thielberg

TAR CONCRETE FOR FACTORY FLOORS

At the last gas congress in Marseilles, France, a paper was read by Mons. D. Hedde on what he considered a new and very practical floor for machine shops and factories. This floor is not only proving resistant to the usual mechanical wear and tear in machine shops, but is also easily cleaned and not quickly soiled, and has the further merit that it is cheap to lay and to maintain in good condition. The mixture consists of 95 parts by weight of stone dust and 5 parts of tar, mixed by hand or by machine according to the amount to be made. Of course machine-mixing is cheaper and more thorough than hand mixing.

Care must be taken that the 5 per cent proportion of tar is not exceeded, as in such a case either the mixture would not harden sufficiently at ordinary temperatures, or it would get soft in hot weather or under the influence of artificial heating. In laying this floor-covering it is not necessary to see that the under-flooring is perfectly smooth or even perfectly level; only to be sure that there are no great bumps or hollows. The earth is first well tamped in order to give it sufficient resistance to enable it to support the tar and stone layer; then about two inches of the mixture is applied, tamped down firmly and made level.

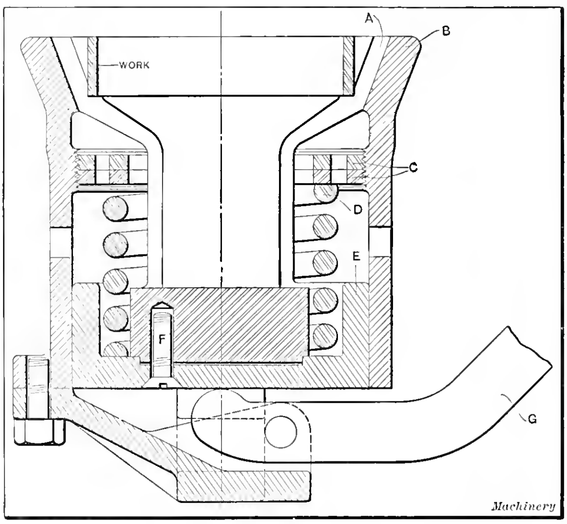
Mons. Hedde says that this floor-covering gets tougher and harder with time, but that during the first month it is desirable to protect it against very heavy weights on small areas. If it is necessary to hasten the hardening process, the floor can be strewn with powdered lime. As regards the cost, European figures have but little value for Americans; but for a floor five centimeters or say two inches thick, the cost is given as 8 centimes or 1.6 cent per square meter, which is about 1.38 cent per square yard. The amounts of material are, however, useful in calculating for American conditions. They are, respectively, 34 and 67.5 kilograms per square meter for the above named thickness; and this would come to nearly 64 pounds and 125 pounds, respectively, per square yard.

Dresden, Germany. Robert Grimshaw

FIXTURE FOR HARDENING STEEL RINGS

The accompanying illustration shows a fixture which has proved very successful in hardening steel rings of thin section. It is particularly important for these rings to be hardened without distortion, and it was to attain this end that the fixture was designed. Referring to the illustration it will be seen that the sliding member *A* is bored to exactly the required size to receive the work. This member is slotted to make it the equivalent of a spring chuck or collet, and then hardened and tempered. The body *B* of the fixture is made of cast iron and is threaded to receive the two adjusting nuts *C*. The function of these nuts is to regulate the tension under which the spring *D* works. It has been found that the best results are obtained by so adjusting the spring tension that it is proportional to the cross-section area of the work. The ring *E* serves as a bottom guide for the chuck, and also takes the thrust of the spring. Three screws *F* are used to hold the chuck *A* to the ring *E*.

The fixture is carried by a pivot on the edge of the tank containing the hardening bath, and is operated by the lever *G*. This lever compresses the spring *D* and opens the chuck so that the work may be put in place. When the lever is released the chuck is closed by the tension of the spring *D*, and the whole fixture is then turned on the pivot to immerse it in the bath. After the work has been quenched, the fixture is tilted back and unloaded by reversing the process. It will be



Fixture used in hardening Steel Rings to prevent Distortion

seen that recesses are cut in the chuck to provide space to get hold of the work when it is being removed. It must be clearly understood, however, that the chuck grips the work all the way to its upper edge except at the points where the recesses are cut. It will also be noticed that holes are drilled in the side of the body *B* of the fixture so that there will not be any air pressure to overcome.

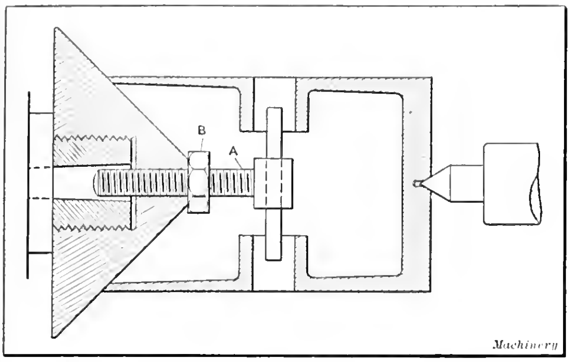
Bristol, Conn. Frederick A. Hotchkiss

METHOD OF HOLDING AND DRIVING GAS ENGINE PISTONS WHEN TURNING

The accompanying illustration shows a fixture that will be found useful, principally in repair shops, for turning gas engine pistons. The open end of the piston is supported by a cone having an included angle of about 90 degrees, which is

screwed onto the nose of the lathe spindle. The diameter of the cone base, in this instance, is 9 inches. The other end of the piston is held by the tailstock center. Screw *A*, which is $\frac{7}{8}$ inch in diameter, is screwed into the end of the cone. It is about $3\frac{1}{2}$ inches long and has a square head $1\frac{1}{4}$ inch wide with a $\frac{1}{2}$-inch hole drilled through it. A rod is driven through the head, which is long enough to engage the wrist-pin bosses inside the piston. The driver *A* is adjusted for pistons of different sizes by means of lock-nut *B*.

Before the piston is placed in this fixture, it should be chucked so that the end can be faced and chamfered where



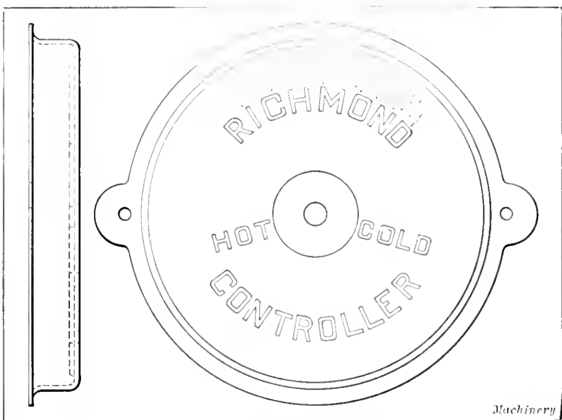
Method of holding and driving Gas Engine Pistons when turning

it bears on the cone. The center for the tailstock end can be put in on a drill press after the opposite end is faced square.

Dubuque, Iowa E. J. BUCHET

WHY THE BLANKS WRINKLED

In blanking and forming work in a combination cutting, forming and embossing die, trouble was experienced after about three thousand good blanks had been finished. At this point the work suddenly started to wrinkle badly at a point



Embossed Work that caused Trouble by wrinkling over Word "Richmond"

above the word "Richmond" and the metal in the letters of this word also seemed to be crushed. This state of affairs developed all of a sudden and without any perceptible cause. The die was taken off the machine and sent to the toolroom for repairs. It was thoroughly overhauled, and as everything appeared to be all right it was returned to the press department. The press was set up and started again but the work showed the same defect that it had before the die had been inspected.

About this time the assistant press foreman came along and the trouble was explained to him. He picked up one of the blanks, looked at it closely and then told the press operator to clean the stock thoroughly in order to remove oil and grease. This was done, and when the press was started on stock which had been carefully cleaned the work was found to be perfect. The foreman told us that the oil had caused the trouble by taking up sufficient space between the punch and die to cause a deformation of the work. This may be a matter that has come to the attention of some of MACHINERY'S readers, but I think that the majority of them have not been confronted by this particular problem.

New Britain, Conn. W. C. BETZ

GAGE FOR U. S. S. THREAD TOOLS

Away back in the days when the form of thread which we now call the U. S. standard was but little known, a machinist received instructions to design and make a gage for grinding the thread tools. To understand the difficulty of the task, we must remember that he had but one of the precision tools which now seem so indispensable, *viz.*, a one-inch micrometer of the old type with exposed thread and beveled points. The only machine tools available were a lathe and planer.

After much cogitation he decided to utilize the wedge principle and evolved the arrangement shown in Fig. 1. The upper edge of the movable scale *A* rests against the two buttons *B* which are adjusted to locate the lower edge of the scale at right angles to the axis of the 60 degree vee. The scale is tapered at such an angle that a movement of 1/32 inch corresponds to 0.001 inch in the width of the exposed edge representing the width of the thread tool flat.

Fortunately, the machinist referred to knew enough about

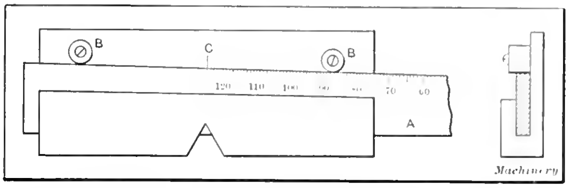


Fig. 1. Gage for U. S. Standard Thread Tools

trigonometry to know how this angle must be calculated, and he could use logarithms so that no lengthy figuring was necessary. He soon determined that the angle must be that whose logarithmic sine is 8.44268, for as $1/32 \sin a \; 2 \tan 30$ degrees $= 0.001$

$\sin a = 0.016 \cot 30$ degrees.

8.20412 Log 0.016
0.23856 Log cot 30 degrees

8.44268 Log sin *a*

The gage was now complete, *on paper*. The machine steel body was made on the planer. The sides of the vee were casehardened and lapped to fit a 60-degree center-gage, but how could the taper scale be ground in the lathe to the proper angle?

A piece of flat stock was lapped to 0.1875 inch thickness, to use as shown in Fig. 2. Dividing 0.1875 by the sine of *a*, gave 6.765 + or about 6 49/64 inches as the distance from the end of the straightedge to the point of contact with the 0.1875-inch block. By this means the compound rest of the

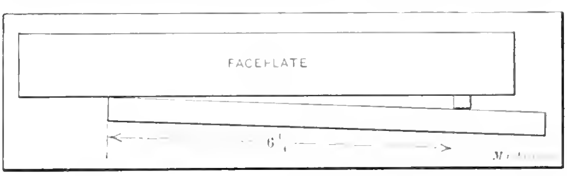

Fig. 2. Method of locating Scale for grinding One Side to Required Taper

lathe was set at the desired angle with the faceplate. The blank was clamped to the tool-block, parallel with the faceplate and was ground with an emery wheel carried by the live spindle.

The scale was easily graduated by a method in common use at that early date. The surface was first covered with asphaltum varnish. The scale was then clamped to the tool-block and the graduations were scratched by a scriber point held on a bar between the lathe centers, the necessary tra-

verse of 1/32 inch being obtained by turning the lead-screw to which a gear was attached to serve as an index plate. After the figures had been scratched with a scriber, the rest of the scale received a coat of asphaltum and it was then immersed in etching fluid.

The gage was then assembled and its zero point C determined. This could easily be done now, by using a size block, but nothing of the kind was then available. Even the 3/16-inch piece used to get the angle did not have square corners that were accurate; hence, the only way was to insert a round piece in the vee and determine by calculation what the reading of the gage should be when the scale was in contact with this size plug. A knurled head screw (not shown in Fig. 1) was used to lock the scale when desired.

This gage did excellent work, being as accurate and convenient as the well made and expensive tools we find in the shops at the present time. A similar gage can be made for Acme and worm thread tools, making the vee 29 degrees and tapering the scale to the angle whose logarithmic sine is 8.79146.

For either 60-degree or 29-degree tools, the gage can be designed to give 1/16-inch instead of 1/32-inch movement for 0.001 inch increase in width of tool point, the only objection being the greater length of scale required.

New London, N. H. GUY H. GARDNER

HOW A PIECE-WORK RATE WAS SMASHED

One of the methods of concave turning described in the article entitled "Machining Convex and Concave Surfaces" by Albert A. Dowd, which appeared in the January, 1914 number of MACHINERY, reminded me of an incident that occurred some six years ago in a certain manufacturing plant. This plant makes a great many cast-iron disks 8 or 10 inches in diameter, which are hollowed out "saucer fashion" on one side. The time-honored method of handling this work was to rough out the concave surface and then hand-tool it to fit a templet. One day a new man was hired and put on this job. He was anxious to speed up as much as possible, being paid by the piece; and after giving the matter a little thought, he sharpened the ends of a piece of drill rod of a length equal to the radius of the concave surface, and inserted the points in center punch marks in the cross-slide and tailstock. He then started the cross feed, keeping the carriage pressed against this radius rod, and proceeded to amass wealth.

In the afternoon caution somewhat over-balanced acquisitiveness, and he worked at less than his maximum rate; but when the whistle blew at closing time, he had finished six times as many pieces as his predecessor had ever turned out in a day. A little reckoning brought him to the happy conclusion that he had about $18 coming to him as the result of a day's work. He now virtuously resolved to do his utmost the next day, and being a dexterous youth, he saw from $20 to $24 almost within his grasp. But this, alas, is a world of disappointments; and before he could begin the day's work that was to add materially to his "bank roll," he received the disheartening tidings that the rate had been cut to one-eighth of its former enticing magnitude, and he had to hustle like a squirrel in a wheel to make $3 a day. Now this primitive method of working with a hand tool and templet was not used in "Lonelyville" but within three miles of MACHINERY'S office in New York City.

New London, N. H. GUY H. GARDNER

HIGH-SPEED STEEL JIG BUSHINGS

The inquiry of C. R. in the March number of MACHINERY, relative to the use of a high-speed steel jig bushing, calls attention to the prevalent misunderstanding regarding the degree of hardness of heat-treated high-speed steel as compared with heat-treated carbon tool steel. It is generally admitted by those who have tested the relative hardness of the two steels, that carbon steel can be heat-treated to give a considerably harder surface than any heat-treatment will give to high-speed steels. Carbon steel would, therefore, appear to be the better material to use in all places where wearing hardness is desired. The reason that high-speed steel is so desirable for cutting tools is that it retains its hardness under a service that develops considerable heat. A cutting tool of high-speed steel used in a lathe, for example, may be run continuously under a service which may generate sufficient heat to raise the temperature of the tool to a dull red heat. In other words, the cutting tool retains its hardness for effective cutting purposes even at a dull red. A carbon steel tool would, under these conditions, lose its hardness at once.

To recapitulate, high-speed steel, while relatively softer, retains its hardness under temperatures that are considerably in excess of those allowable for carbon steel. If this is clearly understood, it will do away with misunderstanding regarding its use. Tests with the Shore scleroscope as well as wearing tests made with cutting tools bear out the statement that high-speed steel is less hard after heat-treatment than is carbon steel. In resharpening carbon steel cutting tools great care had to be taken to prevent heating the cutting edge sufficiently to blue it. This led to the use of water grinding machines for resharpening cutting tools. With the advent of high-speed steel cutting tools, wet grinding was at first considered necessary. Repeated experiments have shown, however, that it is not necessary for the life of the tool, and that it is in most cases positively injurious to water-cool the tool when resharpening it. As C. R. desires hardness in his jig bushings for the sake of wearing qualities, and as the bushings are, while in use, relatively cool, carbon steel is the best for his purpose. CASE

As regards the question of the practicability of using high-speed steel for jig bushings there can be no possible advantage in its use for this purpose, unless there is an unusual heat developed by friction. The cost of high-speed steel is prohibitive and its resistance to wear is no greater than that of hardened high-carbon steel. The principal advantage in the use of high-speed steel for any purpose is that it will not lose its hardness at a low red heat—hence its value in the cutting of metal at high peripheral speeds.

To illustrate the above assertions regarding the wearing qualities of high-speed steel, the writer's experience along this line may be of some value to readers of MACHINERY. In the drilling of holes in hard carbon, we found that high-speed steel did not wear as long as glass-hard high-carbon drills when operated at low speeds, but when operated at high speeds with heavy feeds, the carbon steel drill points became blued very rapidly, losing their hardness, and consequently were short-lived. The high-speed drills operated in like manner would wear about five times as long, although the points become blue the same as on the carbon steel drills.

Cleveland, Ohio J. E. WASHBURN

SELECTING DIAMONDS

In reply to J. Towler's query in the January number of MACHINERY concerning the selection of diamonds, I would say that he is not alone in his experience of having apparently good stones crumble to dust almost immediately after they are put in use. Diamonds are a product of nature and their composition and temper were thus placed beyond human control. No dealer is justified in guaranteeing them. From the time they leave the hands of the diamond syndicate at the mines, and in passing from the cutter to the importer, and from the importer to the dealer, each man buys without a guarantee. Naturally the user is expected to do the same.

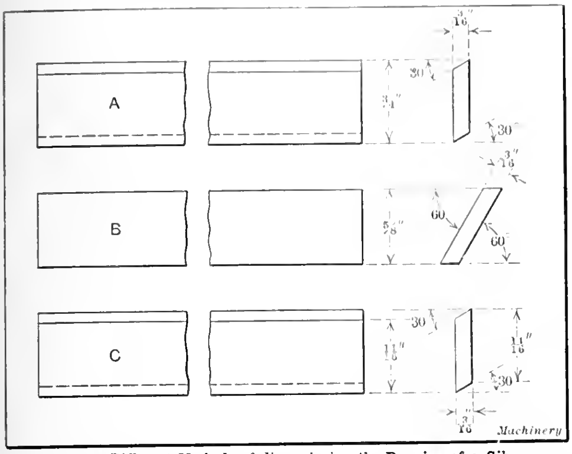
The firm with which the writer is connected is a large user of diamonds, but after fifteen years' experience in their selection we still have stones that "look good" go wrong. Permit me to suggest that those who are still using black diamonds investigate what are known as the Brazilian bortz or brown stones. These are sometimes called South African "premiers" and by other trade names. For truing up grinding wheels they are just as satisfactory as the black diamonds, and for $15 you can buy a brown bortz stone equal in size and weight to a black diamond costing $70 or $75. By way of conclusion, I would say that in selecting stones, the best plan is to avoid those which appear to have seams, as such stones are likely to crack along these seams,

while the smooth skinned stone is the most likely to prove satisfactory. Of course, the more points a stone has the better.

GRINDING WHEEL MANUFACTURER

DIFFERENT METHODS OF DRAWING A GIB

The accompanying illustration shows three different methods of drawing a gib. In making a gib the first thing a milling machine or planer operator wants to know is what size of stock is needed to produce the piece without wasting time or material. It appears to the writer that the method illustrated at *A* enables anyone to see at a glance just the size of stock that is required. This illustration shows the thickness and the full width so that all that is necessary is to machine the gib to the required angle.



Three Different Methods of dimensioning the Drawing of a Gib

The illustration *B* shows the width of the gib after it has been machined to the proper angle; but how much stock is required to obtain this size? Illustration *C* shows the width of the gib from one edge to the other. In illustrations *B* and *C* the operator must either stop to figure out the size of stock that is required or else resort to guesswork. These drawings made by different draftsmen started an argument in regard to the best method of illustration. The writer claims that the method shown at *A* is the correct one, while another man advocates that shown at *B*, and still another claims that the one shown at *C* is the best. Who is right?

Pearl River, N. Y. W. BUTZ

CUTTING A SPIRAL ON A LODGE & SHIPLEY LATHE

A spiral is a very difficult thing to machine and a special lathe is generally required for this purpose. The accompanying illustration shows a Lodge & Shipley lathe cutting a 4-pitch spiral in a plate 6 inches in diameter, and it is the purpose of this article to describe the fixture used for this

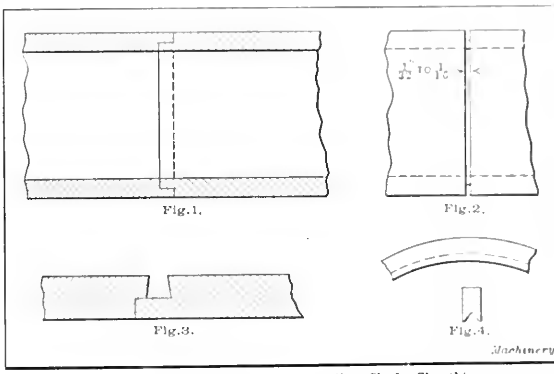
Lathe Fixture used for cutting a Spiral

operation. After the blank was turned it was chucked as shown in the illustration. The feed is regulated by a screw with a pitch equal to the desired pitch of the spiral. This screw is driven by a miter gear which meshes with a gear fastened to a mandrel supported between centers. The screw works in a nut mounted at the rear end of the carriage, and the feed clutch on the apron may be disengaged to allow the carriage to be moved. This attachment is simple and may be constructed from odd pieces found around the shop. The gears are not necessarily miter gears, although these are preferable, as they simplify the calculation of the pitch of the screw.

Chattanooga, Tenn. RUSSELL K. ANNIS

BRONZE SHEATHING OF PROPELLER SHAFTS

The tail-shafts of ships, that is, the length of the propeller shafting which passes through the hull of the ship and on which the propeller is carried, is fitted with bronze sheaths or liners to prevent corrosion due to the action of the sea water. These liners are usually made in lengths of from five to six feet and are arranged so that when in position on the shaft a male and female joint come together as shown in Fig. 1. The method of securing them on the shaft is by shrinking. The liners are bored out smaller in diameter than the shaft, the usual allowance being 0.001 inch per inch of diameter of the shaft. Heat is applied either by means of a steam jet or by a gas or oil burner, until the liners have expanded sufficiently to allow them to be slipped over the shaft. Provided the shaft has been turned parallel and there has been little variation in the bore of the liner, a perfectly



Joints between Sections of Propeller Shaft Sheathing

solid contact should result. The solidity can readily be tested by lightly tapping the liner with a hammer

Great difficulty has been experienced in getting the liners to butt closely at the joints when cold. This, of course, is due to shrinkage. Local cooling with water at the joints has been tried, but fails to obtain the desired result and invariably we find that there is a space of 1/32 to 1/16 inch between the ends, as shown in Fig. 2. Such a condition is not acceptable in cases where rigid inspection obtains. To close this gap electric welding often is used. The joints are welded and the surplus metal is afterward removed in the lathe. With this method great difficulty was experienced in obtaining a homogeneous weld.

To overcome the annoyance and expense incurred by faulty welds, the following method has been devised. The liners are shrunk onto the shaft and the outside is finished as before. The space between the liners is enlarged until a groove 1/4 inch wide and just deep enough to reach the outside of the male joint is obtained between each pair of liners. The sides of the grooves are then cut away slightly to form a dovetail. (See Fig. 3.) Into these grooves are driven segments of material having a cross-section similar to that shown in Fig. 4, until the circle has almost been completed. In fitting the last segment a space must be left around the circumference to allow for the expansion of the metal when all the segments are forced into the groove. This amount, of course, depends on the circumference of the groove.

To fasten the segments securely into the groove, the tail-shaft is revolved in a lathe and a knurling tool is pressed against the outside of the segments until they are completely flattened. A light cut is then taken with a finishing tool, to remove all surplus metal. The material used for the segments should be a soft combination brass such as is used for calking pieces in turbine work.

Sparrow's Point, Md. JOHN GRAHAM

WORK SPEEDS IN GRINDING

I hope your editorial in the December number entitled "A Question for the Grinding Expert" will bring forth a friendly discussion among grinding machine makers and users. It would certainly redound to the benefit of all. Grinding is no longer the "hit or miss" machine shop practice it used to be, but is becoming one of the leading shop operations. Yet no one has a monopoly of the knowledge of it.

Unfortunately many of those who are in a position to write authoritatively and entertainingly on grinding practice have not yet been "moved by the spirit." Charles H. Norton of the Norton Grinding Co. and J. H. Hollinger of the Landis Tool Co. have both, in times past, contributed to MACHINERY'S columns. I hope they will both continue and that we shall hear from some of the others as well. J. Kenyon, of the Brown & Sharpe Mfg. Co.; H. T. Shearer, of the Landis Tool Co.; B. M. W. Hanson, of the Pratt & Whitney Co.; H. K. Spencer, of the Blanchard Machine Co., and Mr. Wight, of the Diamond Machine Co., all could contribute funds of information regarding grinding operations.

To return to the subject suggested by your editorial, the satisfactory working of any grinding wheel (I refer now to automatic grinding operations) depends upon the question of feeds and speeds. Of course, in manufacturing grinding operations where similar pieces are constantly being ground, the wheel maker can supply a suitable grain and grade of wheel to meet whatever conditions of speeds and feeds the user may have established. But, when a grinding machine is used for all sorts of work—the "run of the shop"— it is manifestly impossible to change the wheel for every new job, and here is the importance of knowing how to change the feeds and speeds to do the various jobs quickly and efficiently.

The larger the surface of contact between work and wheel, the softer should be the wheel. The effect of a soft wheel can often be obtained by reducing the wheel speed. Inversely, if a wheel is wearing too rapidly, increasing the wheel speed will overcome the difficulty. I question your statement that "comparatively soft wheels are conceded to be the most efficient for roughing." Consider two specific operations, *viz.*, roughing cams and roughing crankshafts. For the former, very satisfactory results are being obtained on Landis and Norton grinders with 24-O corundum wheels, some (The Maxwell Motor Co.) preferring even coarser and harder wheels, *viz.*, 16-P corundum. Many operators may be surprised to know that such coarse hard wheels can be used for any automatic grinding operations, but they can and with excellent results. For finishing the cams, 46-K or 46-L corundum wheels are used.

For crank grinding, there are a variety of preferences as to grade, but none of the grades used could be considered "comparatively soft." No. 24 combination N is a favorite wheel for crank grinding, and from this up to grade Q, the latter being used by one of the largest auto manufacturers in the country. In crank grinding the usual practice is to use a wheel just as thick as the width of the pin to be ground, and to feed heavily right in without traverse. The wheel is then dressed true with a diamond, and the same wheel used for finishing, the finish cut being a light one.

Again I question your statement that the work speed is reduced for finishing. As a general rule, I believe that increasing the work speed, with a very light cut and a slow traverse, will improve the finish. One mistaken impression exists in many minds that a fine wheel must be used for finishing. A good commercial finish can be obtained with a wheel as coarse as 36, if it is kept true. For surface grinding, wheels *finer* than 30 or 36 are rarely used.

The above grains and grades referred to are those of the American Emery Wheel Works.

Providence, R. I. JAMES O. SMITH

CHART OF EXPERIENCE AND WAGES

The accompanying illustration shows a chart that can be conveniently used by a man in applying for work. The horizontal base line of the chart is laid off in years, while the left-hand vertical lines are laid off to represent wages. In the left-hand chart, the writer's experience between the years 1899 and 1908 is shown, the wages being expressed in Swedish crowns per month. In 1908 the writer moved to America, and at this point of his career a new chart was started on which the wages are shown in dollars per week. Where such a chart is sent to a prospective employer, it shows at a glance just what experience the applicant has had and the wages he has received. Such a method could be extensively used to the mutual advantage of the employer and employe.

Duluth, Minn. R. POITZEL

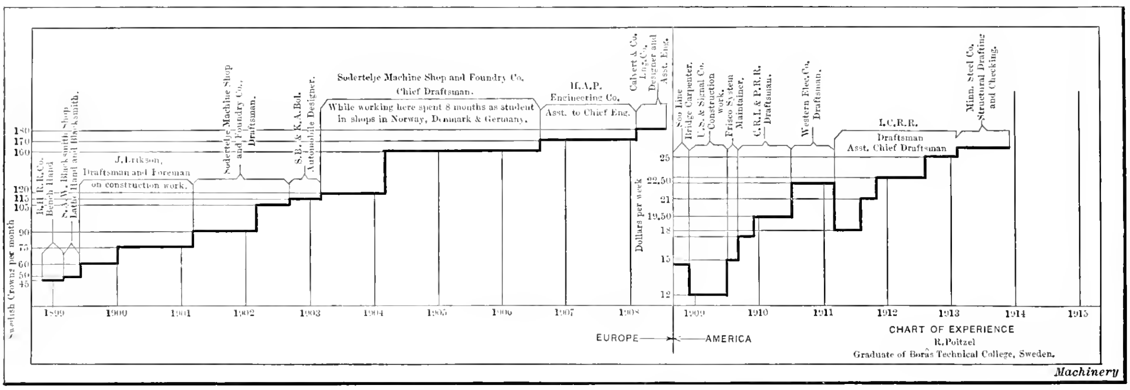


Chart of Experience and Wages used in applying for a Position

LUBRICATING STICK

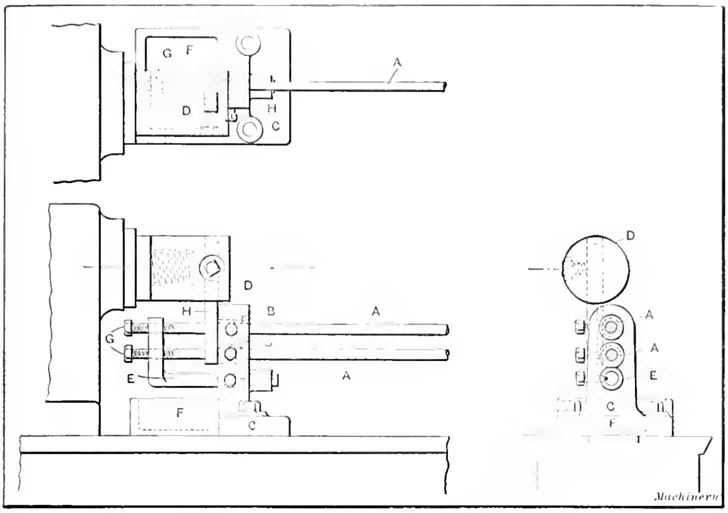
When sawing or drilling small copper, brass, or German-silver pieces, with small saws or drills, a fine lubricant is prepared as follows: (1) Make a solution of two parts of camphor in four parts of turpentine. (2) Melt together two parts of pure mutton tallow and one part of beeswax. To this melted mixture add about 5 per cent by volume of solution No. 1 and also a few drops of oil of lavender to offset any offensive odor. This mixture, while hot, is poured into paper tubes about one-half an inch in diameter and four inches long. These are made by winding typewriter paper around an arbor, gluing the layers together, and shellacking the outside when dry. When cold, these sticks should be quite hard, and may be handled without soiling the hands;

they are as convenient as a piece of beeswax and give better results. This stick has the end exposed by removing a narrow ring of the paper and is touched to the revolving cutter; the heat generated by cutting melts that which sticks to the cutter and lubricates thoroughly. In cases where cleanliness is a primary factor, this method is giving perfect satisfaction.

Southbridge, Mass. WARREN E. THOMPSON

LATHE ATTACHMENT FOR CUTTING OFF PINS

In setting up machines a great many pins for use in collars, dowel pins, etc., are required. It is the purpose of this article to describe an attachment for use on a lathe which provides for cutting off pins of various lengths from wire of different diameters. Referring to the illustration, it will be seen that the fixture provides for cutting off two pins at a time, the wires *A* from which the pins are cut passing through the bushings *B*, which are supported in a bracket *C*. This bracket is screwed to the bed of the lathe. The bushings are made interchangeable so that a number of sizes may be used for cutting pins from wire of different diameters. The cutter *D* is held in the tool-holder by means of a set-screw, the tool-holder being threaded to fit the lathe spindle. The bracket *E* acts as an adjustable stop, being fastened in any required position to suit the length of pins to be cut off by means of a set-screw. In operating the attachment, the wires are pushed through the bushings until they come in contact with the stops; the cutter then comes around and shears them off. Immediately after two pins have been cut off, the wires are pushed up against the stops in position for the next cut. As the pins are cut off they fall into the trough *F* which is an integral part of the bracket that supports the attachment.



Lathe Attachment for cutting off Two Pins simultaneously

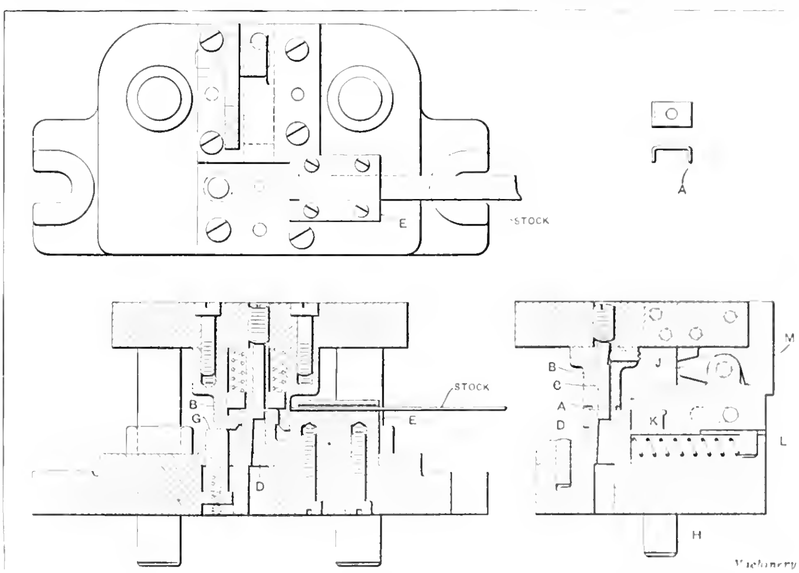
It is possible that the cutter could be made longer and that a greater number of bushings could be used, in which case more pins could be cut off at each revolution of the cutter. The possibility of development along this line would depend upon the operator's ability to push more than two wires up to the stop before the cutter comes around for the next cut. By using different sized bushings and setting the stop-screws *G* in different positions, it is possible to cut off pins of different lengths and diameters at the same time. In operating this attachment, it is important to have the bracket *C* adjusted to such a position that the cutter slips over the surface *H* so as to give a good shearing action.

If it is desired to cut off long lengths of wire, the shearing cutter *D* could be fastened to a bar carried on centers and driven by a driving dog. In this case the bracket *C* would be placed on the bed of the lathe near the cutter, and a separate bracket with adjustable stops would be employed to control the length of the work. The second bracket would be fastened to the bed of the lathe. The attachment shown in the illustration is self-contained and when it is not in use it can be easily removed from the lathe. W. R. O.

A NOVEL PUNCH AND DIE

The punch and die illustrated herewith is used for cutting off, forming and piercing pieces of the form shown in detail at *A*. These pieces are parts of an electrical switch and are made of 1/16-inch sheet brass. The interesting feature of the punch and die used in producing them is that an ejecting mechanism is provided to remove the finished pieces from the die, thus making it unnecessary for the operator to put his hands under the punch. After all, this is the surest method of preventing punch press accidents. The use of an automatic ejecting mechanism also permits the punch to run continuously instead of making it necessary to stop after each stroke to remove the work. In the illustration, *B* is the forming punch, *C* the piercing punch and *D* the die.

It will be seen that ribbon stock is used which is fed through a guide *E* until it comes up against the stop *G*. The punch is shown at the end of the down stroke. On the up stroke the hardened cam *H* engages the lever *J* which pushes the slide *K* forward and knocks the finished piece of work *A* off the die. The spring *L* returns the slide and the



Combination Cutting-off Forming and Piercing Die provided with a Novel Ejecting Mechanism

cam is so timed that it advances the slide before the stock can be fed forward for the next operation. The plate *M* is held in the punch-block to return the lever to the working position should it fail to return after the cam passes it on the down stroke. The work is cut off against the face of the

guide E, and the arrangement of the strippers is evident from the illustration without requiring further description.

LAWRENCE FAY

SYSTEMATIC CALCULATIONS

The use of systematic methods of calculation is a subject which seems to have been neglected by the technical press. The writer's experience has been that the majority of draftsmen do not try to systematize their notes and computations. On the contrary, most of them use the loose and shiftless method of scratching upon a scrap of paper, marks and figures arranged in haphazard form, that are disconnected and incomplete. Such a habit is of no profit to either the draftsmen or their employers. In case a question arises in regard to the strength of a certain part of a machine, the draftsman would save himself and his employer much time and trouble if he had made his computations in such a manner as to make reference to them both intelligible and accurate.

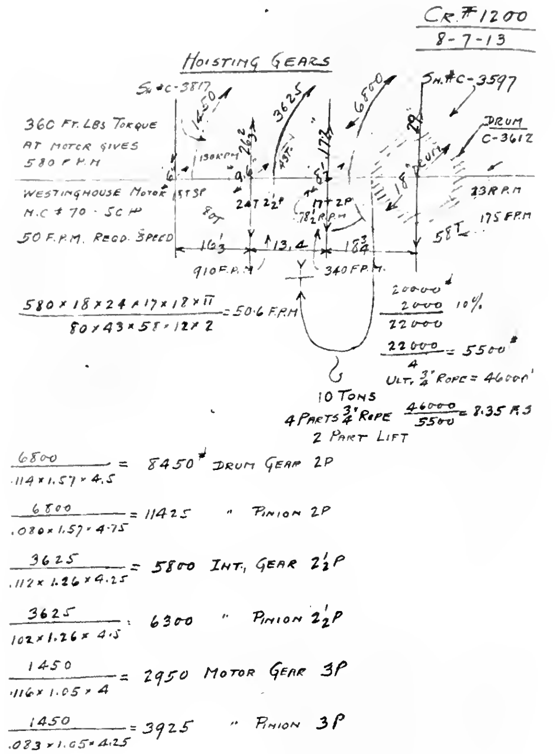


Fig. 1. Computation Sheet for Hoisting Gears—kept for Reference Purposes

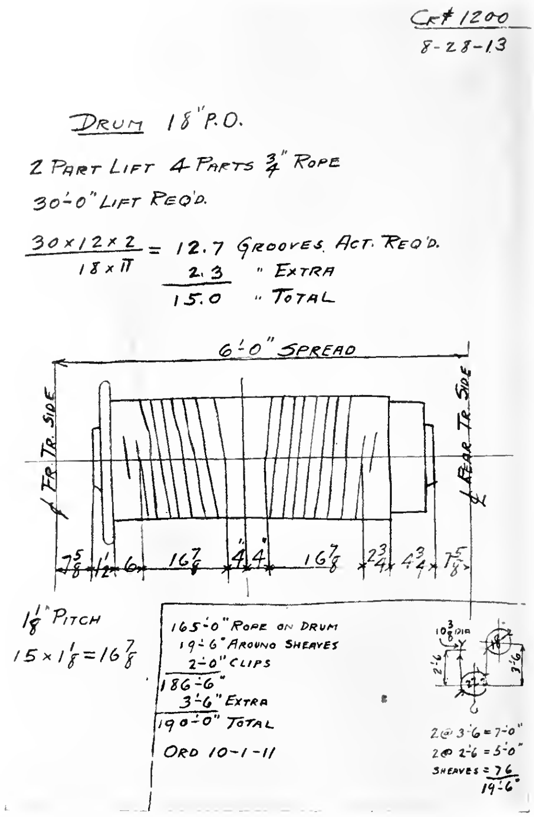

Fig. 2. Calculations for Hoisting Drum Grooves and Rope Length

To begin with, all the data regarding the calculations for a certain part of a machine should be put down. This is advisable because, while the designer knows exactly all the conditions of the case under consideration, a year or more afterward he will have forgotten them or, perchance, will have changed his position. If a mistake is made, instead of destroying the sheet of figures it is better to mark it void, because oftentimes computations which were thought to be wrong are found to be right. A "new" machine is seldom entirely new, but is generally an adaptation and modification of some other design. In this event carefully made and preserved notes and calculations of the old design are often useful. Then, too, proposals, estimates and bids which are generally required in a minimum length of time can be made up more quickly by the aid of such records.

Fig. 1 shows a computation sheet for hoisting gears. A careful perusal of this sheet will show that all the necessary and important data are given. The contract or machine number should appear on all such sheets, as well as the date of computing. It is often found necessary to use certain parts called for on different drawings, as for instance, in a train of gears it is desirable to use gears detailed on different drawings; in that case the number of each drawing should be noted upon the computation sheet with arrows clearly indicating just what gears are covered by that particular drawing. Such practice will prove of value in designing because, when the details are to be made, the designer knows just exactly what parts he intended to use. The gear centers are put down on this sheet and are found useful in laying out the general arrangement of the mechanism.

A method for figuring drum grooves and the length of rope required is shown in Fig. 2, together with an illustration of the drum giving the necessary dimensions for making a drawing. Many designers prefer to make their notes and calculations in a permanently bound blank book. The writer has found it convenient to use loose sheets held together with a spring paper clip, until the design for a machine is completed; the sheets are then riveted together for future reference.

The habit of making all notes, sketches and calculations clear, intelligent and complete, cannot be emphasized too strongly. The faithful and conscientious use of the aforementioned hints will, the writer believes, prove to be a great help to any draftsman and designer.

Toledo, Ohio CARL E. SCHIRMER

* * *

A successful engineer must build a man below him to take his place. He must do this with his eyes open to the fact that in time of grave financial crisis he may be discharged, so that the work can be carried on with a reduced pay roll, but this contingency is, after all, very remote. The 99-per-cent-certain result is that he, himself, is the logical candidate for advancement, because he will leave no aching void when he steps higher.—*J. M. Eaton in the Journal of the Worcester Polytechnic Institute.*

SHOP AND DRAFTING-ROOM KINKS

INGENIOUS MEANS AND SHORT CUTS FOR SAVING LABOR AND MATERIALS

HOW TO COOL STEEL WITHOUT HARDENING IT

Very often a mechanic is working with a piece of tool steel and wants to cool it off without hardening it. Very simple you say. Lay the piece on the floor behind the forge and you will be able to handle it in fifteen minutes. When the piece is wanted for immediate use, however, it can be cooled quickly by plunging it into a pail of soapy water. When this practice is followed the steel will be soft enough to cut with a tool.

Middletown, N. Y. DONALD A. HAMPSON

FOR LAPPING SMALL HOLES

The most convenient method of handling emery or other cutting powder is in combination with ordinary non-fluid engine grease. Make a mixture by adding a small percentage of emery to the grease and stirring thoroughly. Care must be taken not to add enough powder to destroy the sticking properties of the grease. This may be applied to the lap by a stick and will not fly off as oil will. This mixture will also cut much faster than emery and oil.

Southbridge, Mass. WARREN E. THOMPSON

LUBRICATION OF SCREW MACHINE CUTTING TOOLS

After having had considerable trouble with oil gumming the movements of small automatic screw machines, all the oil was washed out of the machine and clean kerosene used in its place. For cutting screws from soft steel, German silver, and copper alloy wire, no better lubricant can be desired and the machines are never gummed or disagreeable to work on. The ordinary geared pumps handle kerosene satisfactorily if speeded a little higher than for heavier oil.

ENLARGING THE PILOT OF A COUNTERBORE

Experience has shown me that a very quick way of enlarging the pilot of a counterbore for counterboring an odd sized hole for which you do not wish to make a bushing is to cover the pilot with solder and then turn the solder down to the exact size of the hole. If care is taken to cover the pilot all over with solder and not to turn into the cutting edge of the counterbore when turning down to the required size, this method will be found very satisfactory for handling an emergency job.

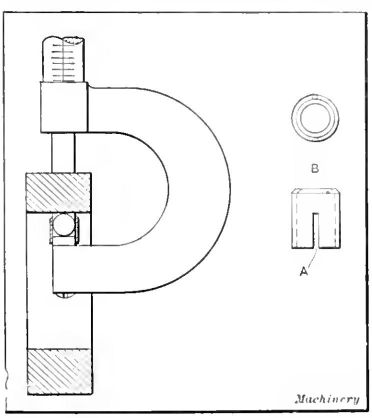
MEASURING THE BORE OF RINGS AND CYLINDERS

The following describes a rapid and accurate method of measuring the bore of rings or cylinders which have been machined on the outside. The first step is to measure the outside diameter of the work. The diameter of the bore that it is required to machine is then deducted from the measurement of the outside diameter, which leaves twice the thickness of the wall of the ring or cylinder. An outside micrometer is fitted with a steel ball 1/4 inch in diameter, the ball being held in place by a short piece of 1/4-inch tubing. This piece of tubing is split at *A* and spun over at *B*, thus forming a retainer which holds the ball in place on the anvil. After boring the hole to within 1/32 inch of the required size, the thickness of the wall is measured with the micrometer, as shown in the accompanying illustration. Then 0.250 inch is deducted from the micrometer reading to correct for the diameter of the ball. The thickness of the wall, as determined by calculation, is then subtracted from the corrected reading, which gives the amount of metal that still has to be removed. By this method holes can be bored or ground more accurately than when measurements are made with an inside micrometer. To obtain satisfactory results it is evident that the outside of the work must run perfectly true. To accomplish this, an accurate indicator may be used or the work may be held in a special spring chuck or on a magnetic chuck.



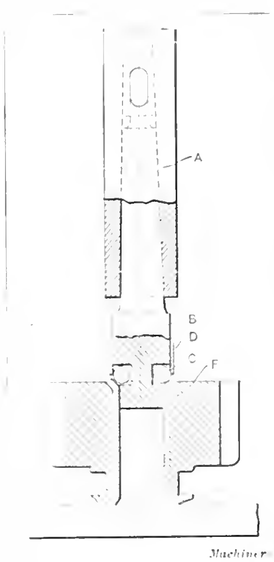
Measuring Bore of Ring with Outside Micrometer

New Britain, Conn. W. C. BETZ

A BEADING TOOL

The tool shown herewith was designed to rapidly bead over the ends of small bronze bushings such as are used extensively in motor car manufacture. In this way, the bushings are held securely in the bore of the sliding gears to which they are fitted. The beading was formerly done by hand but required too much time and the work was irregular. With the tool now used, the work is done rapidly as well as more uniformly.

This tool is used in a sensitive drilling machine. In the illustration, *A* represents the drill spindle and *B* the shank of the tool. The latter is made from steel and is hardened at its lower end where there is a groove carrying the balls *C*. These balls, which are kept in position by ring *D*, press against the upper rim of the bushing *F* while rotating and bead over the ends as the illustration indicates.



Ball Beading Tool for Gear Bushings

Turin, Italy. C. BOELLA

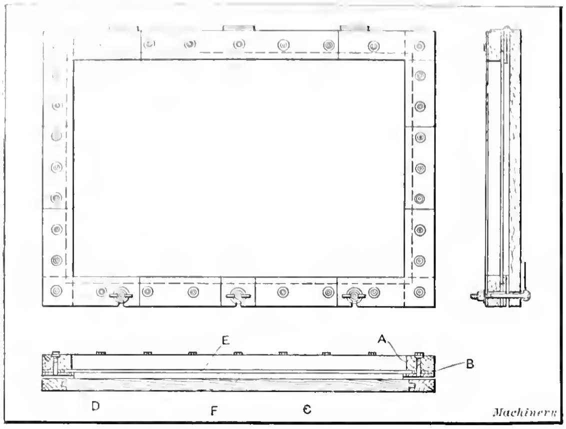
BLUEPRINTING FRAME

A frame for blueprinting by sunlight, in which a good contact between the glass and paper is secured is described by the following: The frame is made of hard wood and a sheet of glass is selected which is quite clear and free from bubbles. The glass must be of sufficient thickness to support the pressure and a sheet of 1/4-inch plate glass will be found satisfactory for the purpose. The frame is mounted on a carriage that enables it to be placed in a convenient position for taking advantage of the best sunlight. It will be seen that this is not a "turn-over" frame but that the blueprint paper and tracing are inserted by lifting the cover in which the glass is set. The pressure is applied by means of three wing nuts carried by bolts which slip into slots in the cover.

The use of a frame of this kind is particularly convenient when it is desired to blot out any section of a tracing on the blueprint. As the tracing is always right side up and in plain view, it is unnecessary to turn the frame over in order to see whether the shield over the part to be blotted out is properly located, and ready to be exposed to the sunlight.

Although the first cost of a frame of this kind is a little more than that of a stock frame, the rapidity with which blueprinting can be done will soon make up for the difference.

Referring to the cross-sectional view, *A* represents the hardwood top strip, *B* the separating strip and *C* the base of the frame. Strips *D* are employed to hold the plate glass *E* in



Frame for blueprinting that gives Good Contact between Paper and Glass

the frame. A sheet of felt *F* ½ inch in thickness is used to form a pad which takes up any inequalities in the pressure and insures having the blueprint and tracing held firmly against the glass at all points.

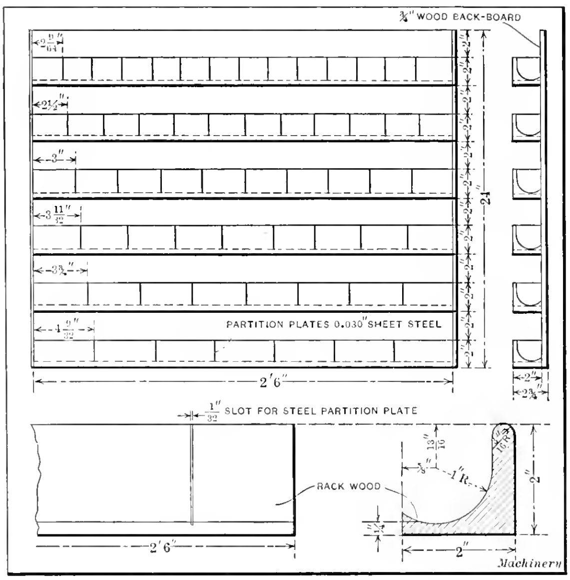
RACK FOR SMALL DRILLS

The accompanying illustration shows what has proved to be a very handy as well as space-saving drill rack for small drills varying from No. 1 to No. 60. A rack of the same general construction could be used equally well for small taps. The tills are made from 2-inch square stock, planed in the carpenter shop to the shape shown in the sectional view. Care



Rack for Small Drills or Taps

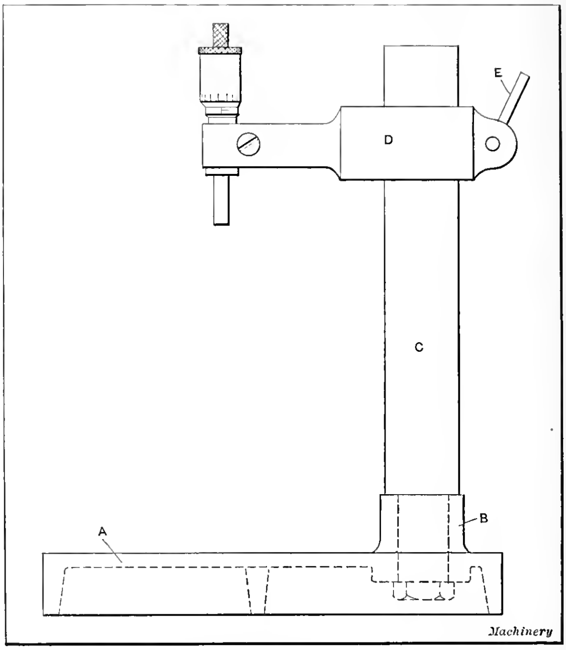
should be taken to form the tills so that there are no sharp corners into which the drills can roll.

The strips are cut 2 feet 6 inches long and are sawed for the steel partition plates, the spacing varying from 4 9/32 inches for No. 1 drills to 2 9/64 inches for No. 60 drills. The partition plates are made of sheet steel. These are assembled after the tills have been fastened to the back-board. Sheet metal end plates are used to close the outer ends and help support the tills. The cost of this rack is very small as compared with the drill cabinets often used. It should be placed on the wall within easy reach of the store-room window and will save the attendant many steps. There is ample space on the front of each till for marking the size of the drill and inserting a hook for the workman's check.

Pittsfield, Mass. C. E. PORTER

ADJUSTABLE MICROMETER HEIGHT GAGE

The adjustable micrometer height gage illustrated herewith was made to meet certain requirements in inspection work that were not fulfilled by standard gages; this special gage has also been found useful for a variety of purposes, other than in the inspection department, and will doubtless be of interest to readers of MACHINERY. It consists of two castings, a piece of turned steel and a micrometer head. The base casting *A* is of rather light section and is provided with a boss *B* in which the post *C* is carefully fitted. It will be seen that the post is turned to form a shoulder which abuts against the face of the boss *B*. The casting *D* carries a standard micrometer head in a hole bored for the purpose, while a hole is bored at its opposite end to fit over the post *C*. Both ends of the casting *D* are split in to the bored holes. The micrometer head is permanently secured by means of a screw which tightens the arm onto it. The position of the arm on the post may be adjusted by means of the binding screw *E*, which tightens it in any desired position.



Adjustable Micrometer Height Gage for use in Inspection Department

It is evident that a gage of this nature must be very accurately made to give satisfactory results. The upper face of the base casting *A* must be finished so that it is exactly perpendicular to the axis of the micrometer screw for all positions of the arm *D* on the post *C*. The micrometer head is set by means of an accurate standard. With the zero point determined in this way, pieces of work may be measured with the standard as the basis of comparison. The provision of the swinging arm, which can be adjusted to different heights, and the broad base of the gage has made it possible to measure many classes of work that cannot be handled with an ordinary micrometer or snap gage. This tool has found favor with all who have had occasion to use it.
